METALS HANDBOOK

1948 EDITION

A 37985

This copy of the ASM Metals Handbook (number listed above) is recorded in the National Office of the American Society for Metals, 7301 Euclid Ave., Cleveland 3, Ohio, as the property of

P H

When the next edition of the ASM Metals Handbook is ready for distribution, members in good standing of the American Society for Metals will be notified and the conditions will be specified under which this book may be exchanged for the new edition.

CONDENSED TABLE OF CONTENTS

Complete Table of Contents on pages vii to xi
Index on pages 1269 to 1332

GENERAL SECTION

Definitions and Physical Data 1
Shaping of Metals 33
Welding, Brazing and Soldering 71
Mechanical Testing 85
Nondestructive Inspection 141
Metallurgical Examination and Control 159
Structure and Properties of Metals 193
Fundamentals of Heat Treatment 255
Industrial Heating 267
Surface Treatments 299

FERROUS METALS

Steel Compositions and Physical Data 307
Manufacture of Iron and Steel 315
Shaping and Fabrication 343
Testing of Ferrous Metals 389
Structure and Properties of Iron 423
Alloying Elements in Steel 453
Hardenability of Steel 489
Ferrous Metal Products 503
Stainless Steels and Heat-Resisting Alloys 549
Magnetic Materials and Other Special-Purpose Alloys 587
Heat Treatment of Steel 607
Tool Steels 653
Case Hardening 677
Metallic Coatings 703
Surface Treatments 725

NONFERROUS METALS

General Articles 739
Aluminum and Aluminum Alloys 761
Properties 810
Wrought Alloys 811
Casting Alloys 824
Copper and Copper Alloys 841
Properties 903
Wrought Alloys 909
Casting Alloys 935
Lead and Lead Alloys 943
Properties 960
Magnesium and Magnesium Alloys 967
Properties 1013
Nickel and Nickel Alloys 1025
Properties 1046
Tin and Tin Alloys 1063
Properties 1070
Zinc and Zinc Alloys 1077
Properties 1086
Precious Metals 1093
Silver and Silver Alloys 1110
Gold and Gold Alloys 1116
Platinum and Platinum Alloys 1121
Palladium and Palladium Alloys 1126
Miscellaneous Metals 1133

CONSTITUTION OF ALLOYS

Binary Alloys 1146
Ternary Alloys 1241

IMPORTANT REFERENCE TABLES

Aluminum Alloys, temper designations 809
AISI-SAE Standard Steels, compositions 307
Conversion Tables
Hardness Numbers 98–104
Percentages (Atomic % – Weight %) 197
Temperature (°C – °F) 30
Density 24, 312
Electrical Resistivities of Steels 314
Elements, periodic table 22
Elements, physical properties 19–21
Etching Reagents
Aluminum and Aluminum Alloys 798-801
Copper and Copper Alloys 901
Iron and Iron Alloys 390, 394
Lead and Lead Alloys 955
Magnesium and Magnesium Alloys 1011
Nickel and Nickel Alloys 1045
Precious Metals 1109
Tin and Tin Alloys 1069
Zinc and Zinc Alloys 1086
Grain Size Standards for Steel 401–403
Hardenability of H Steels 501, 502
Hardness Conversions 98–104
Heat Conductivity 26, 314
Heat Content 27
Machinability Ratings 68, 370
Percentages (Atomic % – Weight %), conversion 197
Periodic Table of the Elements 22

FOREWORD

THE 1948 EDITION OF THE METALS HANDBOOK is more than a revision of the 1939 edition, which it supersedes. It is a new book, in a new form.

The 1939 edition has had to be completely revised. The ink was hardly dry on that edition before World War II threw the whole world into a frenzy of activity that called for the greatest ingenuity of which the metallurgical profession was capable. There was no time for publication of new theories and new developments; indeed many of these were of such a high order of originality and so important as assets in the hands of the nations at war that a cloak of secrecy was thrown about them. Nevertheless the demand for metallurgical information was so great that the Society found it necessary to reprint the 1939 edition in 1942 and again in 1944. Normally, a revision of the text would have preceded reprinting, but such a burden could not have been carried by the hundreds of collaborators necessary for such a task, along with the press of wartime production, nor could the war effort countenance the expenditure of effort in that direction.

The release of restricted matter, the organization of committees to undertake the gathering together of the latest material bearing on the various branches of metallurgy covered by the Handbook, and the preparation of the material in suitable form for publication followed immediately the cessation of war activities in 1945, and culminated in this new 1948 edition.

So extensive have been the coverage, the rewriting and the revisions that the continuation of the 6-by-9-inch page size of the previous editions would have made the 1948 edition unhandy. It has thus been necessary not only to undertake a complete revision of the text but also to make a radical change in the physical make-up of the book.

The metallurgical profession and the Society are indebted to all those who have contributed their time and effort to this vast undertaking.

FRANCIS B. FOLEY
President, American Society for Metals

PREFACE

THE 1948 EDITION OF THE METALS HANDBOOK represents a fresh attack on the problem of providing an authoritative reference volume about metals. The Handbook presented here is the seventh in a series that began in 1924 as looseleaf data sheets and continued with the publication of bound volumes in 1929, 1930, 1933, 1936, and 1939. The 1948 edition is a thorough revision and substantial enlargement of the 1939 edition.

The aim of the Metals Handbook Committee has been to provide a single volume that will serve the needs of those who wish to know the accurate facts, the specific meaning and the real significance of metallurgical subjects. To include every item that might answer a query would make a morgue of little-used details and defeat easy use of the book. Therefore the plan of this work has been to stress the fundamental or essential aspects of the various subjects by means of explanatory articles, rather than merely to display opaque facts in a solid array.

The body of technical knowledge enlarges with each passing year. Information multiplies. As the number and diversity of metallurgical subjects have increased, the range of authorship of the Metals Handbook has widened correspondingly until, in the present edition, 68 subcommittees and more than 500 individuals are named as contributors. The accuracy and authority of the material included in this volume are assured by the names of the contributors. All are specialists who represent the best metallurgical learning of the day.

In the present revision, more than two-thirds of the 1939 edition has been completely rewritten and much new material has been added. The 1948 edition is almost 40% larger than the 1939 edition. Important changes have been made in the scope, form and arrangement of the subject matter.

THE NEW BOOK is divided into four principal sections: General, Ferrous Metals, Nonferrous Metals, and Constitution of Alloys.

General Section. In this section have been grouped 74 articles that deal with metals, processes, or methods in general — or with both ferrous and nonferrous metals. Forty-six of these articles are entirely new; most of the others have been completely revised. Included for the first time are sections dealing with the mechanical testing and nondestructive inspection of metallic materials. A group of articles on industrial heating is almost entirely new. The articles on dilatometry, wear, oxidation, stress corrosion, relief of residual stress, and service failures have not appeared in previous editions. The glossary of definitions starting on page 1 has been expanded greatly.

Ferrous Metals. This section contains 131 articles, of which 62 are new and most of the rest extensively revised. Notable changes include a correlated set of ten articles on the alloying elements in steel, a completely new section on hardenability, and a greatly expanded treatment of the cast and wrought materials that are used at high temperature or in corrosive environments. The eight articles dealing with the manufacture of iron and steel have been rewritten and information on the iron blast furnace process has been added. The articles on tool steel have been co-ordinated through a new classification of principal types of tool steel.

Nonferrous Metals. The Nonferrous Section has been almost entirely rewritten and has been expanded and changed greatly in form. The new section contains 102 articles and 220 data sheets. Eighty per cent of the articles and all the data sheets are new.

For the first time, discussions of melting, shaping, treating, and corrosion are a prominent part of the Nonferrous Section. Such articles have been given three times as much space as before, and five times as many authors have contributed.

Specific data for 220 nonferrous metals and alloys have been presented according to a new, semitabular arrangement. This data sheet form has been used so that the reader can easily find information of the same kind for various alloys by following key numbers, which are the same throughout the Nonferrous Section. A guide to the use of the data sheets and a list of the key numbers are printed on the inside of the back cover.

A new section is included for the eight precious metals, and another for twenty miscellaneous metals not discussed elsewhere.

Constitution of Alloys. The first extensive collection of alloy phase diagrams to be published in America is a part of this edition of the Metals Handbook.

In previous editions, articles about the constitution of binary and ternary alloys were distributed throughout the several ferrous and nonferrous sections of the book. For the present edition, all such articles, with the included phase diagrams, have been placed in a single section and prepared according to a uniform style.

Index. Much time and effort have been expended in order to increase the usefulness of the index, which now contains five times as many entries as before.

TAYLOR LYMAN, *Editor*

SUGGESTIONS FOR USING THE METALS HANDBOOK

TO ENJOY your Metals Handbook, and to profit from it, you must use it. The suggestions offered here will help you to use the Handbook to your greatest advantage. While you are reading this folder, have the 1948 Handbook nearby, so that you can consult the pages mentioned.

The Metals Handbook was designed to be a useful working whole — not merely a collection of articles, tables, data sheets, and diagrams. To be readily and effectively usable, such a volume must have aids that will direct the reader into the book. The following aids are a part of the 1948 Metals Handbook:

Condensed Table of Contents
Front flyleaf
Complete Table of Contents
Pages vii to xi
Guide to the Nonferrous Data Sheets
Inside back cover
Guide to the Phase Diagrams
Page 1145
Index (of subjects)
Pages 1269 to 1331
Index of Important Reference Tables
Front flyleaf
Index of Government Specification Numbers
Page 1332

Systematic use of these indexes, guides, and tables of contents will enable you to find the available information in a minimum time.

Condensed Table of Contents

On the flyleaf just inside the front cover, you will find a Condensed Table of Contents that lists all the principal sections of the Handbook. Note first that there are four main divisions:

GENERAL SECTION *(pages 1 to 305)*
FERROUS METALS *(pages 307 to 736)*
NONFERROUS METALS *(pages 739 to 1144)*
CONSTITUTION OF ALLOYS *(pages 1146 to 1268)*

Under these four headings are listed the 37 sections of the Handbook. *Take 90 seconds now to read these section titles.*

This list of section titles will often provide a short-cut to the page of text that is wanted. For instance, after you have used the TOOL STEELS SECTION a few times, you will become familiar with the way it is organized, and frequently you will be able to find the information you are seeking as soon as you have located that section of the book. The Condensed Table of Contents tells you at a glance that the TOOL STEELS SECTION begins on page 653.

Complete Table of Contents

The complete Table of Contents (pages vii to xi) lists the titles of all articles in the Handbook. There are 803 titles, and it would take you about 30 minutes to read them all. However, in half that time you can get a fair idea of the way the articles are grouped in sections. As the arrangement is somewhat different from that in the previous editions, it would probably be worth while to spend ten minutes surveying the Table of Contents.

General Section. When you examine page vii, which is the Contents for the GENERAL SECTION, you will see that in this part of the Handbook have been grouped articles, tables and definitions that deal with metals, processes, or methods in general — or with both ferrous and nonferrous metals. Note the glossary of metallurgical terms starting on page 1. These definitions have been increased twofold in the 1948 edition.

Ferrous Metals. Page viii is the Contents for the FERROUS METALS SECTION, which is the longest of the four principal parts of the Handbook. Don't be surprised to find a few alloys in here that have less than 50% iron. For instance, some of the heat-resisting alloys and magnetic materials contain more nickel or cobalt than iron, but it is most convenient for the reader to have these materials discussed with the iron-base alloys used for similar purposes.

Nonferrous Metals. In looking over pages ix and x (the Contents for the NONFERROUS METALS SECTION) you will note that the seven principal nonferrous metals are discussed in alphabetic order, with sections concerning precious metals and miscellaneous metals at the end.

Each section about a nonferrous metal has a similar pattern: *first*, a group of explanatory articles; *second*, compilations of properties for individual alloys.

The explanatory articles follow the same sequence in each nonferrous section: general survey (The *X* Industry), melting and casting, mechanical working, heat treatment, joining, machining, finishes, corrosion, and metallography.

Nonferrous Data Sheets

In this edition of the Metals Handbook, nearly all the data about properties of nonferrous metals and alloys have been presented according to a new, semitabular arrangement. These compilations will be called data sheets. Turn now to page 832 in the Handbook, where you will find a typical data sheet for an aluminum casting alloy (Al–4.5 Cu). Note that each item of data is preceded by a letter and number (A2, B1, D6, etc.). By following these key symbols, which are the same throughout the NONFERROUS METALS SECTION, you can easily find information of the same kind for various alloys.

Note especially item K, Mechanical Properties. These properties include hardness, tensile strength, yield strength, elongation, modulus of elasticity, compressive strength, shear strength, impact, creep, fatigue, and other relationships between stress and strain. Because of the large number of mechanical properties reported in the data sheets, various tabular and graphical arrangements have been used instead of a multiplicity of subordinate symbols under item K.

The outline, with the key symbols, was made inclusive enough so that there would be a place for every type of information that might be important for some metal or alloy. Thus, in any one data sheet, numerous omissions occur in the sequence of numbers.

Key symbols for the items most frequently used throughout the nonferrous data sheets are listed on the inside of the back cover of the Handbook. You can read this list in about two minutes and become familiar with the outline.

Phase Diagrams

All of the 284 phase diagrams that are included in the 1948 Metals Handbook have been placed in a single section, which occupies the last text pages in the book (pages 1145 to 1268). The alloy systems are listed in the Contents, on page xi. Note that they are arranged in the alphabetic order of the chemical symbols of the components. For example, silver-aluminum is listed under "Ag", iron-carbon under "C". Consequently, this section of the book is self-indexing.

The form of the phase diagrams has been standardized to a considerable extent. In the following explanation the letters refer to corresponding notations on the cobalt-iron diagram *(see cut on the next page)*. Note first that the co-ordinates are in weight percentage and degrees Centigrade. Atomic percentages are marked on the top and degrees Fahrenheit on the right of each diagram.

(A) All binary phase diagrams are reproduced to a scale of 10 weight per cent equals one centimeter.

(B) The temperature scale has been drawn so that either 25, 50, 100, 200, or 400 degrees Centigrade equals one centimeter. Thus, both weight percentages and degrees Centigrade can be read directly from each binary diagram by using a centimeter scale.

(C) The component having alloys of the greater commercial importance in the binary system appears at the left side of the diagram.

(D) Temperatures of reaction horizontals are indicated in Centigrade, with a plain degree sign.

(E) Compositions at line intersections are shown in weight per cent, with the per cent sign omitted.

(F) A dashed line signifies doubt concerning the position of the line in question.

(G) Dotted lines show the temperatures of magnetic changes.

(H) A dot-dash line indicates the existence of an ordered structure (superstructure).

(I) Melting points of the pure components are shown according to the temperatures given in the table of Physical Properties of the Elements, on page 20.

(J) Polymorphic transformation in an element is shown as occurring at the same temperature in each diagram involving that element.

(K) The magnetic changes in iron, nickel and cobalt are shown consistently also.

The Index

The 1948 Metals Handbook has been thoroughly indexed. The index, printed on green paper, is the last 64 pages in the book (pages 1269 to 1331). You will be able to use this index efficiently if you meet the index-maker part way in understanding the problems involved in compiling an index for a large, technical book.

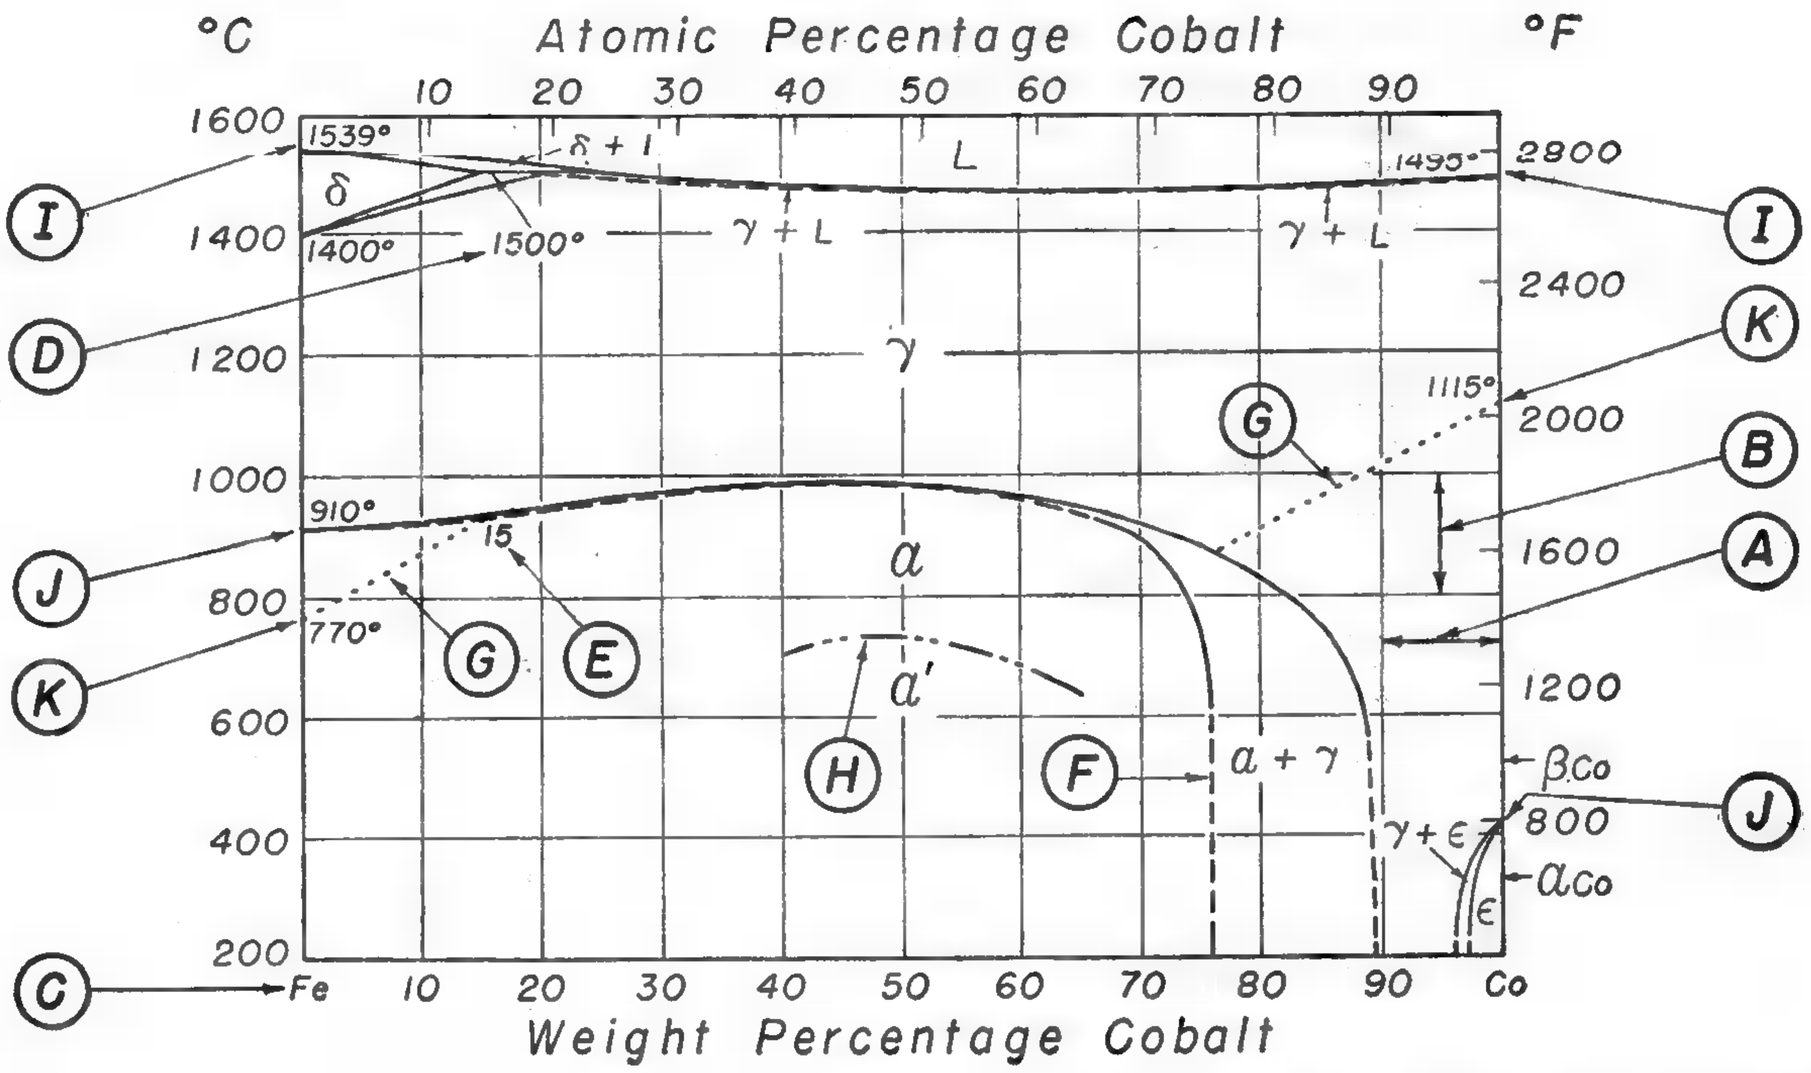
Probably the most useful fact to remember about the Handbook index is this:

> ***The Metals Handbook is a book about* metals, *and most subjects are indexed under the names of* metals (*or alloys*).**

Suppose, for example, that you want to know the value for the electrical resistivity of cartridge brass. Look under the name of the metal, *Cartridge brass,* not under *Electrical* or *Resistivity.* You will find the index entry:

Cartridge brass,
properties 915–917

The subentry *properties* sends you to the data sheet for cartridge brass (70 Cu–30 Zn). Being familiar with the outline of the nonferrous data sheets, you will know that electrical resistivity is always given as item E2, and you can easily find the line of print you are seeking on page 915.



Phase diagram for the cobalt-iron system (W. C. Ellis and E. S. Greiner, 1948 Metals Handbook, page 1192)
For explanation of the features marked, see top of column 2 on the preceding page of this folder.

Perhaps an engineer or purchasing agent of your acquaintance has the habit of telephoning you for miscellaneous information of this sort. Now that you know the secrets of the data sheets and the index, you can cope with such an individual rather easily. You can give him the answers to his questions in less than 60 seconds, if you keep the Handbook in close juxtaposition with the telephone. Gradually you will build up a reputation for this kind of service, and your telephone will be ringing most of the time.

What Are *the Names of Metals?* As the names of metals are important in the index, a few words about metallurgical nomenclature are in order.

Suppose you want information about the ferrous alloy containing 1.2% carbon and 12% manganese. This is *austenitic manganese steel.* However, it is also called *Hadfield's manganese steel,* and sometimes *high-manganese steel,* or simply *manganese steel.* In the Handbook, the term preferred is *austenitic manganese steel,* and under that main heading in the index you will find 31 subentries of the following form:

Austenitic manganese steel 526–534
  applications 529–531, 533, 534
    based on magnetic properties 531
    based on wear resistance 529–531
  creep (F) 531
  etching reagents (T) 395, 532
  low-temperature properties 212, 531
  machining (F) 533

[The letter (T) or (F) in parentheses after an index entry means that the information is in a Table or Figure.]

But suppose you had looked instead under one of the other names. You would have found:

Hadfield's manganese steel 526–534
High-manganese steel, austenitic 526–534
Manganese steel, austenitic 526–534
Steel, austenitic manganese 526–534

It would not be feasible to print the 31 subentries five times in the index. Therefore the "second-choice" items simply refer you to the inclusive pages 526–534 where the article on austenitic manganese steel is given. Note that in these second-choice entries you are not asked to "See also *Austenitic manganese steel.*" The purpose of the index is to get you into the Handbook as soon as possible — not to give you exercise as an index-athlete, hurdling back and forth in the green pages. Wherever possible, cross references have been omitted in favor of a direct reference to the text.

Of course, some cross references are necessary or decidedly helpful; for instance, the following:

Bronze
  See also *Aluminum bronze, Architectural bronze, Commercial bronze, Leaded tin bronze, Manganese bronze, Phosphor bronze, Silicon bronze,* etc.

Carbon steel
  See also *High-carbon steel, Low-carbon steel, Carbon tool steel.*

Now for another example. Suppose you have a commercial specification for a copper casting alloy that contains 83% copper, 4% tin, 6% lead and 7% zinc, and you want to find some infor-

mation about the properties and uses of this alloy. The rule is: Look under the name of the metal. But you may have forgotten that the "common name" of this alloy is *leaded red brass* or that it is sometimes called *hydraulic bronze*. Does this mean that you will need to thumb through the entire COPPER SECTION of the Handbook looking for this particular alloy? No, it does not. If you don't know the name of this alloy, look under *Copper-tin-lead-zinc alloys*. You will find the following entry, which sends you to the data sheet you are looking for:

Copper-tin-lead-zinc alloys
Cu – 4 Sn – 6 Pb – 7 Zn, properties 938

Most alloys are indexed in this way (under the names of the components, with the base metal given first) as well as under the common names.

What About Numbers? Suppose you are looking for data on the case hardening of 1020 steel. The rule is still: Look under the name of the metal. But since the name of this metal is a number, you will need to know how numbers are indexed. The general rule is: Numerical trade designations are grouped under the name of the base metal. Numerical steel designations are listed under *Steel, SAE-AISI*. Thus:

Steel, SAE-AISI trade designations,
1020,
approximate solubility of
carbon in austenite (F) 678
case depth and carbon content 695
case depth–time–temperature (F) 696
cyaniding 695, 696

For the numerical designations of stainless steels, both cast and wrought, look under *Stainless steel, trade designations* or *Heat-resisting alloys, trade designations*. If the alloy number is 17S, referring to an aluminum alloy, look under *Aluminum alloys, trade designations*.

And now for a final example of alloy names. Suppose you have a blueprint calling for QQ-B-611a, Comp E. Your first reaction to this assembly of signs may be nerve-shattering fear. But don't be alarmed. This is simply the way the U. S. Government spells *cartridge brass*. This is the language of Federal specifications. To help you translate these designations, we have indexed about 300 of them on the last page of the index, page 1332.

Processes and Methods. Several times we have repeated the suggestion that, when using the index, you should look under the name of the metal about which you want data. Now we must tell you that the index doesn't always work that way. For instance, when you are seeking a general discussion of some process or method, you *should not* look under the name of any metal. Processes and methods have been indexed as such. For example, if you look for *Precision casting* in the index you will find:

Precision casting 54, 55
advantages and limitations 55
applications 54
process and equipment 54

These are all references to the article on precision casting that appears in the GENERAL SECTION of the Handbook. The information in this article relates to precision casting in general, and there are no specific data about casting particular metals. But if you look again in the index, you will see a second group of headings under *Precision casting*:

Precision Casting of
aluminum alloys 765, 766
cobalt-base high-temperature alloys 580
copper alloys 853, 854
precious metals 1098–1101

This second group of entries refers you to information about casting specific metals. You could have found the same page references if you had looked under the names of the metals for the subentry *precision casting*. In other words, this particular information is indexed twice. So is a lot of other information in the Handbook, but it is not practicable to index everything twice. That is why we have been recommending that, when you are looking for specific information about a definite metal, you should look first under the name of the metal.

It Pays to Use the Index. This last example is supposed to have as a moral: *Don't get reckless and by-pass the index*. We are imagining that you have the problem of making a small hand hammer and you want to find out what steel to use and what hardness is recommended.

Your first reaction may be that a hammer is a tool and that you should look in the TOOL STEELS SECTION for the information. So you turn directly to that section of the book but, hunt as you will, you can find virtually nothing about hammers. However, you haven't used the index. Before you give up, look for *Hammers* in the index. There you'll find a reference to page 633, which, surprisingly enough, is not in the TOOL STEELS SECTION at all. Hammers are not ordinarily made of tool steel. They are usually made of an open hearth grade of carbon steel, and page 633, which is in the article on heat treatment of carbon steels, gives you some information about heat treating a hammer. On page 633, column 1, line 46, you will read that the final hardness on the striking face is usually Rockwell C 50 to 58, and on the claws, 40 to 47. Does that answer your question?

TAYLOR LYMAN
Editor, Metals Handbook

Joining Nickel and Nickel Alloys 1034
Machining Nickel and Nickel Alloys 1036
Grinding and Polishing of Nickel Alloys 1039
Pickling of Nickel and Nickel Alloys 1040
Resistance of Nickel Alloys to Corrosion 1041
Metallography of Nickel and Nickel Alloys 1044

Properties of Nickel and Nickel Alloys

Nickel (99.95 Ni + Co) (Electrolytic Nickel) 1046
Nickel (99.4 Ni + Co) ("A" Nickel) 1047
95 Ni – 4.5 Mn ("D" Nickel) 1047
94 Ni – 4.5 Al ("Z" Nickel) 1048
97 Ni – 1.5 Si (Cast Nickel) 1049
67 Ni – 30 Cu – 1.4 Fe – 1 Mn (Monel) 1049
63 Ni – 32 Cu – 1.6 Si – 1.5 Fe (Cast Monel) 1052
66 Ni – 29 Cu – 2.75 Al – 0.9 Fe – 0.75 Mn ("K" Monel) 1052
63 Ni – 30 Cu – 4 Si – 2 Fe ("S" Monel) 1053
57 Ni – 20 Mo – 20 Fe (Hastelloy A) 1054
62 Ni – 30 Mo – 5 Fe (Hastelloy B) 1055
58 Ni – 17 Mo – 15 Cr – 5 W – 5 Fe (Hastelloy C) 1056
85 Ni – 10 Si – 3 Cu (Hastelloy D) 1057
80 Ni – 14 Cr – 6 Fe (Inconel) 1057
78 Ni – 13.5 Cr – 6 Fe – 2 Si (Cast Inconel) 1058
58 Ni – 22 Cr – 6 Cu – 6 Mo – 6 Fe (Illium "G") 1058
80 Ni – 20 Cr 1060
60 Ni – 24 Fe – 16 Cr 1060
35 Ni – 50 Fe – 15 Cr 1061
45 Ni – 55 Cu (Constantan) 1062

Tin and Tin Alloys

The Tin Industry 1063
Casting of Tin and Tin Alloys 1065
Working and Joining of Tin 1066
Tin Coatings and the Resistance of Tin to Corrosion 1067
Metallography of Tin and Tin Alloys 1069

Properties of Tin and Tin Alloys

Pure Tin 1070
Tin (99.8 Sn) 1072
99.6 Sn – 0.4 Cu (Hard Tin) 1073
95 Sn – 5 Sb (Antimonial Tin Solder) 1073
95 Sn – 5 Ag (Tin-Silver Solder) 1073
70 Sn – 30 Pb (Soft Solder) 1074
63 Sn – 37 Pb (Soft Solder) 1074
91 Sn – 4.5 Sb – 4.5 Cu (Tin Babbitt) 1074
89 Sn – 7.5 Sb – 3.5 Cu (Tin Babbitt) 1075
83.4 Sn – 8.3 Sb – 8.3 Cu (Tin Babbitt) 1075
65 Sn – 18 Pb – 15 Sb – 2 Cu (Tin Babbitt) 1075
92 Sn – 8 Zn (Tin Foil) 1076
92 Sn – 8 Sb (White Metal) 1076
Sn – 7 Sb – 2 Cu (Pewter, Brittannia Metal) 1076

Zinc and Zinc Alloys

The Zinc Industry 1077
Casting and Production of Zinc Alloys 1078
Working of Zinc and Zinc Alloys 1082
The Use of Zinc for Cathodic Protection 1084
Metallography of Zinc and Zinc Alloys 1085

Properties of Zinc and Zinc Alloys

Pure Zinc 1086
Zn – 4 Al – 0.04 Mg (die-casting alloy) 1088
Zn – 4 Al – 1 Cu – 0.04 Mg (die-casting alloy) 1089
Zn – 4 Al – 3 Cu – 0.03 Mg (die-casting alloy) 1089
Zn – 4.75 Al – 0.25 Cu (slush-casting alloy) 1090
Zn – 5.5 Al (slush-casting alloy) 1090
Zn – 0.08 Pb (commercial rolled zinc) 1090
Zn – 0.06 Pb – 0.06 Cd (commercial rolled zinc) 1091
Zn – 0.3 Pb – 0.3 Cd (commercial rolled zinc) 1091
Zn – 1 Cu (rolled zinc alloy) 1092
Zn – 1 Cu – 0.010 Mg (rolled zinc alloy) 1092

Precious Metals

The Precious Metals Industry 1093
Melting Precious Metals 1096
Jewelry Casting 1098
Dental Casting 1100
Working of Platinum Metals 1101
Forming and Cutting of Gold Alloys 1102
Joining and Cladding Precious Metals 1102
Electroplating With Precious Metals 1106
Polishing Precious Metals 1109
Metallography of Precious Metals 1109

Properties of Precious Metals

Silver and Silver Alloys

Silver 1110
Silver-Copper Alloys 1112
Silver-Copper-Zinc(-Cadmium-Tin) Brazing Alloys 1113
Silver Materials for Electrical Contacts 1114
33 Ag – 52 Hg – 12.5 Sn – 2 Cu – 0.5 Zn 1116

Gold and Gold Alloys

Gold (99.99+ Au) 1116
Gold-Copper-Silver Alloys (Green, Yellow and Red Golds) 1117
Gold-Nickel-Copper-Zinc Alloys (White Gold) 1118
Gold-Silver-Copper-Nickel-Zinc Alloys (Pink or Suntan Golds) 1119
Gold Alloys in Dentistry 1120
69 Au – 25 Ag – 6 Pt 1121

Platinum and Platinum Alloys

Platinum 1121
Commercial Types of Platinum 1123
Platinum Alloys Containing from 3.5 to 20% Rhodium 1124
Platinum Alloys Containing from [illegible] to 30% Iridium 1124
Platinum Alloys Containing 5 and 10% Ruthenium 1125
Platinum Alloys Containing from 1 to 5% Nickel 1125
84 Pt – 10 Pd – 6 Ru 1126
96 Pt – 4 W 1126

Palladium and Palladium Alloys

Palladium 1126
60 Pd – 40 Ag 1128
60 Pd – 40 Cu 1128
Palladium-Silver-Copper Alloys 1128
Palladium-Gold-Silver Alloys 1129
Palladium-Platinum-Silver Alloys 1129
95.5 Pd – 4.5 Ru and 95 Pd – 4 Ru – 1 Rh 1130

Iridium, Osmium, Rhodium and Ruthenium

Iridium 1130
Osmium 1131
Rhodium 1132
Ruthenium 1132

Miscellaneous Metals

Antimony 1133
Arsenic 1133
Beryllium 1134
Cadmium 1134
Calcium 1135
Chromium 1135
Cobalt 1136
Columbium 1137
Lithium 1138
Manganese 1138
Molybdenum 1139
Selenium 1140
Silicon 1140
Sodium 1141
Tantalum 1142
Tellurium 1143
Titanium 1143
Tungsten 1144
Vanadium 1144
Zirconium 1144

CONSTITUTION OF ALLOYS

Binary Alloys

Ag-Al	Silver-Aluminum	1146
Ag-Au	Silver-Gold	1146
Ag-Cd	Silver-Cadmium	1147
Ag-Co	Silver-Cobalt	1148
Ag-Cr	Silver-Chromium	1148
Ag-Cu	Silver-Copper	1148
Ag-Fe	Silver-Iron	1148

Cr-W	Chromium-Tungsten	1195
Cs-Fe	Cesium-Iron	1195
Cu-Fe	Copper-Iron	1196
Cu-Ga	Copper-Gallium	1197
Cu-Ge	Copper-Germanium	1197
Cu-Li	Copper-Lithium	1197
Cu-Mg	Copper-Magnesium	1197
Cu-Mn	Copper-Manganese	1198
Cu-Ni	Copper-Nickel	1198
Cu-O	Copper-Oxygen	1199
Cu-P	Copper-Phosphorus	1200
Cu-Pb	Copper-Lead	1200
Cu-Pd	Copper-Palladium	1201
Cu-Pt	Copper-Platinum	1201
Cu-S	Copper-Sulfur	1202
Cu-Sb	Copper-Antimony	1202
Cu-Se	Copper-Selenium	1203
Cu-Si	Copper-Silicon	1203
Cu-Sn	Copper-Tin	1204
Cu-Te	Copper-Tellurium	1205
Cu-Ti	Copper-Titanium	1205
Cu-Zn	Copper-Zinc	1206
Cu-Zr	Copper-Zirconium	1207
Fe-Ge	Iron-Germanium	1207
Fe-H	Iron-Hydrogen	1208
Fe-He	Iron-Helium	1209
Fe-Hg	Iron-Mercury	1209
Fe-Ir	Iron-Iridium	1209
Fe-K	Iron-Potassium	1209
Fe-Kr	Iron-Krypton	1209
Fe-Li	Iron-Lithium	1209
Fe-Mg	Iron-Magnesium	1209
Fe-Mn	Iron-Manganese	1210
Fe-Mo	Iron-Molybdenum	1210
Fe-N	Iron-Nitrogen	1211
Fe-Ni	Iron-Nickel	1211
Fe-O	Iron-Oxygen	1212
Fe-P	Iron-Phosphorus	1213
Fe-Pb	Iron-Lead	1214
Fe-Pd	Iron-Palladium	1214
Fe-Pt	Iron-Platinum	1214
Fe-Rb	Iron-Rubidium	1215
Fe-Rh	Iron-Rhodium	1215
Fe-Rn	Iron-Radon	1215
Fe-Ru	Iron-Ruthenium	1215
Fe-S	Iron-Sulfur	1215
Fe-Sb	Iron-Antimony	1216
Fe-Se	Iron-Selenium	1216
Fe-Si	Iron-Silicon	1217
Fe-Sn	Iron-Tin	1217
Fe-Sr	Iron-Strontium	1218
Fe-Ta	Iron-Tantalum	1218
Fe-Ti	Iron-Titanium	1219
Fe-V	Iron-Vanadium	1219
Fe-W	Iron-Tungsten	1220
Fe-Zn	Iron-Zinc	1220
Fe-Zr	Iron-Zirconium	1221
Hg-Sn	Mercury-Tin	1222
Hg-Zn	Mercury-Zinc	1222
In-Pb	Indium-Lead	1223
Ir-Pt	Iridium-Platinum	1223
K-Pb	Potassium-Lead	1223
Li-Mg	Lithium-Magnesium	1224
Li-Pb	Lithium-Lead	1224
Mg-Mn	Magnesium-Manganese	1225
Mg-Ni	Magnesium-Nickel	1225
Mg-Pb	Magnesium-Lead	1226
Mg-Si	Magnesium-Silicon	1226
Mg-Sn	Magnesium-Tin	1227
Mg-Zn	Magnesium-Zinc	1227
Mg-Zr	Magnesium-Zirconium	1228
Mn-Ni	Manganese-Nickel	1228
Mn-Pd	Manganese-Palladium	1229
Mn-Pt	Manganese-Platinum	1229
Mn-Zn	Manganese-Zinc	1229
Mo-Ni	Molybdenum-Nickel	1230
Mo-W	Molybdenum-Tungsten	1230
Na-Pb	Sodium-Lead	1231
Ni-O	Nickel-Oxygen	1231
Ni-Pd	Nickel-Palladium	1231
Ni-Pt	Nickel-Platinum	1232
Ni-S	Nickel-Sulfur	1232
Ni-Si	Nickel-Silicon	1233
Ni-Sn	Nickel-Tin	1234
Ni-Ta	Nickel-Tantalum	1235
Ni-Ti	Nickel-Titanium	1235
Ni-W	Nickel-Tungsten	1235
Ni-Zn	Nickel-Zinc	1236
P-Sn	Phosphorus-Tin	1237
Pb-Sb	Lead-Antimony	1237
Pb-Sn	Lead-Tin	1238
Pb-Te	Lead-Tellurium	1238
Pb-Zn	Lead-Zinc	1239
Pt-Rh	Platinum-Rhodium	1239
Sb-Sn	Antimony-Tin	1239
Sn-Te	Tin-Tellurium	1240
Sn-Zn	Tin-Zinc	1240

Ternary Alloys

Ag-Au-Pd	Silver-Gold-Palladium	1241
Ag-Cu-Pd	Silver-Copper-Palladium	1241
Ag-Cu-Zn	Silver-Copper-Zinc	1242
Ag-Pd-Pt	Silver-Palladium-Platinum	1242
Al-Cu-Ni	Aluminum-Copper-Nickel	1243
Al-Cu-Zn	Aluminum-Copper-Zinc	1244
Al-Fe-Ni	Aluminum-Iron-Nickel	1245
Al-Fe-Si	Aluminum-Iron-Silicon	1245
Al-Mg-Mn	Aluminum-Magnesium-Manganese	1245
Al-Mg-Si	Aluminum-Magnesium-Silicon	1246
Al-Mg-Zn	Aluminum-Magnesium-Zinc	1247
Al-Mn-Si	Aluminum-Manganese-Silicon	1247
Al-Mn-Zn	Aluminum-Manganese-Zinc	1247
Be-Cu-Ni	Beryllium-Copper-Nickel	1248
C-Cr-Fe	Carbon-Chromium-Iron	1248
C-Cu-Fe	Carbon-Copper-Iron	1250
C-Fe-Mn	Carbon-Iron-Manganese	1251
C-Fe-Mo	Carbon-Iron-Molybdenum	1252
C-Fe-Ni	Carbon-Iron-Nickel	1254
C-Fe-Si	Carbon-Iron-Silicon	1254
C-Fe-Ti	Carbon-Iron-Titanium	1255
C-Fe-V	Carbon-Iron-Vanadium	1256

Definitions of Metallurgical Terms

THE DEFINITIONS included in this glossary have been prepared by four committees. In determining the usage of various terms, these committees have consulted numerous technical publications and have been aided greatly by discussions with many other metallurgists. The contributions of the four committees were as follows:

The Joint AFA-ASM-ASTM-SAE Committee on Definitions of Terms Relating to Heat Treatment* has defined 64 terms concerning the heat treatment of metals. These terms are indicated in the glossary by a superscript star(*).

The ASM Committee on Powder Metallurgy* has prepared definitions of 110 terms in this field. In the glossary these definitions are indicated by the sign *Powd met* immediately after the term being defined.

The definitions of metallurgical terms that appeared in the 1939 edition of this Handbook—approximately 200 terms relating chiefly to the metallurgy of iron and steel—have been revised by the Committee on Definitions Relating to Ferrous Metallurgy.†

The remainder of the glossary—approximately 500 terms—has been compiled by the Committee on Definitions Relating to Nonferrous Metallurgy.‡ The majority of the definitions formulated by this committee relate to physical metallurgy and mechanical metallurgy generally; those that relate specifically to nonferrous metals are designated as such by the wording of the definition or by *Nonfer met.*

Definitions of terms used in X-ray metallography are republished from the 1939 edition, with minor changes, in a separate glossary beginning on page 16.

* Starred terms have been defined by the Joint AFA-ASM-ASTM-SAE Committee on Definitions of Terms Relating to Heat Treatment. The members of the committee are H. Bornstein, *Chairman* (Deere & Company), R. H. Aborn (United States Steel Corporation), J. R. Adams (The Midvale Company), O. W. Ellis (Ontario Research Foundation), L. H. Fry, *Vice Chairman* (Steam Locomotive Research Institute, Inc.), T. S. Fuller (General Electric Company), V. O. Homerberg (Massachusetts Institute of Technology), Taylor Lyman, *Secretary* (Metals Handbook Committee), G. A. Roberts (Vanadium-Alloys Steel Company), R. B. Schenck (Buick Motor Division, General Motors Corporation) and J. S. Vanick (International Nickel Company, Inc.).

* The members of the Committee on Powder Metallurgy are F. N. Rhines, *Chairman* (Carnegie Institute of Technology), C. W. Balke (Fansteel Metallurgical Corporation), J. J. Cordiano (Hardy Metallurgical Corporation), R. P. Koehring (Moraine Products Division, General Motors Corporation), C. H. Samans (American Optical Company), Alexander Squire (Westinghouse Electric Corporation), N. E. Woldman (Upper Montclair, N. J.), F. E. Wormser (Metal Powder Association) and L. L. Wyman (General Electric Company).

† The members of the Committee on Definitions Relating to Ferrous Metallurgy are R. H. Aborn (United States Steel Corporation), V. O. Homerberg (Massachusetts Institute of Technology), Taylor Lyman (American Society for Metals) and G. A. Roberts (Vanadium-Alloys Steel Company).

‡ The members of the Committee on Definitions Relating to Nonferrous Metallurgy are R. M. Brick, *Chairman* (University of Pennsylvania), R. S. Busk (Dow Chemical Company), A. H. Geisler (General Electric Company), E. N. Skinner, Jr. (International Nickel Company, Inc.) and F. H. Wilson (The American Brass Company).

A

acicular powder. *Powd met.* Needle-shaped particles.

acid bottom and lining. In a melting furnace, the inner bottom and lining composed of materials that have an acid reaction in the melting process—either sand, siliceous rock or silica bricks.

acid brittleness. The brittleness induced in steel, especially wire or sheet, when it is pickled in dilute acid to remove scale, or during electroplating. Commonly attributed to absorption of hydrogen.

acid steel. Steel melted in a furnace that has an acid bottom and lining, and under a slag that is dominantly siliceous.

activation energy. In metallurgical processes, the energy required for initiating or continuing a reaction; important in theoretical analyses of flow, diffusion and other processes.

* **age hardening.** A process of aging that increases hardness and strength and ordinarily decreases ductility. Age hardening usually follows rapid cooling or cold working. See *aging.*

* **aging.** In a metal or alloy, a change in properties that generally occurs slowly at atmospheric temperature and more rapidly at higher temperatures. See also *age hardening, precipitation hardening* and *strain aging.*

aging. *Nonfer met.* See *precipitation heat treatment, interrupted aging, progressive aging.*

air classification. *Powd met.* The separation of powder into ranges of particle size by means of a controlled stream of air.

air-hardening steel. An alloy steel that is hardened by cooling in air from a temperature higher than the transformation range. Also called *self-hardening steel.*

alclad. The common name for a type of clad wrought aluminum products, such as sheet and wire, with coatings of high-purity aluminum or of an aluminum alloy different from the core alloy in composition. The coatings are anodic to the core so they protect exposed areas of the core electrolytically during exposure to corrosive environments.

alkali metals. Metals of group IA of the periodic system, including lithium, sodium, potassium, rubidium, cesium and francium.

alkaline earth metals. Metals of group IIA of the periodic system, including calcium, strontium, barium and radium.

alligatoring. The longitudinal splitting of flat slabs in a plane parallel to the rolled surface. Also called "fishmouthing".

allotriomorphic crystal. See *idiomorphic crystal.*

allotropy. See *polymorphism.*

alloy. A substance that has metallic properties and is composed of two or more chemical elements of which at least one is a metal.

alloying elements. Chemical elements constituting an alloy; in steels, usually limited to the metallic elements added to modify the properties of the steel.

alloy powder. *Powd met.* A powder, each particle of which is composed of the same alloy of two or more metals.

alpha iron. The form of iron that is stable below Ae_3 (910 C, 1670 F) and characterized by a body-centered cubic crystal structure. See *transformation temperature* for definition of Ae_3.

alternate-immersion test. A type of corrosion test in which the specimen is immersed cyclically in the corrosive medium, held for a definite period, and removed at intervals.

alumel. A nickel-base alloy containing about 2.5% Mn, 2% Al and 1% Si, used chiefly as a component of pyrometric thermocouples.

amalgam. A mercury-base alloy.

amalgamation process. A process in which finely divided gold or silver ore, suspended in water, is carried over a surface of liquid mercury, so as to form recoverable amalgams.

amorphous. Noncrystalline.

angle of nip. In the rolling of sheet, the angle between the radius of the rolls at the point of initial contact and the normal to the sheet surface at this point.

* **annealing.** A process involving heating and cooling, usually applied to induce softening. The term also refers to treatments intended to alter mechanical or physical properties, produce a definite microstructure, or remove gases. When applicable, the following more specific terms should be used:

black annealing	isothermal annealing
blue annealing	malleablizing
box annealing	process annealing
bright annealing	spheroidizing
full annealing	stabilizing annealing
graphitizing	

Definitions of the above terms are given in their alphabetical positions in this glossary. When applied to ferrous alloys, the term "annealing", without qualification, implies full annealing. Any process of annealing will usually reduce stresses, but if the treatment is applied for the sole purpose of such relief, it should be designated as "stress relieving".

annealing. *Nonfer met.* A heat treatment designed to effect: (1) softening of a cold worked structure by recrystallization or grain growth or both; (2) softening of an age hardened alloy by causing a nearly complete precipitation of the second phase in relatively coarse form; (3) softening of certain age hardenable alloys by dissolving the second phase and cooling rapidly enough to obtain a supersaturated solution (this usage is generally applied to nickel-base and copper-base alloys; the treatment should be called more precisely a *solution heat treatment*); (4) relief of residual stress and change in properties induced during the thermal flattening of magnesium alloy sheet at slightly elevated temperatures.

annealing twin bands. Bands found in wrought and annealed metals with face-centered cubic structures; for example, copper, brass, nickel, 18-8 stainless steel. In unstrained crystals, the bands have straight parallel sides that represent the *twinning plane,* which is the octahedral plane for these face-centered cubic structures. The orientation relationship between band and matrix is fixed; one may be converted to the other by a rotation of 180 deg about the normal to the *twinning plane.* These twins originate during annealing for recrystallization of a previously strained crystal or during straining at an elevated temperature.

anode copper. Specially shaped slabs of copper cast from a fire-refining (anode) furnace and used as anodes in electrolytic refining.

anode effect. A sudden increase in voltage across an aluminum reduction cell, associated with the decrease of the concentration of the alumina in the fused electrolyte while the metal is being produced.

anode mud. Deposit of insoluble residue formed in an electroplating or electrorefining cell during solution of the anode; sometimes called "anode slime".

anodic coating. A coating or film of a metal compound, usually oxide, formed on metals by an electrolytic oxidation treatment.

anodic treatment. A cleaning, polishing or oxidizing treatment in which the specimen or work is made the anode in a suitable electrolyte; an inert metal is used as cathode and a potential is applied.

anodizing. *Nonfer met.* Subjecting metal to anodic oxidation.

apparent density. *Powd met.* The weight of a unit volume of powder, determined by a specified method of loading and usually expressed in grams per cubic centimeter.

arborescent powder. See *dendritic powder.*

arc welding. Welding accomplished by using an electric arc that may be formed between a metal or carbon electrode and the metal being welded; between two separate electrodes, as in *atomic hydrogen welding*; or between the two separate pieces being welded, as in *flash welding.*

artificial aging. An aging treatment above room temperature. See *precipitation heat treatment* and compare with *natural aging.*

atomization. *Powd met.* The dispersion of a molten metal into particles by a rapidly moving stream of gas or liquid.

* **austempering.** A trade name for a patented heat treating process that consists in quenching ■ ferrous alloy from a temperature above the transformation range, in a medium having a rate of heat abstraction sufficiently high to prevent the formation of high-temperature transformation products; and in maintaining the alloy, until transformation is complete, at ■ temperature below that of pearlite formation and above that of martensite formation.

austenite. A solid solution in which gamma iron is the solvent; characterized by a face-centered cubic crystal structure.

* **austenitizing.** The process of forming austenite by heating a ferrous alloy into the transformation range (partial austenitizing) or above the transformation range (complete austenitizing).

autofrettage. A process for manufacturing gun tubes and pressure vessels, in which the inner surface layers of a plain tube are initially stressed by expansion beyond the yield strength, so that residual compressive stresses are created.

autogenous welding. A method of uniting two pieces of metal by melting their edges together without solder or any added welding metal.

B

baghouse. A large chamber for holding bags that are used in the filtration of gases from a furnace in order to recover metal oxides and similar solids suspended in the gases.

ball mill. A mill in which material is finely ground by rotation in a steel drum along with pebbles or steel balls. The grinding action is provided by the collision of the balls with one another and with the shell of the mill.

banded structure. A segregated structure of nearly parallel bands aligned in the direction of working.

bark. The decarburized skin or layer just beneath the scale that results from heating steel in an oxidizing atmosphere.

base bullion. Argentiferous lead containing 10 to 60% silver with or without some gold.

basic bottom and lining. In a melting furnace, the inner lining and bottom composed of materials that have a basic reaction in the melting process—either crushed burned dolomite, magnesite, magnesite bricks or basic slag.

basic steel. Steel melted in a furnace that has a basic bottom and lining, and under a slag that is dominantly basic.

basin. See *pouring basin.*

Bauschinger effect. The phenomenon by which plastic deformation of a metal raises the yield strength in the direction of plastic flow and decreases the yield strength in the opposite direction.

Bayer process. The process for extracting alumina from bauxite ore before the electrolytic reduction. The bauxite is digested in a solution of sodium hydroxide, which converts the alumina to soluble aluminate. After the "red mud" residue has been filtered out, an aluminum hydrate is precipitated from the filtrate. Then the hydrate is filtered out and calcined to alumina.

beading. Raising a ridge on sheet metal.

beating. (1) Producing very thin sheet by hammering. (2) Forming sheet by hammering into or over a form of the desired shape, usually made of wood. See *hammering.*

bending rolls. Three staggered rolls adjusted to put the desired curvature in plate or used for coiling and uncoiling strip or wire.

bend radius. The radius corresponding to the curvature of a bent specimen or bent area of a formed part, and measured on the inside of a bend.

bend tests. Various tests used to determine the ductility of sheet or plate that is subjected to bending. These tests may include determination of the minimum radius or diameter required to make a satisfactory bend and the number of repeated bends that the material can withstand without failure when it is bent through a given angle and over a definite radius.

Bessemer process. A process for making steel by blowing air through molten pig iron contained in a suitable vessel, and thus causing rapid oxidation, mainly of silicon and carbon.

beta structure. Structurally analogous body-centered cubic phases, or electron compounds (similar to beta brass) that have ratios of three valence electrons to two atoms.

Betts process. A process for the electrolytic refining of lead by use of an electrolyte that contains lead fluosilicate and fluosilicic acid.

billet. *Nonfer met.* (1) A section of ingot, hot worked by forging, rolling or extrusion. (2) A casting suitable for rolling or extrusion. See *extrusion billet.*

billet. *Fer met.* See *bloom.*

billet mill. See *blooming mill.*

binary alloy. An alloy containing two principal elements.

binder. *Powd met.* A cementing medium; either a substance added to the powder to increase the strength of the compact and dispelled during sintering, or a substance (usually a relatively low-melting constituent) added to a powder mixture in order to cement together powder particles that alone would not sinter into a strong body.

biscuit. An upset blank from which a forging is produced.

* **black annealing.** A process of box annealing or pot annealing ferrous alloy sheet, strip or wire after hot working and pickling. See *box annealing.*

blank. *Powd met.* A pressed, presintered or fully sintered compact, usually in the unfinished condition and requiring cutting, machining or some other operation to produce the final shape.

blank holder. The tool that prevents the rim of a sheet metal blank from wrinkling while it is being deep drawn.

blanking. Shearing out a piece of sheet metal in preparation for deep drawing.

blast furnace. *Fer met.* A shaft furnace supplied with an air blast (usually hot) and used for producing pig iron by smelting iron ore in a continuous operation. The raw materials (iron ore, coke and limestone) are charged at the top, and the molten pig iron and slag, which collect at the bottom, are tapped out at intervals.

blast furnace. *Nonfer met.* A shaft type of vertical furnace used for smelting coarse copper, lead and tin ores; similar to the type used for smelting iron, but smaller.

blasting. A process for cleaning or finishing metal objects by use of an air blast that blows particles of an abrasive against the surfaces of the work pieces. Small, irregular particles of steel are used as the abrasive in *grit blasting,* sand in *sandblasting,* and steel balls in *shot blasting.*

blending. *Powd met.* The thorough intermingling of different batches of powder of the same substance, to adjust physical characteristics.

blister. A raised spot on the surface of metal, caused by expansion of gas in a subsurface zone during heat treatment. Very fine blisters are called "pinhead" or "pepper blisters".

blister copper. The metal produced when copper *matte* is "blown" in a converter. This metal, which contains 98.5% to 99.5% Cu, is subsequently refined electrolytically.

blocker. A forging die used for giving ■ forging an approximation of the final shape. The *blocker* imparts more detail than either the *edger* or the *fuller.*

bloom (slab, billet). *Fer met.* Semifinished products hot rolled from ingots and rectangular in cross section, with rounded corners. The chief differences are in cross-sectional area, in ratio of width to thickness, and in the intended uses. The American Iron and Steel Institute Steel Products Manual, Section 2 (1943) classifies general usage thus:

Type	Width, in.	Thickness, in.	Cross-Sectional Area, sq in.
Bloom	Width generally equals thickness		36 + (min)
Billet	1½ (min)	1½ (min)	2¼ to 36
Slab .....2 × thickness (min)		1½ (min)	16 (min) [a]

(a) Generally

Blooms, slabs and billets of rerolling quality are intended for hot rolling into common products such as shapes, plates, strip, bars, wire rod, sheet and black plate. Blooms, slabs and billets of forging quality are intended for conversion into forgings or other products to be heat treated.

blooming mill. *Fer met.* A mill that is used to reduce ingots to blooms, billets, slabs or sheet bars. Depending on the product, the mill is called a "blooming mill" ("cogging mill" in England), ■ "billet mill", or a "slabbing mill".

blowhole. A hole produced in a casting when gas, entrapped while the mold is being filled, or evolved during the solidification of metal, fails to escape and is held in pockets.

*** blue annealing.** A process of softening ferrous alloys in the form of hot rolled sheet, by heating in the open furnace to a temperature within the transformation range and then cooling in air. The formation of a bluish oxide on the surface is incidental.

blue brittleness. Reduced ductility occurring as a result of strain aging, when certain ferrous alloys are worked between 300 and 700 F. This phenomenon may be observed at the working temperature or subsequently at lower temperatures.

blue powder. A mixture of metallic zinc dust and zinc oxide obtained as a by-product in the distillation of zinc.

*** bluing.** A treatment for improving the appearance and resistance to corrosion of ferrous alloys by subjecting the surface, initially free from scale, to the action of air, steam, chemicals or other agents at a suitable temperature, thus forming a thin blue film of oxide.

NOTE: This term is ordinarily applied to sheet, strip or finished parts. It is used also to denote the heating of springs after fabrication, in order to reduce the residual stress caused by coiling and forming.

board hammer. A type of drop hammer in which boards attached to the ram are lifted between rollers.

book mold. A split mold that is hinged at the side.

bosh. In a blast furnace (1) the section where the diameter increases to a maximum above the tuyeres; (2) a lining of quartz that is built up during pyritic smelting of copper, narrowing down the internal dimensions at the tuyeres.

bossing. The roughening of roll surfaces to improve their bite on the bar in hot rolling.

bottom board. A flat base for holding the flask in making sand molds.

bowing. Lack of flatness in sheet or strip metal in which the longitudinal or transverse section forms an arc.

*** box annealing.** A process of annealing ■ ferrous alloy in a suitable closed metal container, with or without packing material, in order to minimize oxidation. The charge is usually heated slowly to a temperature below the transformation range, but sometimes above or within it, and is then cooled slowly. This process is also called "close annealing" or "pot annealing". See *black annealing.*

brake. A piece of equipment used for bending sheet; also called a "bar folder". If operated manually, it is called a "hand brake"; if power driven, it is called a "press brake".

brale. A diamond penetrator, conical in shape, used with a Rockwell hardness tester for hard metals.

brasses. Copper-base alloys in which zinc is the principal added element.

brazing. Joining metals by fusion of nonferrous alloys that have melting points above 800 F but lower than those of the metals being joined. This may be accomplished by means of a torch (torch brazing), in ■ furnace (furnace brazing) or by dipping in a molten flux bath (*dip* or *flux brazing*). The filler metal is ordinarily in rod form in torch brazing; whereas in furnace and dip brazing the work material is first assembled and the filler metal may then be applied as wire, washers, clips, bands, or may be integrally bonded, as in *brazing sheet.*

brazing sheet. A clad type of sheet product, coated on one or both surfaces with an alloy that has a melting point lower than the melting point of the core alloy. During brazing, only the coating melts and flows to form fillets in the preassembled article.

bridging. Local freezing across a mold before the metal below solidifies.

bridging. *Powd met.* In ■ powder mass, the formation of arched cavities, which may result in voids or uneven density in a compact, or which may result in stopping or interrupting the flow of powder through a funnel or other feeding device.

*** bright annealing.** A process of annealing usually carried out in a controlled furnace atmosphere so that surface oxidation is reduced to a minimum and the surface remains relatively bright.

bright dip. An acid solution into which articles are dipped to obtain a clean, bright surface.

brightener. Material added to an electroplating bath to give the deposited metal a highly reflective surface.

briquette. See *compact.*

brittleness. A tendency to fracture without appreciable deformation.

broach. (1) A rod inserted into a pierced tube when the tube is reduced by a reciprocating rolling process. (2) A tool employed for broaching.

broaching. Multiple shaving, accomplished by pushing ■ tool with stepped cutting edges along the work, particularly through holes.

buckling. The bending of sheets or plates under a compressive load.

buff. A polishing wheel usually consisting of a large number of treated or untreated muslin disks sewed together.

built-up plate. A pattern plate with the *cope* pattern mounted on or attached to one side and the *drag* pattern on the other. See *matchplate.*

bulging. Local expansion of tubes or shells by internal hydraulic pressure or by compression of a rubber cylinder.

bull block. A power-driven reel for drawing heavy-gage wire through a die.

bullion. An alloy containing sufficient precious metal to make *parting* profitable.

bumper. A machine for ramming sand in a flask by repeated jarring or jolting.

burnishing. Plastic smearing such as may occur on metallic surfaces during buffing.

*** burnt.** A term applied to a metal permanently damaged by having been heated to a temperature close to the melting point.

burr. A rough or sharp edge left on metal by a cutting tool.

bus bar. A metal bar for conducting high-amperage electric current.

button. A globule of metal remaining in an assaying crucible or cupel after fusion has been completed.

butt welding. Joining two edges or ends by placing one against the other and welding them.

C

cake. *Powd met.* A coalesced mass of unpressed metal powder.

cake. A copper ingot rectangular in cross section. See *wedge cake.*

calcination. The heating of ores or concentrates to cause decomposition of carbonates or hydrates.

camber of rolls. The increased diameter at the middle of rolls, designed to counterbalance the bending of the rolls when they are subjected to high pressures during rolling.

camber of sheet. Curvature in the plane of rolled sheet or strip.

capped steel. See *rimmed steel.*

carat. A twenty-fourth part, used to designate the fineness of gold. Thus "14-carat gold" means 14 parts gold, 10 parts base metal.

carbide. A compound of carbon with one or more metallic elements.

***carbonitriding.** A process in which a ferrous alloy is case hardened by first being heated in a gaseous atmosphere of such composition that the alloy absorbs carbon and nitrogen simultaneously, and then being cooled at a rate that will produce desired properties.

carbonization. Coking or driving off the volatile matter from fuels such as coal and wood. (Should not be confused with "carburization".)

carbon steel. Steel that owes its properties chiefly to the presence of carbon, without substantial amounts of other alloying elements; also termed "ordinary steel", "straight carbon steel", "plain carbon steel".

carbonyl powder. *Powd met.* Particles prepared by the thermal decomposition of a metal carbonyl.

*** carburizing.** A process that introduces carbon into a solid ferrous alloy by heating the metal in contact with a carbonaceous material—solid, liquid or gas—to a temperature above the transformation range and holding at that temperature. Carburizing is generally followed by quenching to produce a hardened case.

*** case.** In a ferrous alloy, the surface layer that has been made substantially harder than the interior or *core* by a process of *case hardening.*

*** case hardening.** A process of hardening a ferrous alloy so that the surface layer or *case* is made substantially harder than the interior or *core.* Typical case-hardening processes are *carburizing* and *quenching, cyaniding, carbonitriding, nitriding, induction hardening* and *flame hardening.*

casting. (1) Pouring molten metal into a mold. (2) The metal object produced by such pouring.

casting cracks. See *shrinkage cracks.*

casting shrinkage. See *solidification shrinkage.*

casting strains. Strains resulting from the cooling of a casting and accompanied by residual stresses.

cast steel. Any object made by pouring molten steel into molds.

cast structure. The structure, on a macroscopic or microscopic scale, of a cast alloy that consists of cored dendrites and, in some alloys, a network of other constituents.

cathode copper. The product of electrolytic refining of copper, which is used to charge furnaces in preparation for the final casting of copper and copper alloys.

cathodic protection. The use of a particular metal as cathode in the corrosion cell as a means of protecting that metal against *electrochemical corrosion.* This may be accomplished by the attachment of a more anodic metal or by the use of an applied potential.

caustic dip. Immersion in a solution of sodium hydroxide to clean the surface or, when working with aluminum alloys, to reveal the macrostructure.

cavitation erosion. Damage to a material in contact with a moving liquid, associated with the formation and collapse of cavities in the liquid at the solid-liquid interface.

cell. (1) A combination of two electrodes immersed in an electrolyte. Such a cell may set up an electromotive force, and if the electrodes are connected externally, an electric current will flow. (2) A unit for the electrodeposition of metals from an electrolyte.

cell feed. The material supplied to the cell in the electrolytic production of metals.

*** cementation.** A process of introducing elements into the outer layer of metal objects by means of diffusion at high temperature.

cementation. A process for obtaining a metal from a solution of one of its compounds through displacement by ■ more electropositive element. See *electromotive series.*

cementite. A compound of iron and carbon known as "iron carbide", which has the approximate chemical formula Fe_3C and is characterized by an orthorhombic crystal structure.

centrifugal casting. A casting technique in which the mold is rotated during solidification of the casting. Unusually sound castings may be produced by the action of centrifugal force pressing toward the periphery.

chafing fatigue. Accelerated fatigue caused by the stress-raising effect of frictional contacts.

chaplets. Metal supports for holding the cores of sand molds in place.

Charpy test. A pendulum type of impact test in which a specimen, supported at both ends as a simple beam, is broken by the impact of the falling pendulum. The energy absorbed in breaking the specimen, as determined by the decreased rise of the pendulum, is a measure of the impact strength of the metal. See *Izod test.*

check marks. On the surface of copper wire, defects in the form of V's, which are found in a line and point in the direction of drawing. Also called "crowfeet" and "fishhooks".

cheeks. The intermediate sections of a flask that are inserted between cope and drag to decrease the difficulty of molding unusual shapes or to fill a need for more than one parting line.

chemical deposition. The precipitation of one metal from a solution of its salt by the addition of another metal or reagent to the solution.

Chempur tin. Commercial tin of high purity, for example 99.991%.

chill-cast pig. Pig iron cast into metal molds or chills. If a machine is used the product is known as "machine-cast pig".

chills. Metallic inserts located in positions in sand molds where rapid cooling is desired.

Chinese script. A configuration typical of the constituents in cast aluminum alloys containing specific amounts of iron and silicon. This term applies also to a similar structure found in magnesium alloys containing silicon.

chipping. A method for removing seams and other surface defects with chisel or gouge so that such defects will not be worked into the finished product. Chipping is often employed also to remove metal that is excessive but not defective. Removal of defects by gas cutting is known as "deseaming" or "scarfing".

chlorination. (1) The roasting of prepared ore in contact with a chloride, usually common salt, to convert certain metals into the more easily separated chloride. (2) The degassing or purification of molten metals by fluxing with chlorine.

chrome pickle. A chemical treatment for magnesium in a nitric acid, sodium dichromate solution. The treatment gives some protection against corrosion by producing a film that is also a base for paint.

cladding. A process for covering one metal with another. Usually the surfaces of fairly thick slabs of two metals are brought carefully into contact and are then subjected to co-rolling so that a clad composition results. In some instances a thick electroplate may be deposited before rolling.
classification. *Powd met.* Separation of a powder into fractions according to particle size.
cleavage plane. A crystallographic plane on which fracture occurs in a crystal or grain of metal. A substance may fracture on more than one crystallographic plane.
close annealing. See *box annealing.*
closed dies. Forging dies in which the compressive force is applied to the whole surface of the forging. In *open* dies, there is no constraint to lateral flow in some directions.
closed passes. Grooves in rod rolls designed so that they restrain the metal from forming fins between the rolls.
cloth. *Powd met.* Metallic or nonmetallic fabric used for screening or classifying powders.
cloudburst treatment. Surface hardening by impingement of steel balls.
cluster mill. A rolling mill where each of the two working rolls of small diameter is supported by two or more back-up rolls.
coalesced copper. The product of a patented process for deposition of brittle copper cathodes and subsequent sintering of briquettes of the pieces of broken-up cathodes. The sintered briquettes can be worked into an oxide-free copper of good physical properties.
coalescence. (1) The growth of particles of a dispersed phase by solution and reprecipitation. (2) The growth of grains by absorption of adjacent undistorted grains.
coated particles. *Powd met.* Metal particles of which the surfaces have been covered with another metal.
cockles. Waviness at the edge of sheet metal. See *riffles.*
coercive force. The magnetizing force that must be applied in the direction opposite to that of the previous magnetizing force in order to remove residual magnetism; thus, an indicator of the "strength" of magnetically hard materials.
cogging. *Fer met.* Rolling or forging ingots to blooms or billets.
cogging hammer. *Fer met.* A forging hammer used to reduce ingots to blooms or billets.
cohesive strength. A term used with one of the following meanings: (1) The maximum stress required in order to cause tensile fracture in the absence of any deformation, when two of the three principal stresses equal zero; that is, with an unnotched bar. Sometimes called "initial cohesive strength". (2) The maximum principal stress required in order to cause tensile fracture when triaxial stresses are present; that is, by using a notched test bar. This is frequently called the "technical cohesive strength" and is variable, depending on the relative magnitude of the three principal stresses, the amount of plastic deformation preceding fracture, and the temperature and rate of straining. (3) See *disruptive strength.*
coinage metals. Alloys of gold or silver with nickel or copper, used for minting coins.
coining. A process of impressing images or characters of the die and punch onto a plane metal surface. See also *sizing* for *Powd met* usage.
coin silver. An alloy, standard in the United States, containing 900 parts of silver and 100 parts of copper.
cold pressing. *Powd met.* Forming a compact at room temperature.
cold short. The characteristic of metals that are brittle at ordinary or low temperatures.
cold shut. (1) A discontinuity that appears on the surface of cast metal as a result of two streams of liquid meeting and failing to unite. Pouring the metal when it is too cold may cause such a discontinuity. (2) On a forging, a portion of the surface that is separated by oxide from the main body of metal.
cold work. Plastic deformation at such temperatures and rates that substantial increases occur in the strength and hardness of the metal. Visible structural changes include changes in grain shape and, in some instances, mechanical twinning or banding.
cold working. Deforming a metal plastically at such a temperature and rate that strain hardening occurs. The upper limit of temperature for this process is the *recrystallization temperature.*
columnar structure. A coarse structure of parallel columns of grains, which is caused by highly directional solidification resulting from sharp thermal gradients.
combined carbon. The carbon that is combined with iron or alloying elements to form carbide in cast iron or steel.
comminution. See *pulverization.*
compact. *Powd met.* An object produced by the compression of metal powders with or without the inclusion of nonmetallic constituents. Synonymous with *briquette.*
components. (1) The least number of chemical substances or metals required to create the system under consideration. (2) The individual parts of a stress or strain vector as referred to a system of co-ordinates.
composite compact. *Powd met.* A metal powder compact consisting of two or more adhering layers of different metals or alloys, with each layer retaining its original identity.
compound compact. *Powd met.* A metal powder compact consisting of mixed metals, the particles of which are joined by pressing or sintering or both, with each metal particle retaining substantially its original composition.
compression ratio. *Powd met.* The ratio of the volume of the loose powder to the volume of the compact made from it by the application of a specified pressure in a specified die at a specified pressing speed.
compressive strength. Yield. The maximum stress that a metal, subjected to compression, can withstand without a predefined amount of deformation. **Ultimate.** The maximum stress that a brittle material can withstand without fracture when subjected to compression.
congruent transformation. A solid state or solid-liquid phase change involving no change in composition.
constant-deflection test. A stress-corrosion-cracking or mechanical test in which the specimen is stressed by bending to a definite and constant curvature.
constant-load test. A stress-corrosion-cracking or mechanical test in which the specimen is stressed by applying a dead load.
constituent. A micrographically distinguishable part of an alloy or mixture.
constitution diagram. See *phase diagram.*
continuous casting. A casting technique in which the ingot is continuously solidified while it is being poured, and the length is not determined by mold dimensions.
continuous electrode. In an electric-arc furnace, a type of electrode that is replenished as it is consumed.
continuous phase. In alloys containing more than one phase, the phase that forms the matrix or background in which the other phase or phases are present as isolated units.
★ **controlled cooling.** A process of cooling from an elevated temperature in a predetermined manner, to avoid hardening, cracking or internal damage, or to produce a desired microstructure. This cooling usually follows the final hot forming operation.
converter. A furnace in which air is blown through the molten bath of crude metal or matte for the purpose of oxidizing impurities.
cooling curve. A curve showing the relation between time and temperature during the cooling of a metal sample. Since most phase changes involve evolution or absorption of heat, there may be abrupt changes in the slope of the curve.
cooling stresses. Stresses developed by uneven contraction or external constraint of metal during cooling; also those stresses resulting from localized plastic deformation during cooling, and retained.
cope. The upper or topmost section of a flask, mold or pattern.
core. (1) A body of sand or other material placed in a mold to produce a cavity in a casting. (2) A tubular defect that comes from the surface of a billet and appears at the back end of extruded rod. (3) The center or base portion of a clad product.
★ **core.** In a ferrous alloy, the interior portion that is substantially softer than the surface layer or *case*, after *case hardening.*
cored bar. *Powd met.* A compact of bar shape heated, by its own electrical resistance, to a temperature that melts its interior.
core rod. *Powd met.* The part of a die used to produce a hole in a compact.
coring. Variable composition in solid-solution dendrites; the center of the dendrite is richer in one element, as shown by the pertinent solidus-liquidus lines in a phase diagram.
corrosion. Gradual chemical or electrochemical attack on a metal by atmosphere, moisture or other agents.
corrosion embrittlement. The embrittlement caused in certain alloys by exposure to a corrosive environment. Such material is usually susceptible to the intergranular type of corrosion attack.
corrosion fatigue. The repeated cyclic stressing of a metal in a corrosive medium, resulting in more rapid deterioration of properties than would be encountered as a result of either cyclic stressing or of corrosion alone.
couple. Two dissimilar conductors in electrical contact. An electromotive force is created under proper electrolytic influences or during heating.
coupon. An extra piece of metal (for example, on a casting) from which a specimen for physical or mechanical testing is cut or machined.
creep. The flow or plastic deformation of metals held for long periods of time at stresses lower than the normal yield strength. The effect is particularly important if the temperature of stressing is in the vicinity of the recrystallization temperature of the metal.
creep limit. The maximum stress that will result in creep at a rate lower than an assigned rate.
critical point. *Transformation temperature* is the term preferred.
★ **critical range or critical temperature range.** Synonymous with *transformation range,* which is preferred.
critical strain. The percentage strain at which, or immediately higher than which, large grain growth occurs during heating.
critical temperature. *Transformation temperature* is the term preferred.
crop. The end or ends of an ingot that contain the pipe or other defects to be cut off and discarded; also termed "crop end" and "discard".
cross rolling. The rolling of sheet so that the direction of rolling is changed about 90 deg from the direction of the previous rolling.
crown. In the center of metal sheet or strip, thickness greater than at the edge.
crucible. A ceramic pot or receptacle made of graphite and clay, or clay or other refractory material, and used in the melting of metal. The term is sometimes applied to pots made of cast iron, cast steel or wrought steel.
crystal. A physically homogeneous solid in which the atoms, ions or molecules are arranged in a three-dimensional repetitive pattern.
crystallization. The formation of crystals by the atoms assuming definite positions in a crystal lattice. This is what happens when a liquid metal solidifies. (Fatigue, the failure of metals under repeated stresses, is sometimes falsely attributed to crystallization.)
cup fracture. The type of fracture in which the exterior portion is extended and the interior is relatively depressed, resembling a cup. When only a part of the exterior is extended, the term "half-cupped" or "quarter-cupped" is used.
cupellation. Oxidizing fusion of lead that contains silver and gold, in order to remove the base metal entirely. The process is used also in the manufacture of lead oxide.
cupping. The breaking of wire with a cup fracture accompanied by very little reduction of area; observed during cold drawing. Also the forming of sheet into cuplike objects such as shells, by deep drawing.
curling. Rounding the edge of sheet metal into a closed or partly closed loop.
cut. See *fraction.*
cyanide slimes. Gold precipitated from cyanide solutions used in extracting gold from ores.
★ **cyaniding.** A process of case hardening a ferrous alloy by heating in a molten cyanide, thus causing the alloy to absorb carbon and nitrogen simultaneously. Cyaniding is usually followed by quenching to produce a hard case.

D

damping capacity. The ability of a metal to absorb vibrations, changing the mechanical energy into heat. See *internal friction.*
D. C. (Direct Chill) ingot casting practice. A continuous method of casting ingots for sheet or extrusion by pouring the metal into a short mold that is gradually lowered while the metal solidifies. The mold has no fixed bottom, but the movable platform serves at the start of the operation or "drop". When the platform is gradually lowered, the frozen shell of metal acts as a retainer for the liquid

metal. The ingot is usually cooled by the impingement of water directly on the mold or on the walls of the ingot being lowered.

dead roast. A roasting process for complete elimination of sulfur.

decalescence. The decrease that is caused in temperature when the rate of absorption of heat during transformation exceeds the rate of input of heat while heating steel through the transformation range.

* **decarburization.** The loss of carbon from the surface of a ferrous alloy as a result of heating in a medium that reacts with the carbon.

deep drawing. Forming cup-shaped articles or shells by using a punch to force sheet metal into a die.

deep etching. Macro-etching; etching, for examination at a low magnification, in a reagent that attacks the metal to a much greater extent than normal for microscopic examination. Gross features may be developed—abnormal grain size, segregation, cracks or grain flow.

deformation bands. Bands within individual cold worked crystals. The bands and matrix differ variably in orientation.

degrees of freedom. The number of independently variable quantities (such as temperature, pressure, and concentration within the phases present) that may be altered at will without causing alteration in the number of phases in a system; or, the number of such variables that must be fixed arbitrarily in order to define the system completely.

dendrite. A crystal formed usually by solidification and characterized by a treelike pattern composed of many branches; also termed "pine tree" and "fir tree" crystal.

dendritic powder. *Powd met.* Particles, usually of electrolytic origin, with typical "pine tree" structure. Synonym, *arborescent powder*.

density ratio. *Powd met.* The determined density of a green or sintered compact, divided by the absolute density of metal of the same composition; usually expressed as a percentage.

deseaming. See *chipping*.

dezincification. Corrosion of an alloy containing zinc (usually brass), involving loss of zinc and a surface residue or deposit of one or more less active components (usually copper).

diamagnetic. A material that has less magnetic permeability than a vacuum. The material would be repelled weakly by a magnet.

dichromate treatment. A chemical treatment for magnesium alloys in a boiling sodium dichromate solution, resulting in a surface film that resists corrosion.

die. *Powd met.* The part or parts making up the confining form into which a powder is pressed. The parts of the die may include some or all of the following: die body, punches, core rods. Synonym, *mold*.

die body. *Powd met.* The stationary or fixed part of a die.

die casting. Casting metals into final shapes in metal molds; usually alloys that have relatively low melting points, such as zinc, lead, tin, aluminum or magnesium base alloys. If the metal is forced into the mold, the process is called "pressure die casting"; otherwise, "gravity or permanent mold die casting".

die forging. See *drop forging*.

die insert. *Powd met.* A removable liner or part of a die body or punch.

die lines. Lines or markings caused on drawn or extruded products by minor imperfections in the surface of the die.

die plates. Plates of steel or iron with tapered holes of several sizes for drawing wire.

die radius. The radius on the exposed edge of a deep drawing die, over which the sheet flows in forming drawn shells.

die scalping. Drawing through a sharp-edged die to cut off the surface.

die set. *Powd met.* The parts of a press that hold the die and locate it in proper relation to the punches.

die sinking. Forming or machining a depressed pattern in a die.

differential flotation. A flotation process for separating a complex ore into two or more valuable minerals and gangue.

* **differential heating.** A heating process by which the temperature is varied within the object so that, after cooling, various parts may have different properties as desired.

diffusion. A movement of atoms within a solution. The net movement is usually in the direction from regions of high concentration toward regions of low concentration in order to achieve homogeneity of the solution, which may be a liquid, solid or gas.

diffusion coefficient. A factor of proportionality representing the amount of substance in grams diffusing in one second across an area of one square centimeter through a unit concentration gradient.

diffusion zone. In the clad type of products, the zone between coating and core, in which diffusion between the two has occurred.

dilatometer. An instrument for measuring the expansion or contraction caused in a metal by changes in temperature or structure.

dimpling. A process of cupping sheet so as to permit the use of rivets that have countersunk heads. Dimpling differs from countersinking in that it is a cupping operation and no metal is cut away after the rivet hole has been drilled.

direct extrusion. Extrusion through a die placed at the opposite end of the billet from the ram.

directional properties. Anisotropic condition where physical and mechanical properties vary, depending on the relation of the test axis to a specific direction of the metal; a result of preferred orientation or of fibering of inclusions during the working.

* **direct quenching.** A process of quenching carburized parts directly from the carburizing operation.

discard. See *crop*.

disintegration. *Powd met.* Reduction of massive material to powder.

dislocations. Postulated vacant atom sites in metal crystals. These vacant sites may move under stress or alloy concentration gradients, and such movements are employed to explain plastic deformation, creep, diffusion and other phenomena.

dispersoid. Finely divided particles of a relatively insoluble constituent, apparent in the microstructure of certain alloys.

disruptive strength. The maximum strength of a metal when subjected to three principal tensile stresses at right angles to one another and of equal magnitude.

doré silver. Crude silver containing a small amount of gold, obtained after removing lead in a cupeling furnace, during the processing of slimes from copper anodes.

Dow process. A process for the production of magnesium by electrolysis of molten magnesium chloride.

draft. (1) The amount of taper in the side walls of die impressions. (2) The taper given to the sides of a pattern to enable it to be withdrawn easily from the mold.

drag. The lower or bottom section of a mold or pattern.

drawbench. The stand that holds the die and drawhead used in drawing wire, rod and tubing.

drawing. See *tempering*.

drawing or cupping tools. Major tools involved in deep drawing, such as the *die*, *punch*, *blank holder* and *knockout*.

drawn shells. Articles formed by deep drawing sheet into rectangular, cylindrical, hemispherical or odd shapes.

drop forging. Forming metal, usually under impact, by compression within dies designed to produce the required shape. The term is ordinarily used synonymously with *hot die forging*.

drop hammer. A forging machine that employs the impact resulting from the action of gravity, with or without added steam or air pressure, on a falling ram.

dross. Metal oxides in or on molten metal.

dry cyaniding. Synonymous with *carbonitriding*.

dry sand mold. A casting mold of sand, which is thoroughly dried before being filled with liquid metal.

ductility. The property that permits permanent deformation before fracture by stress in tension.

dummy. Stock that has been given a preliminary rough shaping before being placed between dies for drop forging complicated shapes.

dummy block. A free cylinder that transmits pressure from the ram to the billet in the extrusion of metals.

duralumin. The trade name applied to the first aluminum-copper-magnesium type of age-hardenable alloy (17S), which contains nominally 4% Cu, ½% Mn and ½% Mg. The term is sometimes used to include the class of wrought aluminum-copper-magnesium alloys that harden during aging at room temperature.

Durville process. A casting process that involves rigid attachment of the mold in an inverted position above the crucible. The melt is poured by tilting the entire assembly, causing the metal to flow along a connecting launder and down the side of the mold.

dusting. Applying an agent such as powdered sulfur to prevent the burning of molten magnesium alloys during pouring.

E

ear. A wavy projection formed in the course of deep drawing, as a result of directional properties or anisotropy of the sheet.

edger. The portion of a die used for preliminary forging that distributes the metal in the general proportions of the shape to be forged.

elastic aftereffect. A slight contraction that occurs slowly while metal is standing with no load, subsequent to plastic tensile flow and immediate elastic recovery. *Microscopic stresses*, acting in compression, are responsible for this as well as for the Bauschinger effect.

elastic constants. In the general form of Hooke's law, the elastic moduli, which vary in individual crystals with the direction of test.

elastic deformation. Temporary changes caused in dimensions by stress. The material returns to the original dimensions after removal of the stress.

elastic hysteresis. Energy absorbed by reversed deformation, represented by the closed loop of stress-strain curves in the elastic range, formed by curves for loading and unloading.

elastic limit. The maximum stress that a material will withstand without permanent deformation. (Almost never determined experimentally; *yield strength* is customarily determined.)

electrochemical corrosion. Localized corrosion that results from exposure of an assembly of dissimilar metals in contact or coupled with one another; or of a metal containing macroscopic or microscopic areas dissimilar in composition or structure. The dissimilar elements form short-circuited electrodes, the corrosive medium is the electrolyte, and an electric current is induced, which results in the dissolution of the electrode that has the more anodic solution potential, while the other is unattacked. The same condition may result from local differences within the corroding medium.

electrode potential. See *solution potential*.

electroforming. Production or reproduction of articles by electrolytic deposition.

electrolytic brightening. See *anodic treatments*.

electrolytic deposition. *Powd met.* The production of a metal from a solution of its salts by the passage of an electric current through the solution.

electrolytic oxidation. See *anodic treatments*.

electrolytic polishing. See *anodic treatments*.

electrolytic protection. Protection from electrochemical corrosion by use of the protected material as cathode in the corrosion cell. See also *cathodic protection*.

electromotive (force) series. A list of elements arranged according to their *standard electrode potentials*.

electron microscope. A microscope that utilizes electron beams of short wave length and magnetic fields instead of the visible light and glass lenses utilized in ordinary microscopes. However, since the electron beams will not reflect in the same way as visible light, a thin replica of polished and etched metal surfaces is employed. Magnifications of the replica from ×5000 to 50,000 are readily obtained.

electron valence ratios. In structurally analogous compounds, the ratio of valence electrons to atoms; 3:2, 7:4 and 21:13 are common.

elinvar. An iron-base alloy containing about 36% Ni and 12% Cr, used for its constancy of elastic modulus with temperature.

elongation. The amount of permanent extension in the vicinity of the fracture in the tension test; usually expressed as a percentage of the original gage length, as 25% in 2 in. Elongation may also refer to the amount of extension at any stage in any process that elongates a body continuously, as in rolling.

embossing. Raising a design in relief against a surface.

endurance limit. The maximum stress that a metal will withstand without failure during a specified large number of cycles of stress. If the term is employed without qualification, the cycles of stress are usually such as to produce complete reversal of flexural stress.

endurance ratio. The ratio of the endurance limit for cycles of reversed flexural stress to the tensile strength.

epsilon structure. Structurally analogous, close-packed phases or electron compounds that have ratios of 7 valence electrons to 4 atoms.

equilibrium. A dynamic condition of balance between atomic movements, where the resultant is zero and the condition appears to be one of rest rather than change.

equilibrium diagram. See *phase diagram*.

Erichsen test. A ductility or cupping test in which the depth of impression at fracture, made by forcing a cone-shaped, spherical-end plunger into the sheet specimen, is measured in millimeters.
erosion. The abrasion of metal or other material by liquid or gas, usually accelerated by pressure of solid particles of matter in suspension, and sometimes by corrosion.
etch figures. Markings caused by an etchant on a crystal surface and usually related geometrically to the crystal structure.
etching. In metallography, the process of revealing structural details by the preferential attack of reagents on a metal surface.
eutectic (1) The isothermal reversible reaction of a liquid that forms two different solid phases (in a binary alloy system) during cooling. (2) The alloy composition that freezes at constant temperature, undergoing the eutectic reaction completely. (3) The alloy structure of two (or more) solid phases formed from the liquid eutectically.
eutectic alloy. In an alloy system, the composition at which two descending liquidus curves in a binary system or three descending liquidus surfaces in a ternary system meet at a point. Thus such an alloy has a lower melting point than neighboring compositions. More than one eutectic composition may occur in a given alloy system.
eutectic melting. Melting of local micro areas that are the same as the eutectic in average composition. On cooling rapidly, these areas solidify into a typical eutectic structure. See *rosette*, 1.
eutectoid reaction. The isothermal reversible reaction of a solid that forms two new solid phases (in a binary alloy system) during cooling. As with *eutectic*, the word *eutectoid* can also refer to an alloy composition or structure associated with the reaction.
eutectoid steel. A steel of the eutectoid composition (composition *S* on the iron-carbon diagram). This composition in pure iron-carbon alloys is 0.80% C, but variations from this composition are found in commercial (impure) steels, and particularly in alloy steels, in which the carbon content of the eutectoid is usually lower.
exfoliation. A type of corrosion that progresses parallel to the outer surface of the metal, causing layers of the metal to be elevated by the formation of corrosion product. See also *spalling*.
explosive rivet. A type of blind fastener in which a hollow-shank rivet is used, containing an explosive charge. The rivet shank is expanded by exploding the charge after the rivet has been inserted.
extensometer. Device, usually mechanical, for indicating the deformation of metal while it is subjected to stress.
extrusion. Shaping metal into a chosen continuous form by forcing it through a die of appropriate shape.
extrusion defect. See *core*.
extrusion ingot or billet. Cast or preworked metal used as starting stock in extrusion.

F

fatigue. The tendency for a metal to break under conditions of repeated cyclic stressing considerably below the ultimate tensile strength.
fatigue crack or failure. A fracture starting from a nucleus where there is an abnormal concentration of cyclic stress and propagating through the metal. The surface is smooth and frequently shows concentric (sea shell) markings with a nucleus as a center.
fatigue limit. The maximum stress that a metal will withstand without failure for a specified large number of cycles of stress. Usually synonymous with *endurance limit.*
faying surfaces. The contacting surfaces of overlapped metal in a lapped joint.
feeder head. See *riser*.
ferrite. A solid solution in which alpha iron is the solvent, and which is characterized by a body-centered cubic crystal structure.
ferro-alloy. An alloy of iron that contains a sufficient amount of one or more chemical elements—such as manganese, chromium, or silicon —to be useful as an agent for introducing these elements into steel by admixture with molten steel.
fiber, fibre. (1) A characteristic of wrought metal that indicates directional properties and is revealed by the etching of a longitudinal section or is manifested by the fibrous or woody appearance of a fracture. Fiber is caused chiefly by the extension of the constituents of the metal, both metallic and nonmetallic, in the direction of working. (2) The pattern of preferred orientation of metal crystals after a given deformation process (usually wiredrawing); see "fibering" in the Glossary of Terms Used in X-Ray Metallography. See *preferred orientation.*
fiber stress. Local stress at a point or line on a section over which stress is not uniform, such as on the cross section of a beam under a bending load.
filler metal. In brazing or welding, the added metal melted by the arc or flame and acting to bind edges or fill empty zones.
fillet. A concave junction of two (usually perpendicular) surfaces.
fin. See *flash*.
fineness. Parts per 1000 of gold or silver.
fines. *Powd met.* The portion of a powder composed of particles smaller than a specified size, currently less than 44 microns.
fines. See *shorts*.
finished steel. Steel that is ready for the market without further work or treatment. Blooms, billets, slabs, sheet bars, and wire rods are termed "semifinished".
finisher. Die for making the final impression in forging an article.
finishing temperature. The temperature at which hot mechanical working of metal is completed.
fire scale. Copper oxide subscale formed just under the surface of silver-copper alloys when annealed in air.
fir tree crystal. See *dendrite*.
fishmouthing. See *alligatoring*.
fishtail. An overlapping at the back end of rolled sheet.
flake powder. *Powd met.* Flat or scale-like particles, relatively thin.
flakes. Internal fissures in ferrous metals. In a fractured surface these fissures may appear as sizeable areas of silvery brightness and coarse texture; in wrought products such fissures may appear as short discontinuities on an etched section. Also called "shatter cracks", "chrome checks", "fish eyes" and "snowflakes".
★ **flame annealing.** A process of softening a metal by the application of heat from a high-temperature flame.
★ **flame hardening.** A process of hardening a ferrous alloy by heating it above the transformation range by means of a high-temperature flame, and then cooling as required.
flange. (1) A projection of metal on formed objects. (2) The parts of a channel at right angles to the central section or web.
flapping. An operation that precedes poling in the fire-refining of copper. The surface of the slag is broken by striking with a rabble blade, and the melted metal is exposed to the air in order to hasten oxidation.
flash. A thin fin of metal formed at the sides of a forging or weld when a small portion of metal is forced out between the edges of the forging or welding dies.
flask. The outer metal or wood frame, consisting of the cope and drag, used to hold the sand around the pattern in making a sand mold.
flat sheet. Sheet rolled as pieces of convenient size and then flattened or leveled, usually by stretching. This operation may produce properties slightly different from those of *coiled sheet*.
floating plug. A plug that locates itself inside a tube during drawing, in such a way that the tube is reduced in thickness between the plug and the die.
flotation. The concentration of valuable minerals from ores by agitation of the ground ore with water, oil and flotation chemicals. Normally the valuable minerals are wetted by the oil, are lifted to the surface by air bubbles and are then floated off.
flow rate. *Powd met.* The time required for a powder sample of standard weight to flow through an orifice in a standard instrument according to a specified procedure.
flow stress. The shear stress required to cause plastic deformation of solid metals.
fluidity. The ability of a liquid metal to flow readily, as measured by the length of a standard spiral casting.
fluting. Kinking or breaking caused by the curving of metal strip on a radius so small, in relation to thickness, as to stretch the outer surface well beyond its elastic limit.
flux-coated electrode. A rod of filler metal on which a coating of flux has been baked for use in arc welding.
fluxing. Applying ■ solid or gaseous material to molten metal in order to remove oxide dross and other foreign materials. The treatment of molten magnesium alloys with flux is frequently called *refining*.
fly ash. A finely divided product of combustion, which may appear as inclusions in metal melted in the open hearth type of furnace.
fog quenching. A method of quenching in which a fine vapor or mist is used as the quenching medium. See also *spray quenching*.
foil. Metal in any width but no more than about 0.005 in. thick.
folds. Defects caused in metal by continued fabrication of overlapping surfaces.
forging rolls. Rolling mills that forge comparatively uniform shapes by using variable radii around the circumference of rolls that rotate in the opposite direction from those ordinarily used for rolling.
forging strains. Differential strains that result from forging or from cooling from the forging temperature, and that are accompanied by residual stresses.
fraction. *Powd met.* That portion of ■ powder sample which is between two stated particle sizes or two stated screen-mesh sizes. Synonymous with *cut*.
fracture stress. The maximum principal true stress (fracture load divided by fracture area). See *cohesive strength*.
fracture test. *Fer met.* Breaking a piece of metal for the purpose of examining the fractured surface to determine the structure or carbon content of the metal or to detect the presence of internal defects.
fragmentation. Imperfection of the crystal structure of grains in a metal as the result of working. The fragments differ slightly from one another in orientation, and tend to rotate to a stable orientation.
free ferrite. Ferrite formed from austenite during cooling, without simultaneous formation of carbide.
free machining. The property that makes machining easy because of the forming of small chips, a characteristic imparted to steel by sulfur, to brass by lead, to aluminum alloys by lead and bismuth, to nickel alloys by sulfur or carbon, and so on.
fretting corrosion. Corrosion at the interface between two contacting surfaces, accelerated by vibration between the two sufficient to produce localized deformation.
★ **full annealing.** A softening process in which a ferrous alloy is heated to a temperature above the transformation range and, after being held for a sufficient time at this temperature, is cooled slowly to a temperature below the transformation range. The alloy is ordinarily allowed to cool slowly in the furnace, although it may be removed and cooled in some medium that ensures a slow rate of cooling.
fuller. In preliminary forging, the portion of a die that reduces the cross-sectional area between the ends of the stock and permits the metal to move outward.

G

galling. The damaging of one or both metallic surfaces by removal of particles from localized areas during sliding friction.
galling. *Powd met.* The impairment caused on the surface of a compact or of die parts by adhesion between the die wall and the metal powder. Synonymous with *seizing*.
galvanic corrosion. See *electrochemical corrosion*.
gamma iron. The form of iron stable between Ae_3 and Ae_4 (910 and 1400 C; 1670 and 2550 F) and characterized by a face-centered cubic crystal structure. See *transformation temperature* for definitions of Ae_3 and Ae_4.
gamma structure. Structurally analogous phases or electron compounds that have ratios of 21 valence electrons to 13 atoms; generally a large complex cubic structure.
gangue. In an ore, the commercially undesirable portion that must be removed before further processing.
gas cyaniding. Synonymous with *carbonitriding*.
gaseous reduction. *Powd met.* The conversion of metal compounds to metallic particles by the use of a reducing gas.
gassing. (1) The absorption of gas by ■ metal. (2) The evolution of gas from a metal.
gassing of copper. See *hydrogen embrittlement*.
gas welding. Manual or automatic torch welding of metals, in which the heating is accomplished by an oxyacetylene or oxyhydrogen flame.
gate. (1) The point where molten metal enters the casting cavity. (2) The assembly of *pouring basin*, *sprue*, and *runner*, forming a channel for pouring liquid metal into a casting mold.
gated pattern. Mold patterns designed to permit two or more castings, joined by connecting channels, to be made in one mold.

German silver. An alloy of copper, zinc and nickel, containing no silver and probably not originating in Germany. See *nickel silver.*

germinative conditions. The presence of a critical amount of cold work in a metal, which leads to the development of a very coarse grain structure as a result of heating. See *critical strain.*

globular powder. *Powd met.* Particles approximately spherical.

gold-filled. Consisting of base metal mechanically covered with a layer of gold alloy and used as a substitute for solid gold. The quality of gold-filled articles is controlled by federal authority.

gold leaf. Gold beaten or rolled extremely thin and used for gilding. Imitation gold leaf is made of brass.

grained metal. Metal of a fine particle size produced by stirring or otherwise breaking up the metal while it is cooling through the freezing range.

grain growth. An increase in the grain size of metal.

grain refiner. Any material added to a liquid metal for the purpose of producing a finer grain size in the subsequent casting, or of retaining fine grains during the heat treatment of wrought structures.

grains. Individual crystals in metals.

grain size. In many nonferrous metals, particularly alpha brasses, grain size is expressed in millimeters average diameter and is determined by comparison with standards at 75 diameters in magnification. The grain size may also be expressed in terms of the number of grains per unit area or volume.

granular powder. *Powd met.* Particles that have approximately equidimensional, nonspherical shapes.

granulated metal. Metal in small pellets formed by allowing thin streams of the liquid metal to fall into water. The streams are usually formed by pouring the metal on wire mesh. Another process involves a rotating disk from which the liquid metal is dispersed by centrifugal force.

granulation. *Fer met.* The recrystallization of columnar crystals and dendrites in freshly solidified steel to form more or less equiaxed grains at temperatures near the solidus.

granulation. *Powd met.* The production of coarse metal particles by pouring the molten metal through a screen into water or by agitating the molten metal violently while it is solidifying.

graphitic embrittlement. Reduction in ductility of a metal or alloy, associated with the occurrence of graphite in the grain boundaries.

*** graphitizing.** A heating and cooling process by which the combined carbon in cast iron or steel is transformed, wholly or partly, to graphitic or free carbon. See *temper carbon.*

gravity segregation. Variable composition caused in a casting by the settling of the heavier constituents.

green. *Powd met.* Unsintered.

grizzly. A device consisting of approximately parallel bars used for the coarse separation or screening of ores.

growth. *Powd met.* The increase that may occur in the dimensions of a compact during the sintering operation.

Guerin forming. A method of forming in which the metal is forced to conform to the shape of a male die by the application of a hydrostatic force of confined rubber.

Guinier-Preston zones. In a structure precipitating from solid solution, the two-dimensional platelets that produce streaks on Laue X-ray photograms. These platelets form on specific crystallographic planes of the matrix lattice and produce the first discernible evidence of decomposition of a supersaturated solid solution.

H

Hall process. The usual process of winning aluminum from alumina by electrolytic reduction of a fused bath of alumina dissolved in cryolite.

hammer forging. A forging process in which the work is deformed by repeated blows. Compare with *press forging.*

hammering. Beating metal sheet into a desired shape either over a form or on a high-speed mechanical hammer, in which the sheet is moved between a small curved hammer and a similar anvil to produce the required dishing or thinning.

Hansgirg process. A method for producing magnesium by reduction of magnesium oxide with carbon.

hard drawn. A temper produced in wire, rod, or tube by cold drawing.

***hardenability.** In a ferrous alloy, the property that determines the depth and distribution of hardness induced by quenching.

hardener. A preliminary alloy, of composition high in one or more alloying elements, which is added in making a melt and which permits closer control of composition than is possible with the addition of the pure metals. Also referred to as *rich alloy* or *master alloy.*

*** hardening.** Any process for increasing the hardness of metal by suitable treatment, usually involving heating and cooling.

hard head. A tin-iron alloy obtained in the smelting of slags from the first treatment of tin concentrates in either the blast furnace or the reverberatory furnace.

hardness. Defined in terms of the method of measurement. (1) Usually the resistance to indentation. (2) Stiffness or temper of wrought products. (3) Machinability characteristics.

Hazelett process. A method for casting liquid metal continuously into rolls for sheet or plate.

heading. An upsetting process used to form rivet, screw and bolt heads in making these products from wire or rod.

hearth. In a reverberatory furnace, the portion that holds the molten metal or bath.

heat tinting. Heating in air a specimen with a suitable surface, in order to develop the structure by oxidizing or otherwise affecting the different constituents.

heat treatable alloy. An alloy hardenable by heat treatment.

heat treating film. A thin oxide coating or film formed on the surface of metals during thermal treatments.

*** heat treatment.** A combination of heating and cooling operations, timed and applied to a metal or alloy in the solid state in a way that will produce desired properties. Heating for the sole purpose of hot working is excluded from the meaning of this definition.

heterogeneous structure. A metallic structure with more than one phase.

Heyn stresses. See *microscopic stresses.*

high-temperature oxidation. Preferential attack on certain alloy constituents in light metal alloys during solution heat treatment. See *internal oxidation.*

hold down. The tool that exerts pressure normal to a sheet blank during deep drawing, in order to prevent wrinkling and to cause uniform circumferential compression while the large circumference of the blank is reduced to that of the shell.

holding furnace. A small furnace for maintaining molten metal, from a larger melting furnace, at the right casting temperature.

homogeneous. Usually defined as having identical characteristics throughout. However, *physical* homogeneity may require only an identity of lattice type throughout, while *chemical* homogeneity requires uniform distribution of alloying elements.

*** homogenizing.** A process of heat treatment at high temperature intended to eliminate or decrease chemical segregation by diffusion.

homogenizing treatment. A heat treatment, usually for a long time at a high temperature, designed to make metal chemically homogeneous.

homopolar crystals. Crystals where neighboring atoms share electrons; for instance, diamond, where the four outer (valence) electrons of each carbon atom are shared with its four nearest neighbors, thus completing an outer shell of eight electrons per atom.

Hooker process. A process of cold extrusion in a crank press, employed in making small arms cartridge cases and small thin-walled seamless tubes.

Hooke's law. Stress is proportional to strain in the elastic range.

Hoopes process. An electrolytic refining process for aluminum, in which three liquid layers are used in the reduction cell.

hot bed. A large enclosed area containing closely spaced rolls or rails for holding hot, partially rolled metal.

hot forming. Working operations, such as bending and drawing sheet and plate, forging, pressing, and heading, performed on metal heated to temperatures above room temperature.

hot pressing. *Powd met.* The simultaneous forming and heating of a compact.

hot shortness. Brittleness in hot metal.

hot top. See *sinkhead.*

*** hot quenching.** A process of quenching in a medium at a temperature substantially higher than atmospheric temperature.

hot working. Plastic deformation of metal at such a temperature and rate that strain hardening does not occur. The lower limit of temperature for this process is the recrystallization temperature.

humectant. Any material added to foundry sand to retain moisture.

hydrogen embrittlement. (1) In oxygen-bearing copper, silver, and similar metals, a condition of low ductility resulting from absorption of hydrogen at high temperature, internal reduction of cuprous or corresponding metallous oxide, and creation of intergranular holes or cracks by the accompanying generation of steam. (2) A condition of low ductility resulting from hydrogen absorption and internal pressure developed subsequently.

hydrogen loss. *Powd met.* The loss caused in the weight of metal powder or of a compact when a representative sample is heated for a specified time and temperature in an atmosphere of purified hydrogen; broadly, a measure of the oxygen content of the sample when the test is applied to materials that contain only such oxides as are reducible with hydrogen, and no other hydride-forming element.

hypereutectoid steel. A steel containing more than the eutectoid percentage of carbon. See *eutectoid steel.*

hypoeutectoid steel. A steel containing less than the eutectoid percentage of carbon. See *eutectoid steel.*

I

idiomorphic crystal. A perfect crystal exhibiting geometric arrangement of plane faces, observed occasionally with certain constituents or intermetallic compounds in the microstructure of cast alloys. The normal crystals, generally called "grains" in metallography, are of the imperfect or *allotriomorphic* type, since the outward form is determined more or less by the surroundings.

immersion coating. Coating a metal with a second metal by immersing the first in a solution containing ions of the second.

impact extrusion. A cold forming process in which the metal is forced by impact to flow around the punch, forming a tube with a solid bottom.

impact test. A test to determine the energy absorbed in fracturing a test bar at high velocity. The test may be in tension or in bending, or it may properly be a *notch* test if a notch is present, creating multiaxial stresses.

impoverishment. Loss of any constituent from an alloy or from localized areas of an alloy by oxidation, liquation, volatilization or changes in the solid state. The term "depletion" is also used, particularly in referring to the lowering of the concentration of solute in a solid solution, around particles precipitated from solid solution.

impregnation. *Powd met.* (1) The process of filling the pores of a sintered compact, usually with a liquid such as a lubricant. (2) The process of mixing particles of a nonmetallic substance in a matrix of metal powder, as in diamond-impregnated tools. (3) The process of filling the pores of a sintered or unsintered compact with a metal or alloy of lower melting point.

inclusions. Particles of impurities (usually oxides, sulfides, silicates and such) that are held mechanically, or are formed during solidification or by subsequent reaction within the solid metal.

indentation hardness. The resistance of a material to indentation. This is the usual type of hardness test, in which a pointed or rounded indenter is pressed into a surface under a substantially static load.

indirect extrusion (inverted). An extrusion process in which the metal is forced back inside a hollow ram that pushes the die.

*** induction hardening.** A process of hardening a ferrous alloy by heating it above the transformation range by means of electrical induction, and then cooling as required.

*** induction heating.** A process of heating by electrical induction.

ingot. A casting intended for subsequent rolling or forging.

ingot iron. An open hearth iron very low in carbon, manganese and most other impurities.

inhibitor. (1) A material such as fluoride, boric acid or sulfur, used to inhibit the burning of molten magnesium alloys. (2) An agent added to pickling or other solutions to minimize corrosion.

initial creep. The early part of the time-elongation curve for creep, in which extension increases at a rapid rate.

inoculation. The addition to molten metal of substances designed to form nuclei for crystallization.

inserts. Parts formed from a second material, usually a metal, which are placed in the mold and appear as integral structural parts of the final casting.
insoluble anode. In electrodeposition, an anode that does not go into solution during the electrolytic process.
intercept method. A method of determining surface or volume grain size by counting the number of grains per unit length, intersected by lines parallel to and at right angles to the direction of working. Multiplication of counts along two perpendicular lines gives the surface grain size for the plane defined by the lines, while multiplication of counts along three mutually perpendicular lines gives the volume grain size.
intercommunicating porosity. *Powd met.* In a sintered compact, the type of porosity that connects the pores in such a way that a fluid may pass from one to another through the entire compact.
intercrystalline cracking. Cracks or fractures that follow along grain boundaries in the microstructure of metals and alloys.
interdendritic attack. A type of electrochemical corrosion that sometimes occurs in as-cast alloys or alloys that have had very little working. The attack progresses preferentially through areas around the dendrites and dendritic arms, as a result of composition (coring) gradients.
intergranular corrosion. A type of electrochemical corrosion that progresses preferentially along the grain boundaries of an alloy, usually because the grain boundary regions contain material anodic to the central regions of the grains.
intermediate annealing. An annealing treatment given to wrought materials before fabrication to final gage and final thermal treatment.
intermetallic compound. A compound of two or more metals that has a characteristic crystal structure and may have a definite composition or a range of compositions corresponding to a solid solution.
internal friction. Ability of a metal to transform vibratory energy into heat. Internal friction generally refers to low stress levels of vibration; *damping* has a broader connotation since it may refer to stresses approaching or exceeding the yield strength.
internal oxidation. Preferential oxidation of certain phases or components of alloys before the oxidation of the matrix; a condition encountered when some alloys are heated to high temperatures in certain types of oxygen-containing atmospheres.
internal stress. A misnomer for *residual stress.*
interrupted aging. The aging of an alloy at two or more temperatures by steps, and cooling to room temperature after each step. Compare with *progressive aging.*
* **interrupted quenching.** A process of quenching in which the metal object being quenched is removed from the quenching medium while the object is at a temperature substantially higher than that of the quenching medium.
intracrystalline failures. Fractures across the grains in metal.
inverse segregation. A concentration of certain alloy constituents that have lower melting points, in the region corresponding to that first solidifying; caused by interdendritic flow of enriched liquid through channels where the pressure drops with contraction of dendrites. The internal evolution of hydrogen may also give a positive pressure, aiding this flow and causing a *liquated surface* or *tin sweat.*
investment compound. A refractory used for molds formed around wax patterns.
ion. An atom that is charged electrostatically as a result of losing or gaining an outer electron.
ionic crystal. A crystal where electron transfer results in some atoms having residual positive charges while others have residual negative electrical charges. Found in compounds of strongly electronegative and electropositive elements, for example, sodium chloride.
ironing. Thinning the walls of deep drawn articles by reducing the clearance between punch and die.
irregular powder. *Powd met.* Particles lacking symmetry.
isomorphous. Literally, "of like form"; phases with crystal structures of the same type.
* **isothermal annealing.** A process in which a ferrous alloy is heated to produce a structure partly or wholly austenitic, and is then cooled to and held at a temperature that causes transformation of the austenite to a relatively soft ferrite-carbide aggregate.
* **isothermal transformation.** The process of transforming austenite in a ferrous alloy to ferrite or a ferrite-carbide aggregate at any constant temperature within the *transformation range.*
Izod test. A pendulum type of impact test, in which the specimen is supported at one end as a cantilever beam and the energy required to break off the free end is used as a measure of impact strength. See *Charpy test.*

K

keyhole specimen. A type of notched impact test specimen in which a hole-and-slot notch, shaped like a keyhole, gives multiaxial stresses.
killed steel. Steel deoxidized with a strong deoxidizing agent such as silicon or aluminum in order to reduce the oxygen content to a minimum so that no reaction occurs between carbon and oxygen during solidification.
kiln. A furnace for calcining ores or concentrates.
kip. A load of 1000 lb or 453.59 kg.
knockout. (1) A mechanism for removing work from the die after completion of forming operations, such as deep drawing, forging or stamping. (2) The operation of removing sand cores from castings.
Knoop hardness. Microhardness determined from the resistance of the metal or of individual microconstituents to indentation by a diamond indenter making a rhombohedral impression with one long and one short diagonal.
knurling. Impressing a design into a metallic surface, usually by means of small, hard rollers that carry the design on their surfaces.
Krause rolling mill. A sheet rolling mill using a reciprocating action that accomplishes a high reduction in metal sheet during a single passage through the mill.

L

laminations. Defects resulting from the presence of blisters, seams or foreign inclusions aligned parallel to the worked surface of a metal.
lap. A surface defect appearing as a seam, caused by folding over hot metal, fins or sharp corners and then rolling or forging them into the surface, but not welding them.
lap weld. A term applied to a weld formed by lapping two pieces of metal and then pressing or hammering, and applied particularly to the longitudinal joint produced by a welding process for tubes or pipe, in which the edges of the skelp are beveled or scarfed so that when they are overlapped they can be welded together.
latent heat. Thermal energy absorbed or released when a substance changes state; that is, from one solid phase to another, or from solid to liquid, or the like.
launder. A channel for conducting molten metal.
leaching. Extracting a soluble material from a heterogeneous solid by dissolving out the soluble material in water or in a chemical solution, such as a dilute acid. The solution may be treated later to recover a metal or to analyze for a substance.
lead. Antimonial or hard. Lead containing antimony.
Soft. Lead made from relatively pure ores and containing very small amounts of impurities.
Desilverized. Lead made from argentiferous ores, often of low purity, and purified by the Parkes or Betts electrolytic processes.
ledeburite. The cementite-austenite eutectic structure that forms at point *C* on the iron-carbon diagram.
leveling. Flattening rolled metal sheet. See *roller flattening.*
levigation. Separation of fine powder from coarser material by suspension in liquid.
light metals. Metals and alloys that have a low specific gravity, such as beryllium, magnesium and aluminum.
lineage structure. Deviations from perfect alignment of parallel arms of columnar dendrites growing from a liquid. This type of imperfection may vary from a few minutes to as much as two degrees of arc difference in orientation from one part of the cast crystal to another.
liner. The slab of coating metal that is placed on the core alloy and is subsequently rolled down to clad sheet as a composite.
liquated surface. A surface of an ingot that exhibits exudations or protuberances as a result of inverse segregation. See *tin sweat.*
liquation. The partial melting of an alloy, which can be used to effect a separation of two or more constituents.
liquid gold, silver or platinum. Liquid preparations used for decorating pottery and porcelain. Firing produces bright metallic deposits.
liquidus. A line on a binary phase diagram or a surface on a ternary phase diagram, representing the temperatures at which freezing begins during cooling or melting ends during heating under equilibrium conditions.
loading. *Powd met.* The filling of the die cavity with powder.
loam. A coarse, strongly bonded molding sand used for making loam and dry sand casting molds.
local action. Electrochemical corrosion resulting from chemical or physical differences within the same alloy. Certain microscopic and macroscopic areas may be anodic to other areas and consequently may dissolve.
longitudinal direction. The direction in a wrought metal product parallel to the direction of working (drawing, extruding, rolling).
lost wax process. A precision casting process in which a wax pattern is used. The wax pattern is invested in a plaster slurry; then after the mold is dry, the wax is melted and poured out of the mold cavity.
lower punch. *Powd met.* The lower part of a die, which forms the bottom of the die cavity, and which may or may not move in relation to the die body.
lubricating. *Powd met.* Mixing some agent with a powder or incorporating an agent into a powder to facilitate the pressing and ejecting of the compact from the die body; applying a lubricant to the die walls or punch surface, or both.
Lüder's lines (stretcher strains, flow figures). Elongated markings that appear on the surface of some materials, particularly iron and low-carbon steel, when deformed just past the yield point. These markings lie approximately parallel to the direction of maximum shear stress and are the result of localized yielding. They consist of depressions when produced in tension and of elevations when produced in compression. They may be made evident by localized roughening of a polished surface or by localized flaking from an oxidized surface.
lute. (1) A mixture of fire clay used to seal cracks between crucible and cover or between container and cover when heat is to be applied. (2) To seal with clay or other plastic material.

M

machine-cast pig. See *chill-cast pig.*
macrograph. A photographic reproduction of any object that has not been magnified more than ten times.
macroscopic. Visible either with the naked eye or under low magnification (as great as about 10 diameters).
macroscopic stresses. Residual stresses of such scope that relatively large areas of the material or the whole specimen are involved. These stresses are accompanied by strain measurable with ordinary extensometers under appropriate test conditions.
macrostructure. The structure of metals as revealed by macroscopic examination.
magclad. A name that has been applied to magnesium alloy sheet clad with layers of a more anodic magnesium alloy.
magnetic separator. A device used to separate magnetic materials from less magnetic or nonmagnetic materials. The crushed material is separated while traveling on a conveyer belt past a magnet.
malleability. The property that determines the ease of deforming a metal when the metal is subjected to rolling or hammering. The more malleable metals can be hammered or rolled into thin sheet more easily than others.
* **malleablizing.** A process of annealing white cast iron in such a way that the combined carbon is wholly or partly transformed to graphitic or free carbon or, in some instances, part of the carbon is removed completely. See *temper carbon.*
mandrel. (1) A rod used to retain the cavity in hollow metal products during working. (2) A metal bar around which other metal may be cast, bent, formed or shaped.
Mannesmann process. A process used for piercing tube billets in making seamless tubing. The billet is rotated between two heavy rolls mounted at an angle, and is forced over a fixed mandrel.
* **martempering.** The process of quenching an austenitized ferrous alloy in a medium at a temperature in the upper portion of the temperature range of martensite formation, or slightly above that range,

and holding in the medium until the temperature throughout the alloy is substantially uniform. The alloy is then allowed to cool in air through the temperature range of martensite formation.

martensite. An unstable constituent in quenched steel, formed without diffusion and only during cooling below a certain temperature known as the M_s (or Ar'') temperature. The structure is characterized by its acicular appearance on the surface of a polished and etched specimen. Martensite is the hardest of the transformation products of austenite. Tetragonality of the crystal structure is observed when the carbon content is greater than about 0.5%.

master alloy. See *hardener*.

match plate. A plate of metal or other material, on which patterns, split along the parting line, are mounted back to back with the gating system to form an integral piece.

matrix. The principal phase in which another constituent is embedded.

matrix metal. *Powd met.* The continuous phase of a polyphase alloy or mechanical mixture; the physically continuous metallic constituent in which separate particles of another constituent are embedded.

matte. An impure metallic sulfide product obtained from the smelting of sulfide ores of metals such as copper, lead and nickel.

mechanical metallurgy. The science concerned with the relationships among the measured mechanical properties of metals and their mechanical behavior in service, and with the way these properties and service characteristics vary with chemical composition, structure and temperature. The field also includes mechanical processing such as rolling, drawing and the like.

mechanical properties. Those properties of a material that reveal the elastic and inelastic reaction when force is applied, or that involve the relationship between stress and strain; for example, the modulus of elasticity, tensile strength and fatigue limit. These properties have often been designated as "physical properties", but the term "mechanical properties" is much to be preferred.

mechanical testing. Methods of determining *mechanical properties*.

mechanical twins. Lens-shaped or narrow band markings found in body-centered cubic, close-packed hexagonal and other crystal types (excepting the face-centered cubic). These may be formed during plastic deformation by shearing movements of successive planes of atoms, resulting in a fixed and sudden change in orientation at the interface or *twinning plane*. Compare with *annealing twin bands*.

mechanical working. Subjecting metal to pressure exerted by rolls, dies, presses, or hammers, to change its form or to affect the structure and consequently the mechanical and physical properties.

Medart straightener. A roller straightener that bends and straightens rods and tubes by means of ■ concave roll.

melting range. The range of temperature in which an alloy melts; that is, the range between solidus and liquidus temperatures.

mesh. *Powd met.* The screen number of the finest screen of a specified standard screen scale through which almost all the particles of a powder sample will pass. Frequently, but not necessarily, a part of the sample may pass finer screens. Also called "mesh size".

metal leaf. Extremely thin metal sheet.

metallic binding forces. The attraction of the positive ions constituting metallic crystals for the negative electrons that form a "gas" permeating the structure. This attraction holds the structure together and balances the repulsive forces of the ions for one another and electrons for other electrons. The electrons move freely through the lattice and provide good thermal and electrical conductivity.

metallography. The science concerning the constitution and structure of metals and alloys as revealed by the microscope.

metal spraying. A process for applying a coating of metal to an object. The metal, usually in the form of wire, is melted by an oxy-hydrogen or oxyacetylene blast or by an electric arc and is projected at high speed by gas pressure against the object being coated.

metastable. A state of pseudoequilibrium.

metatectic. See *peritectoid*.

microhardness. The hardness of microscopic points within an alloy. The hardness of individual constituent particles and of localized areas of the solid solution matrix can be determined. See *Knoop* or *Tukon hardness*.

micron. A linear distance of 0.001 mm.

microporosity. Extremely fine porosity caused in castings by shrinkage or gas evolution and apparent on radiographic films as mottling.

microradiography. The process of passing X-rays through a thin section of an alloy in contact with a photographic emulsion, and then magnifying the radiograph 50 to 100 times to observe the distribution of alloying constituents and voids.

microscopic stresses. Stresses that are balanced over distances of the order of magnitude of grain diameters; also known as Heyn stresses.

microsegregation. See *coring*.

microstructure. The structure of polished and etched metal and alloy specimens as revealed by the microscope.

microtome. A piece of equipment ordinarily used to prepare thin sections of biological substances for microscopic examination by transmission. In metallurgy, the microtome is sometimes used as a hand-driven shaper to produce a flat surface on relatively soft specimens before metallographic polishing and etching.

middlings. A product of specific gravity intermediate between that of the concentrate and the tailings, which is obtained in the jigging of crushed ores and which, recrushed to a finer size, is then re-treated to obtain a concentrate.

mill finish. A surface finish produced on sheet and plate, characteristic of the ground finish on the rolls used in fabrication.

milling. *Powd met.* The mechanical treatment of material, as in a ball mill, to produce particles or alter their size or shape, or to coat one component of a powder mixture with another.

minus mesh. *Powd met.* The portion of a powder sample that passes through a screen of stated size.

mischmetal. An alloy of rare earth metals containing about 50% cerium with 50% lanthanum, neodymium and similar elements.

misruns. Cast metal that was poured too cold so that it solidified before filling the mold completely.

mixing. *Powd met.* The thorough intermingling of powders of two or more substances.

modification. A process in which the eutectic temperature, structure and composition of aluminum-silicon alloys are apparently altered by the addition of small amounts of a third element, such as sodium. A similar phenomenon can be effected by chill casting.

modulus of elasticity. The slope of the elastic portion of the stress-strain curve in mechanical testing. The stress is divided by the unit elongation. The tensile or compressive elastic modulus is called "Young's modulus"; the torsional elastic modulus is known as the "shear modulus" or "modulus of rigidity".

modulus of rigidity. In a torsion test, the ratio of the unit shear stress to the displacement caused by it per unit length in the elastic range. This modulus corresponds to the modulus of elasticity in the tension test.

modulus of rupture. The ultimate strength or the breaking load per unit area of a specimen tested in torsion or in bending (flexure). In tension, it is the tensile strength.

modulus of strain hardening. When the true stress (σ) is plotted against true strain (δ) in tensile testing, the slope of the tangent to the curve in the plastic range is sometimes called the "strain hardening modulus". A better expression would be "rate of strain hardening", defined as $d\sigma/d\delta$.

mold. A form or cavity into which molten metal is poured to produce a desired shape.

mold. *Powd met.* See *die*.

molder's rule. A ruler used in making patterns for castings, on which the graduations are expanded to account for thermal and solidification contraction of the metal being cast.

mold wash. Usually an aqueous emulsion containing various compounds, such as graphite, silica flour and the like, used to coat the face of the cavity in the casting mold.

Mond process. A process for extracting and purifying nickel. The main features consist of forming nickel carbonyl by reaction of the finely divided reduced metal with carbon monoxide, and decomposing the nickel carbonyl, with deposition of nickel on small nickel pellets.

monotectic. An isothermal reversible reaction in a binary system where a liquid, during cooling, forms a solid and a second liquid of different composition.

monotron hardness test. An indentation type of hardness test for measuring the load required to indent a standard spherical penetrator to a standard depth.

mosaic structure. A structure of units, intermediate between unit cell size and grain size, which is presumed to exist in metals and alloys. Unit blocks are believed to be about 10^{-4} to 10^{-5} cm along an edge.

mossy zinc. Particles of zinc obtained by pouring molten zinc into water. See *granulated metal*.

muffle furnace. A furnace in which the heating is indirect and the charge is contained in a refractory container or crucible heated from the outside. The products of combustion are not in direct contact with the charge, as in the *open hearth* or reverberatory furnace.

N

natural aging. Spontaneous aging of a supersaturated solid solution at room temperature.

necking down. Reduction in area concentrated at the subsequent fracture when a ductile metal is tested in tension.

needles. *Powd met.* Elongated rodlike particles.

network structure. A structure in which the grains or crystals of one constituent are partly or entirely enveloped in another constituent. An etched section through the crystals resembles a network.

Neumann bands. Narrow bands differently oriented within a grain of ferrite. Ordinarily these bands are formed only on deformation by impact, but in some alloys (silicon ferrite, for example) and particularly at low temperatures the bands are formed more readily, as in ordinary cold working processes.

ni-carbing. Synonymous with *carbonitriding*.

nickel silver. A copper-base alloy that contains 17 to 32% Zn and 10 to 30% Ni.

***nitriding.** A process of case hardening in which a ferrous alloy, usually of special composition, is heated in an atmosphere of ammonia or in contact with nitrogenous material to produce surface hardening by the absorption of nitrogen, without quenching.

noble metals. Elements with metallic surfaces that are permanent in air, as gold, silver, platinum and palladium.

nodular powder. *Powd met.* Irregular particles that have knotted, rounded or other similar shapes.

***normalizing.** A process in which a ferrous alloy is heated to a suitable temperature above the transformation range and is subsequently cooled in still air at room temperature.

normal segregation. Concentration of alloying constituents that have low melting points, in those portions of a casting that solidify last. Compare with *inverse segregation*.

notch brittleness. Susceptibility of a material to brittleness in areas containing a groove, scratch, sharp fillet or notch.

notched ingots. Castings with deep grooves designed to facilitate breaking for remelting.

notch fatigue factor. The reduction caused in fatigue strength by the presence of ■ sharp notch in the stressed test section.

notch sensitivity. The reduction caused in nominal strength, impact or static, by the presence of a stress concentration, usually expressed as the ratio of the notched to the unnotched strength.

nowel. A colloquial term for drag mold (castings).

nucleus. The first structurally determinate particle of a new phase or structure that may be about to form. Applicable in particular to solidification, recrystallization and transformations in the solid state.

nugget. A small mass of a metal such as gold or silver, as found in nature. See *weld nugget*.

O

Olsen ductility test. A cupping test in which a piece of sheet, restrained except at the center, is deformed by a standard steel punch with a hemispherical end. This test measures the depth of the impression required to fracture the metal.

open hearth furnace. A furnace for melting metal, in which the bath is heated by the convection of hot gases over the surface of the metal and by radiation from the roof.

operating stress. The stress to which a structural unit is subjected during service.

orange peel effect. A surface roughening encountered in forming products from metal stock that has a coarse grain size, also referred to as "*pebbles*" and "alligator skin".

ordering. A reaction or transformation in certain solid solutions in which a random arrangement of solvent and solute atoms in the crystal is replaced by a regular or ordered arrangement of the different atoms on preferred lattice sites. See *superlattice.*

ore. A mineral from which the metal can be extracted profitably.

ore dressing. The concentration of raw ore and its conversion into a product from which the metal or metals can be recovered at a profit.

orientation. The angular relationship between the axes of a crystal and an external reference system. The orientation of individual crystals is most conveniently represented by poles of simple planes plotted stereographically. Compare *pole figure.*

osmiridium. A natural osmium-rich alloy of osmium and iridium.

overaging. Aging under conditions of time and temperature greater than those required to obtain maximum strength.

overbending. Allowance for spring-back when bending metal to a desired angle.

overdraft. A tendency of metal to curve upwards when leaving rolls, because of lower surface speed of the upper roll.

* **overheated.** A term applied when, after exposure to an excessively high temperature, a metal develops an undesirably coarse grain structure but is not permanently damaged. Unlike a *burnt* structure, the structure produced by overheating can be corrected by suitable heat treatment, by mechanical work, or by a combination of the two.

oversize powder. *Powd met.* Particles coarser than the maximum permitted by a given specification for particle size.

overstressing. Permanently deforming a metal by subjecting it to stresses that exceed the elastic limit.

P

packing material. *Powd met.* Any material in which compacts are embedded during the presintering or sintering operation.

pack rolling. Rolling two or more pieces of thin sheet at the same time, a method usually practiced in rolling sheet into thin foil. This method permits more accurate control of thickness than individual rolling.

paramagnetic. A material that is slightly more permeable than a vacuum and is approximately independent of the magnetizing force.

Parkes process. A process used to recover precious metals from lead, and based on the principle that if 1 to 2% Zn is stirred into the melted lead, a compound of zinc with gold and silver separates out and can be skimmed off.

particle size. *Powd met.* The controlling lineal dimension of an individual particle, as determined by analysis with screens or other suitable instruments.

particle size distribution. *Powd met.* The percentages by weight of the fractions into which a powder sample has been classified according to particle size.

parting. (1) In the recovery of precious metals, the separation of silver from gold. (2) The zone of separation between the cope and drag portions of mold or flask in sand casting.

parting line. A line on a pattern or casting corresponding to the separation between the cope and drag portions of a sand mold.

parting sand. Finely ground sand for dusting on surfaces that are to be separated in making a sand mold.

pass. The opening between rolls. This term is also used more generally to indicate the process of putting metal through a rolling mill.

* **patenting.** In wire making, a heat treatment applied to medium-carbon or high-carbon steel before the drawing of wire or between drafts. This process consists in heating to a temperature above the transformation range, and then cooling to a temperature below that range, in air or in a bath of molten lead or salt maintained at a temperature appropriate to the carbon content of the steel and to the properties required of the finished product.

pattern. (1) A form, frequently of wood, around which sand is packed to make ■ mold for casting metals. (2) A full-scale reproduction of a part used as a guide in cutting. (3) A regular array of characters, such as an X-ray diffraction pattern.

Pattinson process. A process for separating silver from lead, in which the melted lead is slowly cooled so that crystals poorer in silver solidify out and are removed, leaving the melt richer in silver.

pearlite. The lamellar aggregate of ferrite and carbide.

NOTE: It is recommended that this word be reserved for the microstructures consisting of thin plates or lamellae—that is, those that may have a pearly luster in white light. The lamellae can be very thin and resolvable only with the best microscopic equipment and technique.

pebbles. The grain pattern visible at an unconstrained surface when metal of appreciable grain size is deformed. See *orange peel.*

percussion welding. An electric-resistance butt-welding process in which the weld area is upset or forged at the moment of welding.

peritectic reaction. An isothermal reversible reaction in binary alloy systems, in which a solid and a liquid phase react during cooling to form a second solid phase.

peritectoid reaction. An isothermal reversible reaction in binary alloy systems, in which two solid phases react during cooling to form a new solid phase. (The inverse of ■ *eutectoid,* a peritectoid is sometimes called a metatectic.)

permalloy. Nickel alloys containing about 20 to 60% Fe, used for their high magnetic permeability and electrical resistivity.

permanent mold. A mold, ordinarily of metal, that is used repeatedly for the production of many castings of the same form. Liquid metal is poured in by gravity. Not an ingot mold.

permanent set. Inelastic deformation.

permeability. (1) Magnetic permeability, the ratio of the magnetic induction to the intensity of the magnetizing field. (2) In a mold, the porosity of foundry sands and the ability of trapped gases to escape through the sand.

perminvar. A nickel-base alloy with about 22.5% Fe and 7.5% Co, of high magnetic permeability.

pewter. A series of alloys of tin with 5 to 15% Sb, 0 to 3% Cu and 0 to 15% Pb. Also called *britannia metal* or *white metal.*

phase. A physically homogeneous portion of a material system.

phase diagram. A graphical representation of the equilibrium temperature and composition limits of phase fields and phase reactions in an alloy system. In a binary system, temperature is usually the ordinate and composition the abscissa. Ternary and more complex systems require several two-dimensional diagrams to show the temperature-composition variables completely. In metal systems, pressure is usually considered constant, although it may be treated as an additional variable.

photomicrograph. A photographic reproduction of any object magnified more than 10 diameters. The term *micrograph* may be used.

physical metallurgy. The science concerned with the physical and mechanical characteristics of metals and alloys.

physical properties. Those properties familiarly discussed in physics, exclusive of those described under *mechanical properties;* for example, density, electrical conductivity, coefficient of thermal expansion. This term has often been used to describe mechanical properties, but this usage is not recommended. See *mechanical properties.*

physical testing. Testing methods by which physical properties are determined. This term is also used inadvisedly to mean the determination of the mechanical properties.

pickle. Chemical or electrochemical removal of surface oxides.

Pidgeon process. A method for the production of magnesium by the use of ferrosilicon to reduce magnesium oxide.

piercing. The process of spinning and rolling a billet over ■ mandrel in such a way that a hole is opened in the center. Also, opening a hole through a billet by hot punching.

piezoelectricity. Electric charges of opposite signs developed during mechanical stressing of certain hemimorphic crystals; that is, crystals having axes of symmetry that differ at their two ends.

pig. An ingot of virgin or secondary metal to be remelted for use.

pig iron. Iron produced by reduction of iron ore in the blast furnace.

Pilger tube-reducing process. A process of rolling for decreasing the diameter of a pierced tube bloom in making tubing. The rolls have a groove tapered to a decreased diameter over part of their surface while the remainder will permit free passage of the bloom. The bloom, with an inserted mandrel or broach, is forced into the rotating rolls and is advanced and rotated specific amounts at intervals corresponding to passage of the decreased-diameter part of the rolls. A short section of the bloom is reduced during each revolution.

pinch pass. A pass of sheet through rolls that are set to give a very light reduction.

pine tree crystals. See *dendrite.*

pin expansion test. A test to determine the capacity of tubes for expansion by forcing a tapered pin into the open end of a sample.

pinhead blister. See *blister.*

pinhole porosity. Very small holes scattered through a casting, possibly by microshrinkage or gas evolution during solidification.

pipe. A cavity formed by contraction in metal (especially ingots) during solidification of the last portion of liquid metal.

pit. A sharp depression in the surface of metal.

planimetric method. A method of measuring grain size, in which the grains within a definite area are counted.

plastic deformation. Permanent distortion of a material under the action of applied stresses.

plasticity. The ability of a metal to be deformed extensively without rupture.

plate. A flat rolled steel product. See *sheet* for size limitation.

plates. *Powd met.* Flat powder particles that have considerable thickness. See *flake powder.*

plating. Deposition of a thin film of a second metal or alloy on a base object, from a solution containing ions of the plating metal.

platinum black. Finely divided platinum metal obtained by cementation.

platinum solders. White alloys of high melting point, containing palladium and gold, used for soldering platinum-base alloys.

plug. (1) A rod or mandrel over which a pierced tube is forced. (2) A rod or mandrel that fills a tube as it is drawn through a die.

plumbago. Graphite in powdered form. Plumbago crucibles are made from this graphite plus clay.

plus mesh. *Powd met.* The portion of a powder sample retained on a screen of stated size.

ply metals. Sheet consisting of bonded layers of dissimilar metals. See *cladding.*

pointing. The process of reducing the diameter of wire, rod or tubing, over a short length at the end, by swaging or hammer forging to facilitate entry into a drawing die and gripping in the drawhead.

Poisson's ratio. The ratio of the transverse contraction of a strained test specimen to its longitudinal elongation; essentially a statement of constancy of volume during deformation.

pole figure. A stereographic projection representing the statistical average distribution of poles of a specific crystalline plane in a polycrystalline metal, with reference to an external system. In an isotropic metal, that is, in one having a completely random distribution of orientations, the pole density is stereographically uniform; preferred orientation is shown by an increased density of poles in certain areas. This representation is more informative than the description of preferment in terms of one or more ideal orientations.

poling. In the fire refining of copper, the molten metal is rabbled or blown with air to obtain "dry" or "set" copper. Then a carbonaceous material, such as coke, is distributed on the surface of the liquid and the metal is stirred with a green wooden pole, thus reducing the oxygen content to produce tough pitch copper. The nature of solidification of sample buttons, taken at logical intervals, indicates the *set* of the surface; the appearance of the fracture, when the buttons are broken, indicates the degree of reduction of oxygen content.

overpoling is indicated by a convex swollen surface caused by the liberation of excessive amounts of gas, probably sulfur dioxide or water vapor.

underpoling is indicated by a concave surface and a fracture more brittle and redder than is desired.

polycrystalline. Consisting of more than one crystal.

polymorphism. The ability of a material to exist in more than one crystallographic structure. Numerous metals change in crystallographic structure at transformation temperatures during heating or cooling. (If the change is reversible, it is allotropy.)

pore. *Powd met.* A minute cavity in a compact. Synonym, *void.*

pore-forming material. *Powd met.* In a powder mixture, an included substance that volatilizes during sintering and thereby produces a desired kind of porosity in the finished compact.

porosity. Unsoundness caused in cast metals by the presence of blowholes and shrinkage cavities.

porosity. *Powd met.* A multiplicity of pores in a compact.

porthole die. A type of extrusion die consisting of two or more sections and used to extrude shapes that have unusual contours. The metal is extruded as several different streams, which are welded, when they leave the die, to form tubing and intricate closed shapes without requiring the use of separate mandrels.

* **postheating.** A process used immediately after welding, whereby heat is applied to the weld zone either for tempering or for providing a controlled rate of cooling, in order to avoid a hard or brittle structure.

pot. A vessel for holding molten metal. Also used to refer to the electrolytic *reduction cell* employed in winning certain metals, such as aluminum, from a fused electrolyte.

pot annealing. See *box annealing*.

pouring. The transfer of molten metal from the ladle into ingot molds or other types of molds; for example, in castings.

pouring basin. Reservoir into which liquid metal is poured, on top of the gate of a casting.

powder. *Powd met.* Particles of matter characterized by small size, usually within the range of 1 to 1000 microns.

powder metallurgy. *Powd met.* The art of producing metal powders and of utilizing metal powders for the production of massive materials and shaped objects.

power reels. Drums that coil strip and pull it through rolls that are not driven. See *Steckel mill*.

precious metals. Scarce and costly metals that do not form stable oxides at atmospheric pressures; specifically, gold, silver, and metals of the platinum group.

* **precipitation hardening.** A process of hardening an alloy in which a constituent precipitates from a supersaturated solid solution. See also *age hardening* and *aging*.

precipitation heat treatment *Nonfer met.* Any of the various aging treatments conducted at elevated temperatures to improve certain of the mechanical properties through precipitation from solid solution. See *artificial aging, interrupted aging,* and *progressive aging*.

preferred orientation. In a polycrystalline structure, a departure from crystallographic randomness.

preforming. *Powd met.* The initial pressing of a metal powder to form a compact that is to be subjected to a subsequent pressing operation other than coining or sizing. Also, the preliminary shaping of a refractory metal compact after presintering and before the final sintering.

* **preheating.** (1) A general term used to describe heating applied as a preliminary to some further thermal or mechanical treatment. (2) A term applied specifically to tool steel to describe a process in which the steel is heated slowly and uniformly to a temperature below the hardening temperature and is then transferred to a furnace in which the temperature is substantially above the preheating temperature.

preheating. *Nonfer met.* Heating a metal to a relatively high temperature for a relatively long time in order to change the structure before working. Ingots are homogenized by preheating.

presintering. *Powd met.* The heating of a compact to a temperature lower than the normal temperature for final sintering, usually to increase the ease of handling or forming the compact or to remove a lubricant or binder before sintering.

press. *Powd met.* A machine used to form or size a compact by pressure.

pressed density. *Powd met.* The weight per unit volume of an unsintered compact. Sometimes called "green density".

press forging. The forging process in which metal stock is formed between dies, usually by hydraulic pressure. Press forging is an operation that employs a single, slow stroke. Compare with *hammer forging*.

pressing. A term that ordinarily refers to forming sheet or plate by a shallow drawing process. The term is used also to indicate the press forging of thin sections in closed dies.

pressing. *Powd met.* Applying pressure to a powder or compact.

pressing crack. *Powd met.* See *slip crack*.

pressure die casting. The usual die-casting process in which the liquid metal is forced into the mold under pressure.

pressure-tight. A term that describes a casting free from porosity of the type that would permit leaking.

primary crystals. The first dendritic crystals that form in an alloy during cooling below the liquidus temperature.

primes. Metal products, such as sheet and plate, of the highest quality and free from visible surface defects.

principal stresses. Normal stresses along rectilinear co-ordinates that are so chosen in direction that shearing stresses are zero.

prismatic plane. In noncubic crystals, any plane that is parallel to the *C* or principal axis.

* **process annealing.** In the sheet and wire industries, a process by which a ferrous alloy is heated to a temperature close to, but below, the lower limit of the transformation range and is subsequently cooled. This process is applied in order to soften the alloy for further cold working.

process metallurgy. The science of obtaining metals from their ores.

progressive aging. An aging process in which the temperature of the alloy is continuously increased during the aging cycle. The temperature may be increased in steps or by any other progressive method. Compare with *interrupted aging*.

proof stress. In a test, stress that will cause a specified permanent deformation in a material, usually 0.01% or less.

proportional limit. The greatest stress that the material is capable of sustaining without a deviation from the law of proportionality of stress to strain (*Hooke's Law*).

pseudobinary (quasi-binary) system. A three-component or ternary alloy system in which an intermediate phase containing two of the metals in fixed proportions (that is, an intermetallic compound) acts as a single element. A certain vertical section through the ternary diagram is similar to a binary diagram.

puffed compact. *Powd met.* A compact expanded by internal gas pressure.

pull cracks. Cracks caused in a casting by thermal contraction when two portions become anchored as a result of an irregular shape.

pulverization. *Powd met.* The reduction of matter to powder by mechanical means; a specific type of disintegration. Synonymous with *comminution*.

punch. The movable part that forces the metal into the die in equipment for sheet drawing, blanking, coining, embossing and the like.

punch. *Powd met.* Part of a die assembly that is used to transmit pressure to the powder in the die cavity.

punching. Shearing holes in sheet metal with punch and die.

punch radius. The radius on the bottom end of the punch, over which the sheet is bent in deep drawing. This radius is independent of the shape of the punch.

push bench. Equipment used for drawing heavy-gage tubes by cupping sheet and forcing it through a die by pressure against the bottom of the cup.

pyramidal plane. Any plane that intersects all three axes in noncubic crystals.

pyrometallurgy. Process metallurgical operations employing heat, such as roasting and smelting.

pyrometer. An instrument of any of various types used for measuring temperatures.

pyrophoric alloys. Alloys that throw off sparks when struck or abraded, usually iron-cerium alloys; used in cigarette lighters and such.

Q

quaternary alloy. An alloy that contains four principal elements.

* **quench hardening.** A process of hardening a ferrous alloy of suitable composition by heating within or above the transformation range and cooling at a rate sufficient to increase the hardness substantially. The process usually involves the formation of martensite.

* **quenching.** A process of rapid cooling from an elevated temperature by contact with liquids, gases or solids.

quenching crack. A fracture resulting from thermal stresses induced during rapid cooling or quenching. Frequently encountered in alloys that have been overheated and liquated and are thus "hot short".

Q-value. *Powd met.* A "figure of merit" commonly used to designate the ratio of the inductive reactance to the effective resistance of electrical cores made from iron and other powders. This value is determined by means of a Q-meter and a specified procedure.

R

rabbling. A raking or stirring operation performed on a charge of ore or semimolten metal either by hand or mechanically.

radioactive metals. A group of metals with high atomic weights and with atomic nuclei that decompose slowly, giving off continual radiations of positively charged alpha particles, which are relatively slow; negatively charged beta particles, which are faster and lighter; and gamma rays. The gamma rays are similar to X-rays but are more penetrating and are used for radiography of very thick sections. Bombardment by neutrons can make any metal radioactive and small concentrations of such metals are used as "tracers" in the study of diffusion and other phenomena.

radiography. A nondestructive method of internal examination in which metal objects are exposed to a beam of X-ray or gamma radiation. Differences in thickness, density or absorption, caused by internal defects or inclusions, are apparent in the shadow image either on a fluorescent screen or on photographic film placed behind the object.

ramming. The process of packing sand in making a sand mold.

rare earth metals. The group of similar, trivalent metals that have atomic numbers 57 to 71.

rate of oil flow. *Powd met.* The rate at which a specified oil will pass through a sintered porous compact under specified test conditions.

recalescence. The increase in temperature caused when the rate of liberation of heat during transformation exceeds the rate of dissipation of heat during the cooling of steel through the transformation range.

recovery. (1) The removal of residual stresses by localized plastic flow as the result of low-temperature annealing operations; performed on cold worked metals without altering the grain structure or strength properties substantially. (2) In process metallurgy, the proportion of the valuable component obtained from an ore in processing.

recrystallization. A process whereby the distorted grain structure of cold worked metals is replaced by a new, strain-free grain structure during annealing above a specific minimum temperature.

recrystallization temperature. The lowest temperature at which the distorted grain structure of a cold worked metal is replaced by a new, strain-free grain structure during prolonged annealing. Time, purity of the metal, and prior deformation are important factors.

recuperator. A piece of equipment for recovering heat from hot, spent gases and using it for the preheating of incoming fuel or air. This is a continuous operation, in which the incoming materials pass through pipes surrounded by a chamber through which the outgoing gases pass.

red mud. A residue high in iron oxide, resulting from the purification of alumina from bauxite by the *Bayer process*.

red shortness. Brittleness in steel when it is red hot.

red stain. Stain formed on brass by volatilization of zinc during annealing or by redeposition of copper during pickling.

reduction cell. A pot or tank in which a water solution of a metallic salt or a fused salt electrolyte is electrolytically reduced to form free metals. See *reduction pot* and *electrolytic bath*.

reduction in area. The difference between the original cross-sectional area and that of the smallest area at the point of rupture; usually stated as a percentage of the original area; also called "contraction of area".

refining. The operation of purifying crude metals. See also *fluxing*.

refining temperature. A temperature, usually just higher than the transformation range, employed in the heat treatment of steel to refine the structure—in particular, the grain size.

reflector sheet. An alclad product containing on one side a surface layer of high-purity aluminum superimposed on a core or base alloy of commercial-purity aluminum or an aluminum-manganese alloy. The high-purity coating imparts good polishing characteristics and the core gives adequate strength and formability.

refractory. A heat-resistant material, usually nonmetallic, which is used for furnace linings and such.

regenerator. Equipment used for recovering heat from hot, spent gases from a furnace. The regenerator differs from the *recuperator* in that the hot spent gases are used to heat a brick checkerwork; then after

the flow of exhaust gases has been turned off, the gases to be preheated are passed through the checkerwork.

regulus. (1) Metal that separates as a large mass from the slag in a furnace or crucible. (2) Refined antimony.

reheating. A thermal operation designed solely to heat the work back to hot forming temperatures. In general, no structural changes are intended.

relaxation. Relief of stress as the result of creep. Some types of tests are designed to provide diminution of stress by relaxation at constant strain, as frequently occurs in service.

re-pressing. *Powd met.* The pressing of a previously pressed and sintered compact, for the purpose of altering physical properties or size.

residual stress. Macroscopic stresses that are set up within a metal as the result of nonuniform plastic deformation. This deformation may be caused by cold working or by drastic gradients of temperature from quenching or welding.

resilience. The tendency of a material to return to its original shape after the removal of a stress that has produced elastic strain.

resistance thermometer. A pyrometer that functions on the principle that the electrical resistance of metal changes with temperature. The change in resistance of a coil of fine wire, usually platinum, is calibrated with temperature.

resistance welding. A type of welding process in which the work pieces are heated by the passage of an electric current through the contact. Such processes include *spot welding, seam* or *line welding* and *percussion welding. Flash* and *butt welding* are sometimes considered as resistance welding processes.

resolved shear stress. The vectorial component of load acting on the shear plane, divided by the shear plane area.

restriking. Cold striking of a finished forging to remove distortions after it has been quenched.

retort. A vessel or crucible used for distilling volatile metals.

reverberatory furnace. See *open hearth furnace.*

rich alloys. See *hardener.*

riddle. A device, operated by hand or power, for removing large particles of sand or foreign material from foundry sand.

riffles. Waviness at the edge of sheet or strip.

rimmed steel. An incompletely deoxidized steel normally containing less than 0.25% C and having the following characteristics: (*a*) During solidification an evolution of gas occurs sufficient to maintain a liquid ingot top ("open" steel) until a side and bottom rim of substantial thickness has formed. If the rimming action is intentionally stopped shortly after the mold is filled, the product is termed *capped steel.* (*b*) After complete solidification, the ingot consists of two distinct zones—a rim somewhat purer than when poured and a core containing scattered blowholes, a minimum amount of pipe and an average percentage of metalloids somewhat higher than when poured and markedly higher in the upper portion of the ingot.

riser. A reservoir of excess molten metal at the top of the heaviest section or sections of a casting, designed to supply metal in compensation for shrinkage that cannot be fed properly from the gate.

roasting. A process used for treating certain ores by heating to produce a chemical change such as oxidation, or to eliminate a volatile component.

rocking shear. An improved type of guillotine shear that uses a curved blade and a rocker movement to cut across metal.

rod mill. (1) A mill for fine grinding, somewhat similar to the *ball mill,* but employing long steel rods instead of balls as the grinding medium. (2) A mill for rolling metal rod.

roll coating. A mixture of finely divided aluminum and aluminum oxide that may form, under certain conditions, on rolls used to make aluminum alloy sheet.

roll compacting. *Powd met.* The progressive compacting of metal powders by the use of a rolling mill.

rolled gold. Similar to filled gold but of a lower quality. Compare *gold filled.*

roller flattening. The process in which a series of staggered rolls of small diameter is used to remove bow and waves from sheet. While passing through the rolls, the sheet is bent back and forth slightly and is delivered approximately flat.

roller stamping die. An engraved roller used for stamping designations and markings on either circular or flat work.

roller straightening. A process involving a series of staggered rolls of small diameter, between which rod, tubing and shapes are passed for the purpose of straightening. The process consists of a series of bending operations.

roll forming. (1) An operation used in forming sheet. Strips of sheet are passed between rolls of definite settings that bend the sheet progressively into structural members of various contours, sometimes called "molded sections". (2) A process of coiling sheet into open cylinders.

roll table. A conveyer-type table surface that contains a series of small rolls over which metal products pass during processing.

roll threading. Applying a thread to a bolt or screw by rolling the piece between two grooved die plates, one of which is in motion, or between rotating grooved circular rolls.

rosette. (1) Rounded configuration of eutectiferous constituents in the microstructure of an alloy, indicative of *eutectic melting* during heat treatment. (2) Strain gages arranged to indicate at a single position strains in three different directions.

rotary press. *Powd met.* A machine fitted with a rotating table that carries multiple dies in which a material is pressed.

rotary shear. A cutting machine with sharpened circular blades or disk-like cutters used for trimming edges and slitting sheet and foil.

rotary swager. A machine used for pointing wire rod and tubing and for initial working of moderately brittle metals and alloys in which a pair of tapered dies is used. The dies are rotated and are pressed intermittently against the work material by an eccentric action.

roughing stand. The rolls used for breaking down the ingot or billet in the preliminary rolling of metal products.

runner. A channel through which molten metal or slag is passed from one receptacle to another; in a casting mold, the portion of the gate assembly that connects the downgate or sprue with the casting.

runner box. Device for distributing molten metal around a mold by dividing it into several streams.

runout. Escape of molten metal from a furnace, mold or melting crucible.

runout table. In a rolling mill, a plane area at the receiving end, for holding rolled metal. See *hot bed.*

rupture stress. The stress given by dividing the load at the moment of incipient fracture, by the area supporting that load.

S

salt spray test. An accelerated corrosion test in which the metal specimens are exposed to a fine mist of salt water solution either continuously or intermittently.

sand burning. The formation of a hard surface on a sand casting by the reaction between the sand of the mold and the hot metal.

sand control. Procedure whereby various properties of foundry sand, such as fineness, permeability, green strength and moisture content, are adjusted to obtain castings free from blows, scabs, veins and similar defects.

sands. In a crushed material, a size of particles that will settle easily in water. The particle size of sands is coarser than that of *slimes.*

sandwich rolling. The rolling of dissimilar metals together to form composite sheet. See *ply metals* and *cladding.*

scab (scabby). A blemish caused on a casting by eruption of gas from the mold face, or by uneven mold surfaces; or occurring where the skin from a blowhole has partly burned away and is not welded.

scaling. Surface oxidation caused on metals by heating in air or in other oxidizing atmospheres.

scalping. Machining the surface layers from ingots, billets and slabs before fabrication.

scarfing. Cutting surface areas of metal objects, ordinarily by using a gas torch. The operation permits surface defects to be cut from ingots, billets, or the edges of plate that is to be beveled for butt welding. See *chipping.*

scleroscope test. A hardness test where the loss in kinetic energy of a falling metal "tup", absorbed by indentation upon impact of the tup on the metal being tested, is indicated by the height of rebound.

scorification. The oxidizing fusion of impure lead containing precious metals, carried out in the presence of fluxes, in order to concentrate the precious metals by partial removal of the base metal impurities before cupellation.

scrap. Material unsuitable for direct use but usable for reprocessing.

screen. A perforated metal screen placed between the gate and the runner of a casting mold for the purpose of separating entrapped oxides or gases during the pouring.

screen analysis. *Powd met.* Distribution of particle size expressed in terms of the percentage of weight retained on each of a series of standard screens decreasing in mesh size, and the percentage passed by the screen of finest mesh.

screen classification. *Powd met.* The separation of powder into ranges of particle size by the use of a series of graded sieves.

screening. *Powd met.* Separating powder according to particle size, by passing it over cloth of the desired mesh size.

screw stock. Metal in the form of wire or rod, ordinarily a free-machining type of alloy, used for making screw-machine products.

scruff. A mechanical mixture of tin oxide and iron-tin alloy formed as dross on a tin coating bath.

sealing. A process used to render anodic coatings on metals nonabsorbent.

seam. On the surface of metal, a crack that has been closed but not welded; usually produced by some defect either in casting or in working, such as blowholes that have become oxidized or folds and laps that have been formed during working. Seam also refers to lap joints, as in *seam welding.*

seaming. Joining sheet metal by multiple bends.

seam welding. An electric-resistance type of welding process, in which the lapped sheet is passed between electrodes of the roller type while a series of overlapping *spot welds* is made by the intermittent application of electric current.

season cracking. A term used in the copper industry for *stress-corrosion cracking* that involves only residual stresses and specific corrosive agents (usually ammonia or compounds of ammonia).

secondary creep. The second portion of the creep curve following the *initial creep* stage and in which the rate of creep has reached a rather constant value.

* **secondary hardening.** Tempering certain alloy steels at certain temperatures so that a hardness is obtained greater than that resulting from the tempering of the same steel at some lower temperature for the same time.

secondary metal. Metal recovered from scrap by remelting.

seed charge. A quantity of a material added to a supersaturated solution for the purpose of nucleating precipitation; for example, aluminum hydrate, which is added to the aluminate solution in the Bayer process, to precipitate aluminum trihydrate.

segment die. *Powd met.* A die made of parts that can be separated for the ready removal of the compact. Synonymous with *split die.*

segregation. In an alloy object, concentration of alloying elements at specific regions, usually as a result of the primary crystallization of one phase with the subsequent concentration of other elements in the remaining liquid. *Microsegregation* refers to *normal segregation* on a microscopic scale whereby material richer in alloying element freezes in successive layers on the dendrites (*coring*) and in the *constituent network. Macrosegregation* refers to gross differences in concentration (for example, from one area of an ingot to another) which may be *normal, inverse* or *gravity segregation.*

seizing. Damaging of a metal surface by rubbing with another metal surface. See *galling.*

* **selective heating.** A process by which only certain portions of an object are heated, in a way that will produce desired properties after cooling.

* **selective quenching.** A process by which only certain portions of an object are quenched.

self-hardening steel. A steel containing sufficient carbon or alloying element, or both, to form martensite either through air hardening or, as in welding and induction hardening, through rapid removal of heat from a locally heated portion by conduction into the surrounding cold metal. See also *air-hardening steel.*

semikilled steel. Steel incompletely deoxidized, to permit evolution of sufficient carbon monoxide to offset solidification shrinkage.

semipermanent mold. A permanent mold in which sand cores are used.

set copper (dry copper). Copper that contains about 6% cuprous oxide at the end of the oxidizing part of the fire-refining cycle. A button sample shows a brick-red brittle fracture and a deep depression with a bulb at its base.

set (pitch). The shape, concavity or convexity, of the solidifying surface of cast copper.

settling. (1) In general, separation of a denser solid from a liquid by gravity. (2) A process for removing iron from liquid magnesium alloys by holding at a low temperature after the addition of manganese.

shake-out. The operation of removing castings from the mold.

shank. The handle attached to a small ladle.

shaving. Trimming heavy-gage blanks to remove uneven sheared edges.

shear. (1) A type of cutting operation in which the metal object (sheet, wire, rod, or such) is cut by means of a moving blade and fixed edge or by a pair of moving blades that may be either flat or curved. (2) A type of deformation in which parallel planes in metal crystals slide so as to retain their parallel relation to one another, resulting in block movement.

shear crack. A diagonal, transgranular crack caused by shear stresses.

shear modulus. See *modulus of rigidity*.

shear stress. The component of stress acting on the plane of shear.

sheet. A flat rolled product. *Sheet, strip, plate* and *bar* are defined in the American Iron and Steel Institute Steel Products Manual, Section 11 (1946), according to size limitations, as follows:

Hot Rolled Carbon Steel

Width, inches	Thickness, inch: 0.2500 and thicker	0.2499 to 0.2031	0.2030 to 0.1875	0.1874 to 0.0568
To 3½ inclusive	Bar	Bar	Strip	Strip
More than 3½, to 6 inclusive	Bar	Bar	Strip	Strip
More than 6, to 12 inclusive	Plate	Strip	Strip	Strip
More than 12, to 32 inclusive	Plate	Sheet	Sheet	Sheet
More than 32, to 48 inclusive	Plate	Sheet	Sheet	Sheet
More than 48	Plate	Plate	Plate	Sheet

Width, inches	Thickness, inch: 0.0567 to 0.0344	0.0343 to 0.0255	0.0254 to 0.0142	0.0141 and thinner
To 3½ inclusive	Strip	Strip	Sheet	Sheet
More than 3½, to 6 inclusive	Strip	Sheet	Sheet	Sheet
More than 6, to 12 inclusive	Sheet	Sheet	Sheet	Sheet
More than 12, to 32 inclusive	Sheet	Sheet	Sheet	Black Plate
More than 32, to 48 inclusive	Sheet	Sheet	Sheet	Sheet
More than 48	Sheet	Sheet	Sheet	.....

Cold Rolled Carbon Steel

Width, inches	Thickness, inch: 0.2500 and thicker	0.2499 to 0.0142	0.0141 and thinner
To 12 inclusive	Bar	Strip[c]	Strip[c]
More than 12, to 24 inclusive	Strip[a]	Strip[a]	Strip[a]
More than 12, to 24 inclusive	Sheet[b]	Sheet[b]	Black Plate[b]
More than 24, to 32 inclusive	Sheet	Sheet	Black Plate
More than 32	Sheet	Sheet	Sheet

(a) When a particular temper, as defined in ASTM Specification A109, or a special edge, or special finish is specified.

(b) When no special temper, edge or finish is specified.

(c) When the width is greater than the thickness but does not exceed ½ in.; when the cross-sectional area does not exceed 0.05 sq. in., and the edges are rolled or prepared, the material is "flat wire".

shell. (1) An article formed by deep drawing. (2) The metal sleeve remaining when a billet is extruded with a dummy block of somewhat smaller diameter.

shielded-arc welding. Electric-arc welding in which the metal is protected from the air atmosphere. An inert gaseous atmosphere may be used or *flux-coated electrodes*.

shift. A casting defect caused by mismatch of *cope* and *drag*.

Shore hardness test. See *scleroscope hardness*.

shortness. Brittleness in metal.

shorts. In the screening of crushed ores, the product remaining on the screen or sieve (as opposed to *fines*, which pass through).

shotting. A process in which molten metal is dropped from a height to form rounded metal pellets or shot. The droplets freeze into spherical particles before reaching the water tank at the bottom of the fall.

shrinkage. *Powd met.* The decrease that may occur in the dimensions of a compact during sintering.

shrinkage cavity. A void left in cast metals as a result of solidification shrinkage and the progressive freezing of metal towards the center.

shrinkage cracks. Cracks that form in metal as a result of the pulling apart of grains by thermal contraction before complete solidification.

shrinkage rule. See *molder's rule*.

silky fracture. A steel fracture that has a very smooth fine grain or silky appearance.

silver solders. Alloys of silver, copper, zinc and other metals, melting between 650 and 875 C, used for making strong joints that resist corrosion.

single-acting hammer. A forging hammer in which the head is raised by a steam cylinder and piston and the blow is delivered by the free fall of the head. (With the double-acting hammer, the blow is delivered by admitting steam above the piston and employing it also on the downward stroke.)

single-action press. A forming press that operates with a single function, such as moving a punch into a die with no simultaneous action for holding down the blank or ejecting the formed work.

single crystal. A piece of metal consisting of a single crystallographic grain instead of the usual *polycrystalline* mass.

sinkhead or hot top. A reservoir insulated to retain heat and to hold excess molten metal on top of an ingot mold, in order to feed the shrinkage of the ingot. Also called "shrink head" or "feeder head".

sinking tubing. Drawing tubing through a die without use of an interior tool.

sintering. *Powd met.* Bonding adjacent surfaces of particles in a mass of powder or a compact by heating.

sizing. *Powd met.* A final pressing of a sintered compact to secure the desired size. Synonymous with *coining*.

skelp. A plate of steel or wrought iron from which pipe or tubing is made by rolling the skelp into shape longitudinally and welding the edges together.

skimgate. See *screen*.

skimmer. A tool for removing scum and dross from molten metal.

skin. A thin surface layer that is different from the main mass of a metal object, in composition, structure or other characteristics.

skull. A film of metal or dross remaining in a pouring vessel after the metal has been poured.

slab. See *bloom*.

slabbing mill. See *blooming mill*.

slag. A product resulting from the action of a flux on the nonmetallic constituents of a processed ore, or on the oxidized metallic constituents that are undesirable. Usually slags consist of combinations of acid oxides with basic oxides, and neutral oxides are added to aid fusibility.

slenderness ratio. Length of a test specimen divided by the square root of the cross-sectional area.

slime. Material of extremely fine or colloidal particle size, encountered in ore treatments and electrolytic refining. See *anode mud*.

slip. A process of plastic deformation by the irreversible shear displacement of one part of a metal crystal relative to another, in a definite crystallographic direction and usually on a specific crystallographic plane. It is sometimes postulated that the slip process involves migration of "dislocations".

slip bands. A series of parallel lines produced across a crystal grain by deforming the body *after* polishing the surface on which these lines appear. They are traces of the slip planes, or planes joining the displaced crystalline blocks or lamellae, and may be distinguished from twin markings by repolishing and etching. Twin markings will reappear, but slip lines will not.

slip crack. *Powd met.* A rupture caused in the pressed compact by mass slippage of a part of the compact. Synonym, *pressing crack*.

slip direction. Direction of slip in an individual crystal.

slip interference. In a ductile metallic structure, resistance to deformation offered by a hard phase dispersed in the matrix. The resistance to deformation has been found to be proportional to the logarithm of the average length of a straight path through the continuous phase.

slip lines. The line markings evident on a polished surface if the metal is deformed after being polished. These surface displacements are frequently called *slip bands*.

slip plane. The crystallographic plane of slip in an individual crystal. See *slip bands*.

slip plane precipitate. A precipitate formed from solid solution preferentially along planes upon which slip has occurred as a result of quenching stresses or cold working after solution heat treatment.

slush casting. A casting made of an alloy that has a low melting point and freezes within a wide range of temperature. The metal is poured into the mold, and brought into contact with all surfaces so as to form an inner shell of frozen metal; then the excess metal is poured out. Castings that consist of completely enclosed shells may be made by using a definite quantity of metal and a closed mold.

smelting. A metallurgical thermal processing operation in which the metal or matte is separated in fused form from nonmetallic materials or other undesired metals with which it is associated.

***soaking.** Prolonged heating of a metal at a selected temperature.

solder embrittlement. Reduction in ductility of a metal or alloy, associated with local penetration by molten solder along grain boundaries.

soldering. Joining metals by fusion of alloys that have relatively low melting points—most commonly, lead-base or tin-base alloys, which are the soft solders. Hard solders are alloys that have silver, copper, or nickel bases and use of these alloys with melting points higher than 800 F is generally termed *brazing*.

solidification shrinkage. The decrease in size accompanying the freezing of a molten metal.

solid solubility limit. The limit for the amount of alloying element that can be present in the solid metal without forming a second phase.

solid solutions.

(a) *Continuous series.* Condition of complete solubility, a single phase for all compositions of two alloying elements at temperatures lower than the "solidus".

(b) *Intermediate.* Alloy phases that are separated, in the phase diagram, from the pure metals or terminal solid solutions by heterogeneous fields.

(c) *Interstitial.* Solid solutions in which atoms of the alloying element (being very small) occupy spaces between atoms of the solvent element, which retain their original lattice positions.

(d) *Substitutional.* Solid solutions in which atoms of the alloying element occupy atom sites previously filled by atoms of the pure metal. The distribution of unlike atoms is usually random but may be ordered. See *superlattice*.

(e) *Terminal.* Solid solutions of which one boundary in the phase diagram is a pure metal.

solidus line. A line on a binary phase diagram, or a surface on a ternary phase diagram, representing the temperatures at which freezing ends during cooling, or melting begins during heating, under equilibrium conditions.

solute. In a solution, a metal or substance present in minor amounts.

***solution heat treatment.** A process in which an alloy is heated to a suitable temperature, is held at this temperature long enough to allow a certain constituent to enter into solid solution and is then cooled rapidly to hold the constituent in solution. The metal is left in a supersaturated, unstable state and may subsequently exhibit *age hardening*.

solution potential. The difference in potential of a material and of a reference electrode in a solution. For purposes of comparison standard electrodes and solutions are ordinarily used.

solvent. The base metal or major constituent in a solution.
solvus. A name that has been applied to solid solubility curves of alloy equilibrium diagrams.
sorbite. Tempered martensite that has a microstructure of distinctly granular appearance. Further tempering causes the appearance of clearly resolvable carbide particles (spheroidite).
spalling. The cracking and flaking of metal particles from a surface.
specific gravity. A numerical value representing the weight of a given substance as compared with the weight of an equal volume of water, for which the specific gravity is taken as 1.0000.
specific heat. Equivalent to thermal capacity, or the quantity of heat required to produce a unit change in the temperature of a unit mass.
specific surface. *Powd met.* The surface area of the particles in one gram of powder, usually expressed in square centimeters.
spectrograph. An optical instrument for determining the presence or concentration of minor metallic constituents in a material by indicating the presence and intensity of specific wave lengths of radiation when the material is thermally or electrically excited.
speculum metal. A copper-base alloy containing tin and zinc, hard and brittle but capable of taking a high polish and therefore satisfactory for reflectors and mirrors.
speiss. Metallic arsenides and antimonides that result from smelting metal ores, such as those of cobalt.
spelter. Crude zinc obtained by smelting.
spelter solders (brazing solders). Copper-zinc alloys that have low melting points and are used for joining.
spheroidite. An aggregate of globular carbide and ferrite. The terms "spheroidized pearlite", "granular pearlite", "globular pearlite" and "divorced pearlite" should be avoided, even when the structure is undoubtedly the result of spheroidizing a pearlitic structure.
***spheroidizing.** Any process of heating and cooling that produces a rounded or globular form of carbide in steel. Spheroidizing methods frequently used are:

1 Prolonged holding at a temperature just below Ae_1.
2 Heating and cooling alternately between temperatures that are just above and just below Ae_1.
3 Heating to a temperature above Ae_1 or Ae_3 and then cooling very slowly in the furnace, or holding at a temperature just below Ae_1.
4 Cooling at a suitable rate from the minimum temperature at which all carbide is dissolved, to prevent the re-formation of a carbide network, and then reheating in accordance with method 1 or 2 above (applicable to hypereutectoid steel containing a carbide network.)

spiegeleisen (also spiegel). A pig iron containing 15 to 30% Mn and 4.5 to 6.5% C.
spinning. The procedure of making sheet metal disks into hollow shapes by pressing a tool against a rotating form (spinning chuck).
split die. See *segment die.*
sponge. A sintered metallic aggregate of platinum or palladium, sponge-like in appearance, resulting from the thermal decomposition of the metal ammonium chloride.
sponge iron. *Powd met.* The material produced by the reduction of iron oxide with carbon, without melting.
spongy. *Powd met.* A term applied to powder particles (usually reduced oxides) in which a porous condition exists.
spot welding. An electric-resistance welding process in which the fusion is limited to a small area. The pieces being welded are pressed together between a pair of water-cooled electrodes through which an electrical current is passed during a very short interval so that fusion occurs over a small area at the interface between the pieces.
spray quenching. After solution heat treating, a mode of quenching in which a spray of water is directed upon material just removed from the furnace. This method is more effective than *fog quenching.* Both methods are designed to reduce distortion that may attend water bath quenching.
spring-back. An indicator of elastic stresses, frequently measured as the increase in diameter of a curved strip after removing it from the mandrel about which it was held. The measurement is employed as an indicator of the extent of recovery or relief of residual stresses that has been achieved by the transformation of elastic strain to plastic strain during heating or *stress relieving.*
springing. Reversed overbending to straighten, or to reduce residual stresses.
spring temper. See *temper.*
sprue. In casting practice, the vertical channel connecting the *pouring basin* with the *skimming gate,* if any, and the *runner* to the mold cavity, all of which together may be called the *"gate".* In top-poured castings the sprue may also act as *riser.*
***stabilizing anneal.** A treatment applied to austenitic stainless steels that contain titanium or columbium. This treatment consists of heating to a temperature below that of a full anneal in order to precipitate the maximum amount of carbon as titanium carbide or columbium carbide. This eliminates precipitation at lower temperatures, which might reduce the resistance of the steel to corrosion.
stabilizing treatment. A thermal treatment designed to precipitate material from solid solution, in order to improve the workability, to decrease the tendency of certain alloys to age harden at room temperature, or to obtain dimensional stability under service at slightly elevated temperatures.
stamping. A process used to cut lines of letters, figures and decorations on smooth metal surfaces. The impact of a punch with comparatively sharp projecting outlines impresses the characters into the surface of the metal. Stamping is also used to refer to various press-forming operations—*coining, embossing, blanking,* and *pressing.*
standard electrode potential. The potential of a metallic element in equilibrium with a solution containing simple ions of that element at a concentration corresponding to unit activity. The standard potential for hydrogen is assigned the value zero. (A negative sign is used before the potentials of elements that show a larger decrease in free energy than hydrogen shows, while forming ions in solution.)
standard gold. A legally adopted alloy for coinage of gold. In the United States the alloy contains 10% copper; in Great Britain it contains 8.33% copper.
starting sheet. A thin sheet of metal used as cathode in electrolytic refining.
Stead's brittleness. A condition of brittleness that yields rectangular transcrystalline fractures in the coarse grain structure produced by prolonged annealing of thin sheets of steel very low in carbon and rolled previously at a relatively low temperature (lower than 1300 F).
Steckel mill. A rolling mill in which the power is applied to a reel that draws strip through undriven rolls.
stepped extrusion. A type of metal extrusion in which the size of the contour changes abruptly in order to decrease the amount of machining necessary to make tapered members.
sterling silver. An alloy of 925 parts silver and 75 parts copper. Accepted standard for silverware in the United States and England.
Stiefel mill. A machine for making tubes by hot piercing billets. The rolls of the machine have cantilever supports.
stopping-off. (1) Protecting desired areas from chemical action, such as carburizing or electroplating, by an appropriate coating of such areas with a material that is unaffected by the chemical action. (2) Filling part of a mold with sand to keep out molten metal.
strain. Deformation expressed as a pure number or ratio. (1) Ordinarily expressed as epsilon (ϵ), equivalent to the change in length divided by original length. (2) *True* strain (δ or ϵ) is the logarithm of the ratio of the length at the moment of observation, to the original length. True strain δ does not differ much from ϵ until above 20%.
***strain aging.** Aging induced by cold working. See *aging.*
strain hardening. An increase in hardness and strength caused by plastic deformation at temperatures lower than the recrystallization range.
strain hardening exponent. The constant "n" in the expression

$$\sigma = \sigma_0 \delta^n$$

σ = true stress
σ_0 = stress at unit strain
δ = true strain.

Straits tin. Tin metal made from Malay district ores.
streamline tubing. Extruded or drawn tubing of which the cross section is shaped like a teardrop.
stress. The load per unit of area. Ordinarily stress-strain curves do not show the true stress (load divided by area at that moment) but a fictitious value obtained by using always the original area.
stress-corrosion cracking. Spontaneous failure of metals by cracking under combined action of corrosion and stress, residual or applied.
stress raisers. Factors such as sharp changes in contour or surface defects, which concentrate stresses locally.
***stress relieving.** A process of reducing residual stresses in a metal object by heating the object to a suitable temperature and holding for a sufficient time. This treatment may be applied to relieve stresses induced by casting, quenching, normalizing, machining, cold working, or welding.
stretcher flattening. A process for removing bow and warpage from sheet by applying a uniform tension at the ends so that the piece is elongated to a definite amount of permanent set.
stretcher straightening. A process for straightening rod, tubing and shapes by the application of tension at the ends of the stock. The products are elongated a definite amount to remove warpage.
stretch forming. A process of forming panels and cowls of large curvature by stretching sheet over a form of the desired shape. This method is more rapid than *hammering* and *beating.*
stringer. A microstructural configuration of alloy constituents or foreign material lined up in the direction of working.
strip. A flat rolled steel product. See *sheet* for size limitation.
stripper punch. *Powd met.* A punch that serves as top or bottom of the die cavity and later moves further into the die to eject the compact.
stripping. Removing coated or electrolytically deposited metal or oxides from the base.
sub-boundary structure. A network of boundaries which, after etching, appears within the main crystals of the metal structure. The granules within the sub-boundaries seem to have a uniform orientation. The structure may be caused by more intense precipitation at preferred places within grains.
subsieve fraction. *Powd met.* Particles all of which will pass through a 325-mesh screen.
sulfur dome. An inverted container holding a high concentration of sulfur dioxide; used over a pot of molten magnesium in connection with the die casting of magnesium.
supercooling. Lowering the temperature of a molten metal below its liquidus during cooling.
superfines. *Powd met.* The portion of a powder that is composed of particles smaller than a specified size, currently less than 10 microns.
superheating. A process of refining the grains in certain magnesium alloy castings by heating the molten metal between 1500 and 1700 F.
superlattice (superstructure). A crystal structure that exists in a solid solution when atoms of the different types fall into an orderly arrangement in relation to one another. See *ordering.*
supersaturated. Metastable solution in which the dissolved material exceeds the amount the solvent can hold in normal equilibrium at the temperature and under the other conditions that prevail.
surface checking. General breaking and cracking of the surface, which may result from a variety of causes, such as over-rolling, overforming, or atmospheric attack at grain boundaries.
swaging. See *rotary swaging.*
sweating. *Powd met.* The appearance, on the surface of a compact, of some or all of the constituents that have low melting points.
sweating out. On the surface of a solid mass of a mixture or alloy, the appearance, usually in small globules, of one constituent that has a relatively low melting point.
sweeps. Floor and table sweepings containing precious metal.
synthetic. In a binary alloy system, an isothermal reversible reaction whereby two liquids form a solid phase during cooling.

T

tailings (tails). The worthless portion of a crushed ore, separated during concentration.
tangent modulus. The slope of the stress-strain curve of a metal at any point along the curve in the plastic region. In the elastic region the tangent modulus is equivalent to *Young's modulus.*
tap density. *Powd met.* The apparent density of a powder, obtained when the volume receptacle is tapped or vibrated during loading under specified conditions.

tapping. Transferring molten metal from melting furnace to ladle.
tarnish. Surface discoloration on a metal, usually from a thin film of oxide or sulfide.
Taylor process. A method for making extremely fine wire by inserting common wire into a glass tube and stretching the two together at a high temperature.
technical cohesive strength. See *cohesive strength*, (2).
teeming. Pouring metal into ingot molds. See *pouring*.
temper. *Nonfer met.* A condition produced in a metal or alloy by mechanical or thermal treatment and having characteristic structure and mechanical properties. A given alloy may be in the fully softened or *annealed temper*, or it may be cold worked to the *hard temper*, or further to *spring temper*. Intermediate tempers produced by cold working (rolling or drawing) are called "quarter-hard", "half-hard" and "three-quarters hard", and are determined by the amount of cold reduction and the resulting tensile properties. In addition to the *annealed temper*, conditions produced by thermal treatment are the *solution heat treated temper* and the *heat treated and artificially aged temper*. Other tempers involve a combination of mechanical and thermal treatments and include that temper produced by cold working after heat treating, and that produced by artificial aging of alloys that are as-cast, as-extruded, as-forged and heat treated, and worked.
* **temper brittleness.** Brittleness that results when certain steels are held within, or are cooled slowly through, a certain range of temperature below the transformation range. The brittleness is revealed by noched-bar impact tests at room temperature or lower temperatures.
* **temper carbon.** The free or graphitic carbon that comes out of solution, usually in the form of rounded or equiaxed nodules in the structure, during the *graphitizing* or *malleablizing* of white cast iron.
* **tempering.** A process of reheating quench-hardened or normalized steel to a temperature below the transformation range, and then cooling at any rate desired.
Templin grip. A spherically seated grip of the wedge type, used in the tension testing of metals.
tensile strength. The value obtained by dividing the maximum load observed during tensile straining by the specimen cross-sectional area before straining. Also called "ultimate strength".
ternary alloy. An alloy that contains three principal elements.
texture. The pattern of preferred orientation occurring in wrought or cast metal.
thermal analysis. The determination of equilibrium conditions and phase relationships in metals by means of thermal arrests shown on heating and cooling curves.
thermal electromotive force. The electromotive force generated when the junction of two dissimilar metals is heated.
thermal stresses. Stresses in metal, resulting from nonuniform distribution of temperature.
thermit reactions. Exothermic, self-propagating processes in which finely divided aluminum powder is used to reduce metal oxides to free metals by direct oxidation of aluminum to aluminum oxide, with accompanying reduction of the less stable metal oxide.
thermocouple. A device for measuring temperatures by the use of two dissimilar metals in contact; the junction of these metals gives rise to a measurable electrical potential with changes in temperature. See *thermal electromotive force*.
throwing power. The ability of an electroplating solution to deposit metal uniformly on a cathode of irregular shape.
tilt-mold ingot. An ingot made by a casting practice employing a book-type mold that has its bottom nearly vertical at the start of the pouring and is gradually tilted back to a normal horizontal position during pouring. The object of such a practice is to reduce the amount of agitation while the metal stream is being poured into the mold and thus to reduce the tendency toward formation of oxide film and entrapment. See *Durville process*.
tin cry. The peculiar crackling sound heard when pure tin is bent. Assumed to be related to mechanical twinning of crystals.
tinning. Coating with tin, most commonly by immersion into molten tin; electrodeposition and metal spraying are also used.
tin pest. The tendency of tin cooled to low temperatures, specifically lower than 56 F, to crumble into a powder known as "gray tin", an allotropic modification.
tin sweat. The beads of tin-rich low-melting phase that are found on the surface of bronze castings when the molten metal contained appreciable amounts of hydrogen.
tolerance limit. (1) The permissible deviation from the desired value. (2) As applied to magnesium alloys, the specific critical amount of an impurity element which, if exceeded, results in a great increase in rate of corrosion in salt solutions.
top-and-bottom process. Separation of copper and nickel, in molten sulfide form, by the addition of sodium sulfide, which causes the separation of two liquid layers. The lower holds most of the nickel.
torsion. Strain created in a material by a twisting action. Correspondingly, the stress within the material resisting the twisting.
tossing (tin). Purifying tin by pouring from a ladle into a kettle, so as to expose thin sheets of the liquid metal to the air, forming oxide dross.
toughness. Property of absorbing considerable energy before fracture; usually represented by the area under a stress-strain curve, and therefore involving both ductility and strength.
tough pitch copper. Refined copper (usually from electrolytic cells) that has been remelted under conditions producing a final oxygen content from 0.02 to 0.05% by weight. It has been found that copper, poled to the point where it solidifies to a flat set surface, exhibits a high degree of toughness.
trace. Extremely small quantity of an element, usually too small to determine quantitatively.
transcrystalline. Literally, across the crystal. See *intracrystalline*.
* **transformation range or transformation temperature range.** The temperature interval within which austenite forms while ferrous alloys are being heated. Also the temperature interval within which austenite disappears while ferrous alloys are being cooled. The two ranges are distinct, sometimes overlapping but never coinciding. The limiting temperatures of the ranges depend on the composition of the alloy and on the rate of change of temperature, particularly during cooling. See *transformation temperature*.
* **transformation temperature.** The temperature at which a change in phase occurs. The term is sometimes used to denote the limiting temperature of a transformation range. The following symbols are used for iron and steel:

Ac_1. The temperature at which austenite begins to form during heating.
Ac_3. The temperature at which transformation of ferrite to austenite is completed during heating.
Ac_{cm}. In hypereutectoid steel, the temperature at which the solution of cementite in austenite is completed during heating.
Ar_1. The temperature at which transformation of austenite to ferrite or to ferrite plus cementite is completed during cooling.
Ar_3. The temperature at which austenite begins to transform to ferrite during cooling.
Ar_{cm}. In hypereutectoid steel, the temperature at which precipitation of cementite starts during cooling.
A_4. The temperature at which austenite transforms to delta ferrite during heating; the reverse process occurs during cooling.
M_s (or Ar''). The temperature at which transformation of austenite to martensite starts during cooling.
M_f. The temperature at which transformation of austenite to martensite is completed during cooling.

NOTE: All these changes (except the formation of martensite) occur at lower temperatures during cooling than during heating, and depend on the rate of change of temperature. The temperatures of phase changes at equilibrium are denoted by the symbols Ae_1, Ae_3, Ae_{cm} and Ae_4.

transition lattice. An intermediate, unstable crystallographic configuration that forms during solid metal reactions, such as precipitation from solid solution and eutectoid decomposition.
transition point. The temperature of transformation from one solid crystalline form of a substance to another. More broadly, the point where different phases can exist in equilibrium.
transverse. Literally "across", signifying a direction or plane perpendicular to the direction of working.
triple point. The temperature and pressure at which three phases of any substance exist in equilibrium.
trommel. A revolving, cylindrical screen used in grading coarsely crushed ore.
troostite. Tempered martensite that etches rapidly, usually appears dark, and is not resolved by the microscope.

NOTE: Two entirely different structures are frequently confused and called troostite: (1) The nodular, quickly etching microconstituent, found in steels that are cooled just too slowly to be fully martensitic, can be resolved into very fine pearlite. (2) "Temper troostite", the first product of the tempering of martensite, consists of submicroscopic particles of carbide in ferrite, and is frequently indistinguishable from a quickly etching fine pearlite in general appearance. The word "troostite" or "quenching" or "nodular troostite" should not be used to denote the first structure. If the word "troostite" is to be retained it should be reserved for temper troostite.

tube reducer. A machine in which a pair of rolls is used for cold rolling tubing and rod. These rolls have a tapered groove around part of their surface, corresponding to the intended change in outside dimension of the tube or rod. The stock is rotated between working strokes. This process is somewhat different from the *Pilger Process* in that the stock moves in the same direction, as rolling proceeds; the axes of the rolls move back and forth parallel to the stock; and the direction of rotation of the rolls changes between the forward working stroke and the backward return stroke. A fixed mandrel is used in rolling tubing.
Tukon hardness test. A method for determining microhardness by using a Knoop diamond indenter or Vickers square-base pyramid indenter.
tumbling. Cleaning articles by rotating them in a cylinder with cleaning materials.
Turk's-head rolls. Four undriven working rolls arranged in a square that serves as a die for drawing strip or wire to a rectangular section.
twin bands. In a polished and etched section, a band across a crystal grain, brought into relation with the main body of the grain by twinning.
twin crystals (twins, twinned crystals). A crystal grain in which the crystal lattices of two parts are related to each other in orientation as mirror images across the interface known as the "twinning plane".
type metal. A series of alloys containing 54 to 95% Pb, 2 to 28% Sb and 2 to 20% Sn, used to make printing type.

U

ultimate strength. See *tensile strength*.
undercooling. See *supercooling*.
underdraft. The tendency of metal to curve downward when leaving rolls, because of lower surface speed of the lower roll.
undermining pitting. A type of corrosion attack in which pitting develops on the exposed surface and spreads out beneath the surface.
underpoling. See *poling*.
upper punch. *Powd met.* The member of a die assembly that moves downward into the die body to transmit pressure to the powder contained in the die cavity.
upsetting. (1) A metal working operation similar to forging. (2) The process of axial flow under axial compression of metal, as in forming heads on rivets by flattening the end of wire.

V

vacuum refining. Melting in a vacuum, usually by electrical induction, to remove gaseous contaminants from the metal.
valve effect. A characteristic of certain materials to pass electric current in one direction only, thus qualifying these materials for applications in electric rectifiers.
Vegard's law. The lattice parameters of substitutional solid solutions vary linearly with composition expressed in atomic percentage.
veining. See *sub-boundary structure*.
vents. Narrow openings in closed molds to provide escape for gases.
Vickers hardness test. An indentation hardness test employing a 136-deg diamond pyramid indenter and variable loads enabling the use of one hardness scale from very soft lead to tungsten carbide.
virgin metal. Metal obtained directly from ore and not used before.

viscosity. The resistance of fluid substance to flowing, quantitatively characteristic for each individual substance at a given temperature and under other definite external conditions.
void. See *pore.*
volatility. The tendency of a substance to vaporize at the temperature under consideration.

W

wedge. A hardwood stick used as a forming tool in spinning.
wedge cake. A cast shape with slightly tapering sides, used principally for copper that is to be hot rolled to sheet.
weld bead. The built-up portion of a fusion weld, formed either from the filler metal or from the melting of the parent metal.
welding. A process used to join metals by the application of heat. *Fusion welding,* which includes *gas, arc,* and *resistance welding,* requires that the parent metals be melted. This distinguishes fusion welding from brazing. In *pressure welding* joining is accomplished by the use of heat and pressure without melting. The parts that are being welded are pressed together and heated simultaneously, so that recrystallization occurs across the interface.
welding stress. The stress resulting from localized heating and cooling of metal during welding.
weld nugget. The ellipsoidal melted area of a *spot weld.*
white gold. Gold alloyed with nickel, palladium or zinc.
white metal. (1) A general term covering alloys that are based on tin, lead or antimony, such as bearing, type and babbitt metals. (2) A copper matte of about 77% Cu obtained from the smelting of sulfide copper ores.
Widmanstätten structure. A structure characterized by a geometrical pattern resulting from the formation of a new phase along certain crystallographic planes of the parent solid solution. The orientation of the lattice in the new phase is related crystallographically to the orientation of the lattice in the parent phase. This type of structure is familiarly seen in cast steel and in overheated wrought steel that has been cooled rather rapidly, but it may occur in any alloy in which a phase change occurs. In steels exhibiting this structure, ferrite delineates the octahedral planes of austenite.
wire bar. A cast shape, particularly of tough pitch copper, which has a cross section approximately square with tapered ends, designed for hot rolling to rod for wire.
wire rod. A semifinished product from which wire is made. It is generally of circular cross section approximately ¼ in. in diameter.
woody fracture. Fractures having a fibrous appearance. See *fiber.*
woody or wood fiber structure. A structure found in extruded rods, particularly of aluminum alloys, which shows elongated surfaces of separation when fractured.
work hardness. Hardness developed in metal as a result of cold working. See *cold working.*
workability. The characteristic or group of characteristics that determines the ease of forming a metal into desired shapes.
worm. Solidifying copper is said to "throw a worm" when it forces a stream of molten copper through the top crust; high sulfur content is indicated.

Y

Y alloy. An aluminum-base casting alloy that contains about 4% Cu, 2% Ni, 1.5% Mg (142 alloy).
yellow gold. Gold alloys that possess the natural yellow color.
yield point. In mild or medium-carbon steel, the stress at which a marked increase in deformation occurs without increase in load. In other steels and in nonferrous metals this phenomenon is not observed. See *yield strength.*
yield strength. The stress at which a material exhibits a specified limiting deviation from proportionality of stress to strain. An offset of 0.2% is used for many metals such as aluminum-base and magnesium-base alloys, while a 0.5% total elongation under load is frequently used for copper alloys.
Young's modulus. The *modulus of elasticity* in tension or compression.

Definitions of Terms Used in X-Ray Metallography

By L. W. McKeehan*

THIS GLOSSARY is intended primarily for those who have occasion to consult publications in the field of X-ray metallography. The definitions may have secondary value to those who prepare such publications and who wish to use terms that are unambiguous. A part of the glossary has appeared in the Proceedings of the ASTM (Vol 26, Part 1, p 582, 1926) with a report by that society's Committee on X-Ray Metallography. It has been revised and extended here.

A (abbreviation). Angström unit, 10^{-8} cm; also written AU, Å, ÅU.
absorber (for X-rays). A sheet of material placed between the source of X-radiation and the place where it is detected or measured. When this sheet contains elements chosen especially to reduce the intensity of X-rays that have undesired wave lengths, the absorber is usually called a *filter.*
absorption coefficient (for X-rays in a substance). The rate of decrease, per unit distance traversed in a substance, of the natural logarithm of the intensity of a parallel beam; usually written μ.
absorption limit. See *limit.*
amorphous. Without crystal structure, so the X-ray diffraction pattern is like that of a liquid.
angle. See *glancing angle.*
Angström unit. A, 10^{-8} cm.
anisotropic. Having different properties in different directions.
anticathode (in X-ray tubes). The part of the anode that receives most of the cathode rays, and in which the target, if any, is mounted.
asterism (in X-ray diffraction patterns). The appearance of streaks or bands approximately along radii of the pattern.
axial ratio (in crystals). In the tetragonal system and in the hexagonal division of the hexagonal system, the ratio of the parameter for the principal crystallographic axis of highest multiplicity to the parameter for either one of the other principal axes, usually $C = c/a$; in less symmetrical systems the continued ratio of all three parameters, usually written a:b:c.
axis (crystal). One of three noncoplanar intersecting lines, fixed with respect to a crystal, which meet any crystal plane at points whose distances from the intersection of the axes, in terms of three parameters (a, b and c), one for each axis, are in the ratios of small integers. The principal crystal axes are those about which the symmetry is the highest possible to the crystal considered. Less properly, the length of an edge of the unit cell. See *parameter.*
axis of symmetry. In a crystal, a line about which a rotation through 360 deg/N (where N is 2, 3, 4 or 6), with or without a translation parallel to the line and with or without a reflection in a plane perpendicular to the line, replaces every element (point, line and plane) of the crystal by an equivalent element. The axis is said to be N-fold and is a rotation axis if neither translation nor reflection is involved; is a screw-axis if any other than a primitive translation is involved; and is a rotatory-reflection axis (N not equal to 3) if reflection is involved.

back reflection. X-ray diffraction at deviations near 180 deg, especially useful in precise measurement of interplaner distances.
balanced filters (for X-rays). A pair of filters adjusted to give the same absorption except in the range of wave lengths lying between their characteristic absorption limits. When these filters are used alternately, the difference in effect, if any, is due to X-rays that have wave lengths in this range.
basal plane. In tetragonal and hexagonal crystals, a plane perpendicular to the c-axis.
beam (X-ray). A nearly parallel pencil of X-rays from a common source.
body. See *bulb.*
body-centered (concerning space lattices). Having the equivalent lattice points at the corners of the unit cell, and at its center; sometimes called *centered,* or *space-centered.*
Bragg equation (for X-ray reflection). The equation $n\lambda = 2d \sin \theta$. See also *reflection.*
Bragg method (for X-ray or crystal analysis). A method using monochromatic or polychromatic X-rays and a single crystal of large size rotated through a small angle about an axis lying in a crystal face.
bulb (in X-ray tube). The part made of glass or other pressure-tight material; when made of metal, more usually called the "body".

calcite. Natural rhombohedral $CaCO_3$, the primary standard crystal used in X-ray spectrometry.
cassette (in X-ray spectrographs). A box for holding a photographic film or plate in position to receive the X-ray diffraction pattern.
cell. See *unit cell.*
centered (concerning space lattices). Body-centered.
channel (in X-ray spectrographs). A collimating system consisting of a hole through a thickness of metal, usually in two parts to permit cleaning.
chaotic. See *orientation.*
characteristic X-rays. Series of monochromatic X-rays that are emitted (in addition to heterochromatic X-radiation) by a particular element when that element is exposed to cathode rays or X-rays of sufficiently high energy.
close-packed (concerning atomic arrangement in crystals). Having one of the two possible arrangements, one cubic and one hexagonal, in which equal hard spheres can be made to occupy the least total volume; and, by extension, having any of the hexagonal arrangements derived from the second of these by expansion or contraction of the hexagonal axis. See *face-centered* and *hexagonal close-packed.*
coefficient. See *absorption coefficient, mass-absorption coefficient, mass-scattering coefficient.*
collimate. To isolate a parallel, or nearly parallel, beam of rays, as by slits, pinholes or a channel.
continuous spectrum. Heterochromatic X-rays.
Coolidge tube. A type of X-ray tube that has a high vacuum and a hot wire cathode.
covering operation. A general name for translations, symmetry operations, and their combinations in extended structures, by which every element (point, line and plane) of the structure is replaced by an equivalent element. Besides translations and symmetry operations there are screw rotations about screw axes and glide reflections in glide-reflection planes.
critical (concerning voltage, wave length or frequency). Limiting. See *limit.*
cross direction (in rolled metal). The direction parallel to the axes of the rolls during rolling.
crystal. A coherent piece of matter all parts of which have the same anisotropic arrangement of atoms; in metals, usually synonymous with "grain" and "crystallite".
crystal analysis. The determination of crystal structure.
crystalline. Composed of crystals.
crystal unit. Unit of structure.
cube-centered (concerning space lattices). Body-centered cubic.

* Sloane Physics Laboratory, Yale University, New Haven, Conn.

cubic (concerning crystals). Having nonparallel 3-fold axes of symmetry, with other elements of symmetry. Sometimes called "isometric" or "regular". The typical cubic crystal has three equivalent axes (2-fold or 4-fold) mutually perpendicular, and the common parameter is usually written a (or a_0).

dashed (concerning X-ray diffraction patterns from crystal aggregates). Made up of separately distinguishable images of the source.
Debye-Scherrer method (for X-ray crystal analysis). A method using a monochromatic (or polychromatic) X-ray beam defined by pinholes, an aggregate of small crystals oriented more or less completely at random and a photographic film bent into an almost complete cylinder with axis perpendicular to the X-ray beam at the crystalline specimen; almost indistinguishable from the Hull method; sometimes called the *powder method*.
define (X-rays). To limit in angle, as by slits or pinholes; to collimate.
deviation (X-ray). The angle between the direction of incidence produced through the substance, and the direction of diffraction; twice the glancing angle of incidence; usually written 2θ.
diagram (for X-ray diffraction patterns). A representation, either a photograph as taken, or a projection therefrom; for example, the *index diagram*.
diamond cubic (concerning atomic arrangements). Similar to the diamond in having two face-centered cubic arrangements of atom centers, either of which is displaced with respect to the other by one-fourth of the diagonal of the unit cube.
diffraction (X-ray). The deviation of an X-ray beam by scattering from atoms that have some regularity of arrangement or spacing.
diffraction pattern (X-ray). The totality of the intersections, with a plane or other surface, of the beams diffracted by a crystal or by a crystalline aggregate.
discontinuity (in absorption). The ratio between absorption coefficients at a limit.
doublet (in characteristic X-ray spectra). A pair of lines from the same element that differ little in wave length; for example, the K*a*-doublet, Ka_1 and Ka_2.

end-centered (concerning orthorhombic space lattices). Having equivalent points at the corners of the unit cell and at the centers of the pair of opposite faces perpendicular to the c-axis. Same as *side-centered*, with a different choice of axes.
equivalent (concerning points, lines, planes and atoms). Interchangeable by the covering operations appropriate to the structure.
excite (X-rays). To cause to be emitted.
exposure (to X-rays). The time integral of the intensity; with X-ray tubes of the same kind and operated under the same conditions, the exposure is proportional to the product of the electron current through the tube by the time of operation.

face (crystal). A natural surface, or a cut surface parallel to a possible natural surface.
face-centered (concerning cubic space lattices). Having equivalent points at the corners of the unit cell and at the centers of its six faces. A face-centered cubic space lattice is characteristic of one of the close-packed arrangements of equal hard spheres.
family (of crystal planes). The planes in any one crystal that have common indices.
fiber axis. See *fibering*.
fiber diagram. An X-ray diffraction pattern, or a chart prepared therefrom, showing the existence of fibering or measuring its completeness.
fibering. The state of a crystalline aggregate in which the preferred orientations are obtained by rotation about a line, the fiber axis. If fibering is complete, all azimuths about the fiber axis are equally probable. If fibering is incomplete, the preferred orientations may decrease to a small number and the concept of fibering loses its value. Besides simple fibering there may be a helical fibering in which the fiber axis has all the orientations assumed by the tangent to a helix of constant pitch. In ring fibering, the pitch of the helix is zero.
filter (for X-rays). A sheet of material that selectively absorbs secondary or other undesired X-rays. See also *balanced filters*.
fluorescent screen (for X-rays). A sheet of material (usually mounted on paper or other nonabsorbent material) that emits visible or actinic light when exposed to X-rays.
fluorescent X-rays. Characteristic X-rays excited by X-rays.
focus (in X-ray tubes). The spot on the target where the cathode rays are concentrated and which is therefore the principal source of X-rays; its shape and size are controllable by design.
focusing (concerning methods of X-ray or crystal analysis). Using such a shape and position of sample and position of source that the diffracted X-rays from many or all parts of the sample fall close together in the diffraction pattern. Such methods permit the use of wide beams and require relatively short exposures. See *Bragg method* and *Seemann-Bohlin method*.
form (for equivalent crystal planes or lines). Having the same indices, except for sign or order; for example, the planes (110), (101) in a cubic crystal are both of the form {110}; the planes (110), (101) in a tetragonal crystal are not of the same form. The lines [210], [120], [012] in a cubic crystal are of the form $<210>$.
frequency (X-ray). Measured by the equation $\nu = c/\lambda$, wherein c is the velocity of propagation of light (3×10^{10} cm per sec) and λ is the wave length, in centimeters.
frequency factor (for crystal planes of a form). The number of different families of planes having the same form.

general (concerning X-radiation). Heterochromatic.
glancing angle. The angle between the incident X-ray beam and the crystal planes from which reflection takes place, however these may be inclined to the bounding surface of the crystal; usually written θ.
glide-reflection plane. See *plane of symmetry*.
gnomonic projection. A projection in which each plane of a crystal is represented by the point in which the perpendicular allowed to fall upon it from a fixed point meets the plane of the projection.
goniometer. An instrument for measuring angles or for setting objects in known orientations. *Spectrographs* and *spectrometers* are goniometers of a special sort.
grating constant (in crystals). Interplanar distance.
grating space (in crystals). Interplanar distance.

halo (in X-ray diffraction patterns). A diffuse circular band.
hard (concerning X-rays). Having great penetrating power, short wave length, high frequency
hemihedral (concerning crystals). Having only one-half of the symmetry elements possible to the crystal system in which the crystal belongs; having different properties in opposite directions, or on opposite faces, or lacking symmetrically opposite faces.
heterochromatic (concerning X-rays). Having a continuous series of wave lengths, as from a tube operated at less than the critical voltage for its target.
heterogeneous (concerning X-rays). Heterochromatic.
hexagonal (concerning crystals). Having parallel 6-fold rotation axes of symmetry, or a single set of parallel 3-fold rotation axes of symmetry with planes of symmetry perpendicular thereto, and with or without other symmetry elements. The typical hexagonal crystal has two equal axes, b = a, inclined at an angle of 120 deg and a third axis, c, perpendicular to their plane.
hexagonal close-packed (concerning atomic arrangements in crystals). Having atoms at the corners of the hexagonal unit cells, which are right prisms with rhombic bases, and at the centers of those (equilateral) triangular prisms that are similarly located halves of the hexagonal unit cells. The two sets of atoms are not crystallographically equivalent. If the atoms are arranged like hard equal spheres in contact, c = 1.633 or $2\sqrt{6}/3$.
holohedral (concerning crystals). Having all the symmetry elements possible to the crystal system in which the crystal belongs.
homogeneous (concerning matter). Having the same properties in every small region containing many atoms (but not necessarily isotropic).
homogeneous (concerning X-rays). Monochromatic.
Hull method (for X-ray crystal analysis). A method using a monochromatic (or polychromatic) X-ray beam defined by slits or pinholes, an aggregate of small crystals oriented more or less completely at random and a photographic plate or a photographic film (if a film, bent around a cylinder with its axis perpendicular to the X-ray beam at the crystalline specimen); virtually indistinguishable from the Debye-Scherrer method; sometimes called the *powder method*.

identity period (along a crystal line). A primitive translation.
image (in X-ray diffraction patterns). By analogy with optics, a recognizable copy of the source of X-rays or of any aperture defining the X-ray beam.
index diagram. A chart based on an X-ray diffraction pattern and permitting the assignment of indices to the families of planes responsible for the maxima of intensity in the pattern.
indices. See *Miller indices, Miller-Bravais indices, line indices*.
intensifier (for X-rays). A substance placed in, on or under a photographic emulsion or a fluorescent screen, or used in photographic development, to make the effects of X-rays more conspicuous.
intensifying factor (for X-ray intensifiers). The ratio between the exposure when no intensifier is used, and the exposure, for the same effect, when the intensifier is used, provided that all other conditions remain unaltered.
intensifying screen (in X-ray spectrographs). A separately mounted intensifier.
intensity (X-rays). The flux of energy per unit of time and per unit of cross section perpendicular to the direction of propagation.
interplanar distance (in crystals). The perpendicular distance between the nearest equivalent planes of a family; usually written d. The indices of the planes may be written as a subscript; for example, d_{100}.
inversion. A symmetry operation by which each point of a structure is replaced by a point at the same distance from a fixed point (the inversion center) but in the opposite direction therefrom. See also *symmetry operation*.
ionization method. Any method of X-ray or crystal analysis that depends on measuring the electrical conductivity of a gas exposed to the diffracted X-rays; great accuracy in angular measurement is possible, but not easy.
isometric (concerning crystals). Cubic.
isotropic. Having the same properties in every direction.

K. The letter that designates the series of characteristic X-rays having, for each element, the shortest wave lengths. Greek letters and Arabic subscripts are used to distinguish the lines of the K-series; for example copper Ka_1, molybdenum $K\beta$. L and M are used to designate characteristic groups of X-rays of successively greater wave length, but these are rarely used in crystal analysis.
kX (abbreviation). Kilo-X-unit. Differs slightly from an angström unit (10^{-8}cm). See *X*.

lattice. Space lattice. Lattice lines and lattice planes are lines and planes chosen so as to pass through collinear lattice points, and noncollinear lattice points, respectively.
Laue method (for crystal analysis). A method using heterochromatic X-rays, a small fixed crystal and a plane screen, usually a photographic plate; the Laue spot is the image (of a pinhole or of the small crystal itself) characteristic of the resulting diffraction pattern.
layer line (in *revolving-crystal* and *oscillating-crystal methods*). A row of spots caused by families of planes equally inclined to the axis of rotation or oscillation. Compare with *side spectrum, zero spectrum*.
limit (in voltage, wave length or frequency of X-rays). A value, characteristic of the particular chemical element in question, on the two sides of which excitation, absorption, photographic effect or the like, have sharply different values.
line (crystal). A possible edge of a crystal.
line (in X-ray diffraction patterns). A straight or slightly curved narrow region of maximal intensity.
line (X-ray). A group of monochromatic X-rays, not necessarily collimated.
line focus (in X-ray tubes). A focus having one dimension reduced to such an extent that the focus approximates a segment of a straight line on the target in the plane determined by the axis of the tube and the direction from the target to the irradiated object. This secures the advantages of a point source of X-rays without extreme local heating.
line indices. The smallest integers proportional to the co-ordinate differences, in terms of the parameters (a, b and c), between equivalent points lying on a crystal line; written, in general [HKL]; in

particular, for example, [210]. In cubic crystals the line [pqr] is perpendicular to the plane (pqr).

mass-absorption coefficient (for X-rays in a substance). The rate of decrease, per unit mass traversed, of the natural logarithm of the intensity of a parallel beam; usually written μ/ρ. It is often more convenient than the absorption coefficient because its use does not require knowledge of the density ρ. See also *mass-scattering coefficient.*

mass-scattering coefficient (for X-rays in a substance). The rate of decrease, per unit mass traversed, of the natural logarithm of the intensity of a parallel beam, caused by scattering alone; usually written σ/ρ; the excess of the mass-absorption coefficient, μ/ρ, over σ/ρ is called the true mass-absorption coefficient, μ'/ρ.

Miller indices (for crystal planes). The smallest integers proportional to the reciprocals of the intercepts, in terms of the parameters (a, b and c) of the plane on the three crystal axes; written, in general (hkl); in particular, for example (210); see also *form.*

Miller-Bravais indices (for crystal planes in the hexagonal division of the hexagonal system only). The smallest integers proportional to the reciprocals of the intercepts, in terms of the parameters (a, a, a, and c) of the plane on the four axes; written, in general (hjkl); in particular, for example (1120). The index for the hexagonal axis is always written last; $k = -(h + j)$ and may be replaced by a period; thus $(11\bar{2}0)$ and (11.0) are the same. Any two of the three equivalent axes 120 deg apart in the basal plane, together with the fourth axis, are crystallographically sufficient; but the use of four axes makes it easier to recognize planes of the same form.

monochromatic (concerning X-rays). Having a single wave length.

monoclinic (concerning crystals). Having only parallel 2-fold axes of symmetry, or parallel planes of symmetry, or both of these with the axes perpendicular to the planes. The typical monoclinic crystal has three unequal axes, only one of which is perpendicular to two others. The unique axis is usually taken as the b-axis.

multiplicity (for axes of symmetry). The value of N if the axis is N-fold.

order (in X-ray reflection). The integral value of n in the equation $n\lambda = 2d \sin \theta$.

orientation (crystal). Arrangement in space of the axes of a crystal. Every crystal must at every moment have a definite orientation; only aggregates, in space or time, can possess chaotic orientation; if the the orientation is not chaotic, some one or more orientations must be preferred.

orthohexagonal (concerning crystal axes). A set of mutually perpendicular axes for hexagonal crystals. In terms of the more usual hexagonal parameters (a, a, c) the orthohexagonal parameters are $a\sqrt{3}$, a, c.

orthorhombic (concerning crystals). Having only 2-fold axes of symmetry, with planes of symmetry parallel to the axes or perpendicular thereto. The typical orthorhombic crystal has three unequal axes mutually perpendicular.

oscillating-crystal method (for X-ray or crystal analysis). Using a single crystal rotating at constant speed, but alternately in both directions, through less than a complete rotation (usually much less).

parameter (in crystals). A characteristic magnitude defining the unit cell or the position of a point within it. The edges of the unit cell, a, b, c, and the angles, α (between ■ and c), β (between ■ and a), γ (between a and b), are its parameters. The edge of the unit cube, a_o, is the single parameter of a cubic lattice. When the fractional co-ordinates of a point within the unit cell may vary, the values of these fractions (x, y, z) are parameters of the structure.

pattern. *Diffraction pattern.*

photogoniometer. An X-ray goniometer with photographic registration.

pinhole. A small round hole used to define a beam of X-rays.

plane (crystal). A possible face of a crystal.

plane of symmetry. In a crystal, a plane in which a reflection, with or without a translation parallel to the plane, replaces every element (point, line and plane) of the crystal, by an equivalent element. The plane is a *reflection plane* if no translation is involved, and is a *glide-reflection plane* if translation is involved.

point-group. A limited group of points (from 1 to 48 in number) possessing the same symmetry elements as one of the 32 possible classes of crystals.

pole figure (for crystalline aggregates). A stereoscopic projection showing preferred orientations of the normals to planes of a given form.

polychromatic. Having several distinct wave lengths; for example, the characteristic X-rays from a single element.

powder method (for X-ray or crystal analysis). A method using a loose aggregate of small crystals with chaotic orientation; applied early, but somewhat illogically, to methods using solid metals composed of crystalline aggregates; see *Debye-Scherrer method, Hull method.*

preferred. See *orientation.*

primary (concerning X-rays). Emitted directly from the anticathode in the X-ray tube.

primitive. See *translation.*

principal spectrum (in *revolving-crystal* and *oscillating-crystal* patterns). *Zero spectrum.*

pseudocrystalline. Possessing regularities of structure that result in a diffraction pattern unlike that of a liquid or an amorphous solid, although true crystals are not present; for example, stretched rubber is pseudocrystalline.

radiography. The use of X-rays in studying the macrostructure of single objects or assemblies (internal boundaries, inclusions, variations in density or composition).

random (concerning orientation). Chaotic.

rating (for X-ray tubes). The product of the allowable current by the peak operating voltage.

ratio. See *axial ratio.*

reciprocal lattice (for a crystal). A group of points arranged about a center in such a way that the line joining each point to the center is perpendicular to a family of planes in the crystal, and the length of this line is inversely proportional to their interplanar distance.

reflection (X-ray). Diffraction considered to result from scattering by crystal planes as units. These are the reflecting planes. Monochromatic X-rays are reflected only when $n\lambda = 2d \sin \theta$, where n is order, λ wave length, d interplanar distance, and θ glancing angle of incidence on the planes considered.

reflection plane. See *plane of symmetry.*

regular (concerning crystals). Cubic.

revolving-crystal method (for crystal analysis). A method using a small single crystal that rotates uniformly through many complete rotations during the time of the exposure.

rhombohedral (concerning crystals). Having parallel 6-fold rotatory-reflection axes, or a single set of parallel 3-fold rotation axes, in either instance without planes of symmetry perpendicular thereto, and with or without other elements of symmetry. The typical rhombohedral crystal has three equal axes (c = a, b = a) mutually inclined at an angle ■ not usually equal to 90 deg.

rock salt. Natural (cubic) NaCl, the secondary standard crystal used in X-ray spectrometry.

Roentgen rays. See *X-rays.*

rolling direction (in rolled metal). The direction, in the plane of the sheet, perpendicular to the axes of the rolls during rolling.

rotation axis. See *axis of symmetry.*

rotation diagram. A chart used in assigning indices to families of planes that give spots in the diffraction patterns obtained in revolving-crystal or oscillating-crystal methods for crystal analysis.

rotatory-reflection axis. See *axis of symmetry.*

scattering (X-ray). The re-emission of X-rays from irradiated matter, without change of wave length (except as modified by the Compton effect, which is negligible in crystal analysis); scattering takes place in all directions with respect to the incident X-rays, but more intensely (or more often) in some directions than in others.

screen (in X-ray spectrographs). A flat or curved surface on which a diffraction pattern may be observed; for example, a fluorescent screen. Sometimes, but less properly, a shield.

screw axis. See *axis of symmetry.*

secondary (concerning X-rays). Emitted elsewhere than from the anticathode.

secondary spectrum (in revolving-crystal and oscillating-crystal patterns). *Side spectrum.*

Seemann-Bohlin method (for crystal analysis). A method using ■ monochromatic or polychromatic X-ray beam of wide angular aperture; an aggregate of small crystals oriented more or less completely at random and spread on a cylinder having an element that passes along the single slit defining the X-ray beam; and a photographic film bent to fit another segment of the same cylinder. This is a focusing method.

series (in X-ray spectra). A group of characteristic X-rays having the same excitation limit; distinguished as K-series and L-series. See also *K.*

shield (in X-ray spectrographs). A plate, block or the like that prevents X-rays (usually secondary) from reaching the measuring or detecting device; a complete *absorber.*

shutter (in X-ray spectrographs). A removable shield.

side-centered (concerning orthorhombic space lattices). Having equivalent points at the corners of the unit cell, and at the centers of the pairs of opposite faces perpendicular to the a-axis or to the b-axis; the same as end-centered, but with a different choice of crystallographic axes.

side spectrum (in *revolving-crystal* and *oscillating-crystal* patterns). A row of spots indicating planes equally inclined to the axis of rotation or oscillation, but not parallel thereto. Compare with *layer line, zero spectrum.*

simple (concerning space lattices). Having equivalent points only at the corners of the unit cell.

slit. A narrow opening with parallel sides, used to define a beam.

slit system. A series of slits used to define a beam and to shield against secondary X-rays.

slitless spectrograph. *Wedge spectrograph.*

soft (concerning X-rays). Having little penetrating power, long wave length, low frequency.

source (X-ray). See *focus.*

space-centered (concerning space lattices). *Body-centered.*

space group. A group of points infinitely extended and possessing the same elements of symmetry and the same translations as one of the 230 different arrangements theoretically possible for atoms in crystals. The great number of space groups as compared with point groups results from the fact that ■ different location in space for the same symmetry elements is possible in the space group but not in the point group.

space lattice (crystal). A system of equivalent points formed by the intersections of three sets of planes parallel to pairs of principal axes; the space lattice may be thought of as formed by the corners of the unit cells. See *translation group.*

spacing (between crystal planes). *Interplanar distance.*

spectrograph (X-ray). An instrument using an extended surface—a photographic plate or film, or a fluorescent screen—for receiving the X-ray diffraction pattern.

spectrometer (X-ray). An instrument using a movable measuring device for exploring the X-ray diffraction pattern.

spectrum (X-ray). A distribution of X-rays along a line in accordance with the wave length, or a group of X-rays that can be distributed in this way. The set of layer lines furnished by the revolving-crystal method is sometimes called the complete spectrum. See also *side spectrum, zero spectrum.*

stereographic projection. A projection in which each plane of a crystal is represented by the point at which ■ perpendicular, let fall upon it from a fixed point, meets a sphere centered at the fixed point; and these representative points on the sphere are then represented in turn by the points at which lines drawn to them from the pole of a great circle of the sphere meet the diametral plane through the great circle.

structure. The arrangement of parts; in crystals, especially, the shape and dimensions of the unit cell, and the number, kinds and positions of the atoms within it.

symmetry. See *axis of symmetry, inversion, plane of symmetry.*

symmetry element. A general name for axes of symmetry, planes of symmetry and centers of inversion.
symmetry operation. A geometrical operation that interchanges equivalent elements (points, lines and planes) of a rigid geometrical figure. The possible symmetry operations are rotations about rotation axes that pass through the center of the figure and reflections in reflection planes that pass through the same point. A rotatory reflection is a compound operation in which the rotation axis must be perpendicular to the reflection plane, except that an inversion is equivalent to a 2-fold rotatory reflection about any rotatory-reflection axis.
system (crystal). One of the 6 classes into which the 32 possible types of crystal and the 230 possible types of structure have been divided on the basis of symmetry. They are *triclinic, monoclinic, orthorhombic, tetragonal, hexagonal* (including *rhombohedral* and *hexagonal* divisions) and *cubic.*

target (in X-ray tubes). The part of the anticathode, wholly or predominantly of a single metal, or coated with a substance to be analyzed, where the focus lies.
tetartohedral (concerning crystals). Having only one-fourth of the symmetry elements possible to the crystal system in which the crystal belongs.
tetragonal (concerning crystals). Having 4-fold axes of symmetry but no 3-fold axes of symmetry. The typical tetragonal crystal has two equal axes (b = a) perpendicular to each other and to a third axis (c).
translation (in a crystal or space group). A displacement parallel to a crystal line. A primitive translation is one of the least translations, without accompanying rotation or reflection, which replaces every element (point, line and plane) by an equivalent element. Suitable aliquot parts of a primitive translation may be combined with rotation or reflection in screw rotations and glide reflections.
translation group. An infinitely extended group of points having the same translations as one of the 14 space lattices possible in crystals.
transmission method (for X-ray or crystal analysis). Having the diffracted X-rays emergent from a surface that does not face the source.
triclinic (concerning crystals). Having no symmetry elements, or only inversion centers. The typical triclinic crystal has three unequal axes, no two of which are perpendicular.

uniform (concerning X-ray diffraction patterns). Not *dashed.*
unit cell (in crystals). The least parallelopiped that possesses the full symmetry of the crystal, and repetition of which without change or orientation builds up a crystal of any size.
unit cube (in crystals). The unit cell in cubic crystals.
unit of structure (in crystals). The group of atoms included by the unit cell, especially if the arrangement of the group indicates chemical relations among its members.

wave length (X-ray). The value of λ in the equation, $\lambda = \frac{2d \sin \theta}{n}$; wherein d is the interplanar distance in a crystal that reflects the X-rays at the glancing angle θ in the nth order.
wedge spectrograph. An X-ray spectrograph (developed by Seemann) in which the beams of incident and diffracted X-rays are limited by a wedge brought into contact with a face of the crystal; also called *slitless spectrograph.*
Weissenberg photogoniometer. A photogoniometer with a cylindrical film, shielded and axially advanced in such a way during exposure that the spots of a single layer line are recorded consecutively along the direction of travel of the film.
white (concerning X-rays). Heterochromatic.

X (abbreviation). X-unit; also written **XU.** $1XU = 1.00202 \times 10^{-11}$ cm so that 1 kilo-X-unit, or 1kX = 1.00202 A.
X-radiation. X-rays in general, especially when their direction of propagation is not emphasized.
X-ray analysis. The measurement of X-ray wave lengths and intensities.
X-rays. Light rays, excited usually by the impact of cathode rays on matter, which have wave lengths between about 10^{-6} cm, and 10^{-9} cm; also written X-rays; same as *Roentgen rays.*
X-ray tube. An assembly of *cathode, anticathode,* and *bulb* (or body) suitable for the production of X-rays.

zero spectrum (in revolving-crystal and oscillating-crystal patterns). A row of spots resulting from planes parallel to the axis of rotation or oscillation. Sometimes called "zero line". Compare with *layer line, side spectrum.*
zone axis (in a crystal). A line parallel to several crystal planes. The planes to which it is parallel form its zone.

Some Physical Properties of the Elements*

The following table has been compiled from many sources. For the 36 metallic elements that are discussed elsewhere in this Handbook, the numbers given here have been selected by the same specialists who compiled the data on the mechanical and metallurgical properties of these metals. For the less common metals and for the nonmetallic elements, most of the data are from National Bureau of Standards Circular C447, 1943, page 459.

Atomic weights are from the 1947 Report of the International Commission on Atomic Weights. Nearly all the melting points are those most recently quoted by the National Bureau of Standards. Most of the boiling points were selected by K. K. Kelley (Bureau of Mines Bulletin 383, 1935) from smoothed curves of vapor pressure versus temperature.

Most of the lattice constants are those selected by Hume-Rothery in his 1945 edition of "The Structure of Metals and Alloys", Institute of Metals, London; the references he gives have been checked and a few corrections and substitutions have been made when data have been found that the committee judged to be more accurate. The lattice constants have been corrected to 20 C (68 F), when the correction was a minor one, by using the known coefficients of thermal expansion; measurements at very low temperatures are reported as such, uncorrected, with the temperature given. For the polymorphic gases the structure stable at the highest temperature is given.

All entries in this table are for elements of high purity. Impurities may have a great effect on certain properties, for example, on the melting point and electrical resistivity. Most of the data do not apply to commercial metals, which contain greater amounts of impurities than the elements considered here. For metals, most of the properties refer to annealed specimens. Cold working will change certain properties—for example, density and electrical resistivity. Grain size may also affect some properties.

It will be noted that the number of significant figures contained in the various values ranges from one to six. Such differences in the uncertainties of the quoted values may reflect the greater or lesser care that has been taken in measuring the properties. Certain properties are much more difficult to measure than others; for example, the moduli of elasticity of soft and ductile metals and the boiling points of many metals are difficult to determine precisely. It is not uncommon for different investigators to report different values for a given property, depending on the method of measuring; examples are thermal conductivity and latent heat of fusion. Because of these factors, some of the values are probably less accurate than would be inferred from counting the number of digits contained in the values listed.

In using this table, the reader should be guided by the above considerations concerning the probable accuracy of the numbers.

* Compiled under the supervision of the Subcommittee on Physical Properties of the Elements. The members of this subcommittee are R. L. Kenyon, *Chairman* (The American Rolling Mill Company), C. S. Barrett (University of Chicago), J. B. Johnson (Air Materiel Command) and H. W. Russell (Battelle Memorial Institute).

Footnotes for Table on pages 20 and 21

NOTES. (*) Ordinary form; other modifications known or probable. (†) The kX-unit (1000 X-units), used in all crystal structure measurements, differs slightly from an Angström (10^{-8}cm); the tabulated lattice dimensions should be multiplied by 1.00202 to put them in Angströms, as when calculating theoretical densities of elements. (Density is given by the equation $\rho = 1.66020\ \Sigma A/V$, where ΣA is the sum of the atomic weights of the atoms in the unit cell and V is the volume of the unit cell, in cubic Angströms.)

(a) Computed (b) For polycrystalline zinc; in single crystals, varies from 61.5 (parallel to hexagonal axis) to 15 (perpendicular to hexagonal axis (c) From 20 to 60 C (68 to 140 F) (d) At 36 atmospheres pressure (e) From 20 to 100 C (68 to 212 F) (f) At 30 atmospheres pressure (g) At minus 62 C (minus 80 F) (h) From 20 to 50 C (68 to 122 F) (i) Sublimes (j) From 20 to 200 C (68 to 392 F) (k) From 20 to 750 C (68 to 1382 F) (m) At 0 C (32F) (n) At 40 C (104 F) (o) From 0 to 100 C (32 to 212 F) (p) At 100 C (212 F) (q) Monoclinic sulfur (r) At 25 C (77 F) (s) For polycrystalline zinc; in single crystals, varies from 6.16 (parallel to hexagonal axis) to 5.89 (perpendicular to hexagonal axis) (t) Pure zinc has no clearly defined modulus of elasticity (u) The solid helium listed is stable only under pressure.

Linear Thermal Expansions of Metals and Alloys

THE NUMBERS in this table have been collected from the numerous articles and data sheets that record in detail the properties of metals in this Handbook. The values are collected here for the reader's convenience in making general comparisons. For more specific information concerning the expansion of SAE steels, the table on page 309 should be consulted. Additional data for nonferrous metals and alloys will be found under item D6 in the data sheets. Values given here are for as-cast, as-wrought or as-annealed material. The effects of thermal treatment, temperature range and other factors are indicated in the various places mentioned above.

Metal		Temperature, deg Cent	Coefficient of Expansion per deg Cent
	Aluminum and Aluminum Alloys		
			× 10⁻⁶
Aluminum (99.95%)		20 to 100	23.9
	Wrought		
2 S	99.0 Al	20 to 100	23.5
3 S	1.2 Mn	20 to 100	23.2
11 S	5.5 Cu, 0.5 Pb, 0.5 Bi	20 to 100	22.9
14 S	4.4 Cu, 0.8 Si, 0.8 Mn, 0.4 Mg	20 to 100	22.5
17 S	4 Cu, 0.5 Mn, 0.5 Mg	20 to 100	23.0
18 S	4 Cu, 2 Ni, 0.5 Mg	20 to 100	22.4
24 S	4.5 Cu, 1.5 Mg, 0.6 Mn	20 to 100	22.8
25 S	4.5 Cu, 0.8 Mn, 0.8 Si	20 to 100	22.8
32 S	12.5 Si, 1.0 Mg, 0.9 Cu, 0.9 Ni	20 to 100	19.4
A51 S	1.0 Si, 0.6 Mg, 0.25 Cr	20 to 100	23.1
53 S	2.5 Mg, 0.25 Cr	20 to 100	23.8
52 S	1.3 Mg, 0.7 Si, 0.25 Cr	20 to 100	22.9
56 S	5.2 Mg, 0.1 Mn, 0.1 Cr	20 to 100	24.3
61 S	1.0 Mg, 0.6 Si, 0.25 Cu, 0.25 Cr	20 to 100	23.5
75 S	5.5 Zn, 2.5 Mg, 1.5 Cu	20 to 100	23.2

Silver		0 to 100	19.7
Tungsten		20	4.3

(a) For compositions of copper alloys, see page 24. (b) With the grain. (c) Across the grain. (d) Approximately the same for all commercial magnesium alloys.

Densities of Metals and Alloys

THE NUMBERS in this table have been collected from articles and data sheets that record in detail the properties of metals in this Handbook. The values are collected here for the reader's convenience in making general comparisons. For further data on the densities of ferrous alloys, the table on page 312 should be consulted. Additional information concerning densities of nonferrous metals and alloys will be found under item C1 in the data sheets. Values listed here are for as-cast, as-wrought or as-annealed material. The effects of thermal treatment, mechanical working, temperature, and other factors are indicated in the various places mentioned above.

Metal and Composition		Density, g per cu cm	Density, lb per cu in.
Aluminum and Aluminum Alloys			
Wrought

Thermal Conductivities of Metals and Alloys

THE NUMBERS in this table have been collected from articles and data sheets that record in detail the properties of metals in this Handbook. The values are collected here for the reader's convenience in making general comparisons. For further data on the thermal conductivities of ferrous alloys, the table on page 314 should be consulted. Additional information concerning thermal conductivities of nonferrous metals and alloys will be found under item D16 in the data sheets. Values listed here are for as-cast, as-wrought or as-annealed material. The effects of thermal treatment, mechanical working, and other factors are indicated in the various sections.

Metal	Thermal Conductivity near Room Temperature, cal/sq cm/cm/°C/sec	watt/cm/°C	Btu/sq ft/in/°F/sec
Aluminum and Aluminum Alloys			
Wrought			
2 S (99.0+ Al)	0.53	2.2	0.43
3 S 1.2 Mn	0.46	1.9	0.37
11 S 5.5 Cu, 0.5 Pb, 0.5 Bi	0.37	1.55	0.30
14 S 4.4 Cu, 0.8 Si, 0.8 Mn, 0.4 Mg	0.46	1.9	0.37
17 S 4 Cu, 0.5 Mg, 0.5 Mn	0.41	1.7	0.33
18 S 4 Cu, 2 Ni, 0.5 Mg	0.46	1.9	0.37
24 S 4.5 Cu, 1.5 Mg, 0.6 Mn	0.45	1.9	0.36
25 S 4.5 Cu, 0.8 Mn, 0.8 Si	0.37	1.55	0.30
32 S 12.5 Si, 1.0 Mg, 0.9 Cu, 0.9 Ni	0.37	1.55	0.30
A51 S 1.0 Si, 0.6 Mg, 0.25 Cr	0.50	2.1	0.40
52 S 2.5 Mg, 0.25 Cr	0.33	1.4	0.27

Properties of Refractories

THE PROPERTIES listed in Table I refer to pure materials and not to commercial refractories, which may differ because of impurities, bonding materials and process of manufacture. However, the data for specific heat, thermal expansion and thermal conductivity, in Table I, may be used for engineering purposes, especially the data marked with an asterisk(*), which were obtained from commercial products.

Table II presents some chemical and physical properties of certain refractories that are used commercially.

Table I. Properties of Refractory Materials, Except Fire Clay*

COMPILED BY STUART M. PHELPS

Material	Composition of the Pure Material: Formula	Percentage	Melting Point: °C	°F	True Specific Gravity	Hardness (Moh's scale)	Mean Specific Heat[a]	Thermal Expansion[b]	Thermal Conductivity[c]: 1000 F	1600 F	2400 F

Table II. Chemical and Physical Properties of Commercial Refractories

COMPILED BY F. H. NORTON*

Material	Theoretical Composition	Reaction with Basic Fluxes[a]	Reaction with Acid Fluxes[a]	Resistance to Oxidation	Resistance to Reduction
Alumina (fused)	Al_2O_3	Fairly rapid with fluid slags. Slow in cement kilns	Fairly slow	Good	Not affected
Carbon	C	Slow	Slow	Low above red heat	Not affected
Chromite	$FeO.Cr_2O_3$	Slow	Slow	Low above red heat	Reduced to ferrochromium at high temp
Fire clay	$2SiO_2.Al_2O_3$	Rapid	Slow except at high temp	Good	Not affected
Forsterite	$2MgO.SiO_2$	Fairly slow	Fairly slow	Good	Not affected
Graphite	C	Slow	Slow	Good	Not affected
High alumina (diaspore)	$Al_2O_3.H_2O$	Fairly rapid with fluid slags. Slow in cement kilns	Slow at low and medium temp	Good	Same as alumina
Magnesite	MgO	Slow	Rapid except at low temp	Good	Reduced to Mg at high temp
Mullite	$2SiO_2.3Al_2O_3$	Rapid	Fairly slow	Good	Not affected
Porcelain (refractory)	$2SiO_2.3Al_2O_3$	Rapid	Fairly slow	Good	Not affected
Silica (fused)	SiO_2	Rapid	Slow	Good	Not affected except at high temp
Silica (ganister)	SiO_2	Rapid	Slow	Good	Same as fused silica
Silicon carbide	SiC	Fairly rapid	Slow	Fair above red heat	Not affected
Spinel	$MgO.Al_2O_3$	Slow	Fairly rapid	Good	Not affected
Zircon (electrically fused)	$ZrO_2.SiO_2$	Fairly rapid	Slow	Good	Not affected except at high temp
Zirconia (electrically fused)	ZrO_2	Fairly slow	Slow	Good	Forms carbides at high temp

Material	Fusion Point,[b] °F	Temp (°F) for 10% deformation under 25 psi	Mean Coef Linear Expansion between room temp and shrink. temp $\times 10^{-6}$/°F	Specific Gravity	Weight of a Std 9-in. Brick	Resistance to Spalling	Hardness (Moh's Scale)	Specific Heat (0–1200 F)

Block insulator	0.6	0.7	0.8	....	....	....	....	.....	.....	.....

(a) The slag resistance of a refractory is influenced by the physical as well as the chemical properties of the material. Therefore, a dense nonporous structure without flaws is desirable.

(b) The fusion point of refractories is sometimes reported in terms of cone numbers (PCE), but these numbers are not precise, and the use of the Fahrenheit scale is recommended for engineering work.

(c) The figures for thermal conductivity are not exact; there is considerable variation in the published results.

(d) The values for electrical resistivity are approximate; small amounts of impurities influence the resistivity greatly.

* Professor of Ceramics, Massachusetts Institute of Technology, Cambridge, Mass.

Notes for Table I (continued)

(e) General chemical formula for chromite is $RO.R_2O_3$. The RO oxide is usually FeO and may be replaced in part by MgO; the R_2O_3 is mostly Cr_2O_3, but may be replaced in part by Al_2O_3 and Fe_2O_3.

(f) Alpha modification

(g) 90% alumina brick

(h) Other aluminum silicates of the same chemical composition are andalusite and sillimanite.

(i) Commercial diaspore is composed of diasporite grains bonded with clay.

(j) For diaspore brick containing 75% alumina, and having a porosity of about 30%

(k) Dissociates at very high temperatures

(l) For the range 20 to 100 C (68 to 212 F)

(m) For the range 20 to 800 C (68 to 1472 F)

(n) Synthetic, pure

(p) From a virtually pore-free body

(q) Magnesia is amorphous, or crystalline (periclase), depending on heat treatment. (Thermal expansion and conductivity data on commercial brick)

(r) Ganister is the commercial form used for refractories (about 98% silica).

(s) Cristobalite is the stable form of silica above 1470 C; melting point 1713 C (3115 F).

(t) Silica brick, mean expansion in range 20 to 300 C (68 to 572 F)

(u) Quartz, mean expansion in range 300 to 1135 C (572 to 2075 F)

(v) Dissociation temperature; oxidation may begin at 900 C (1652 F).

(w) Varies with temperature

(x) Clay-bonded silicon carbide

(y) For the range 21 to 51 C (70 to 124 F)

(z) Sintered pure material

Temperature Conversions

The general arrangement of this table was devised by Sauveur and Boylston more than 25 years ago. The middle column of figures (in bold-faced type) contains the reading (°F or °C) to be converted. If converting from degrees Fahrenheit to degrees Centigrade, read the Centigrade equivalent in the column headed "C". If converting from degrees Centigrade to degrees Fahrenheit, read the Fahrenheit equivalent in the column headed "F".

Preferred Orientations

COMPILED BY C. S. BARRETT*

PREFERRED ORIENTATIONS (textures) are usually specified by the indices, in square brackets [ ], of the crystal direction parallel to the longitudinal axis of wires or rods, the axis of compression in uniaxial compression or forging, or the direction of rolling in rolled products. Textures in sheets are specified by naming also, in parentheses ( ), the crystal plane that is parallel to the surface of the sheet. The scatter around the principal orientations listed below is often considerable and is usually expressed by means of pole figures.

"Recrystallization textures" are often sensitive to impurities, alloy content, and the temperature and duration of annealing; some reported textures may have been altered by grain growth subsequent to recrystallization.

Deformation Textures

Metal	Crystal Structure	Texture
Wire Drawing and Swaging		
Al, Cu, Ag, Au, Ni, Pd, α brass, bronze	Fcc	[111] and [100]
Pb, (Al after severe reduction)	Fcc	[111]
α-Fe, Mo, W, alloyed ferrites	Bcc	[110]
Mg and Mg alloys, Zr	Hcp	[210]
Mg alloys worked at 450 C	Hcp	[110]
Zn (severe reductions)	Hcp	[001] 70° from wire axis
Rod Extrusion		
Like *wire drawing*, except as follows:		
Zn	Hcp	[001] both 0° and 90° to rod axis
Zn – 10 Al – 2 Cu – 0.03 Mg	Hcp	[001] 90° to rod axis
Cold Rolling (sheet and strip)		
Al, Cu, Ni, Au, Pt, Ag, Fe-Ni, α Cu-Sn, Au-Ag, constantan, Pb alloys	Fcc	(110) [112] (strong); also (112) [111] and weaker (001) [100], (110) [001], (236) [533]
α brass	Fcc	(110) [112] (strong) also (weaker) spread from [113] to [117] in rolling direction
Pb	Fcc	(001) [110]
Fe, alloyed ferrites, Mo	Bcc	(001) [110] with spread around rolling direction as an axis ± 55°, that is, to (1̄11) [110]
Mg, Zr, Co	Hcp	(001); modifications of this in some alloys
Zn, Cd, alloyed Zn	Hcp	(001) about 20° from surface, 70° from rolling direction; modifications of this in some alloys

Recrystallization Textures

Metal	Crystal Structure	Texture
After Wire Drawing		
Al	Fcc	[111]; or [111] + [100]; or sometimes [112]
Cu, α brass	Fcc	[111] + [100]; sometimes [112]
Fe, W, Mo, alloyed ferrites	Bcc	[110]
Zn – 1 Cu	Hcp	[001] 70° to wire axis
After Uniaxial Compression or Forging		
Al, Cu, α brass	Fcc	[110]
Fe	Bcc	[111]
Mg	Hcp	[001]
After Rolling (sheet and strip)		
Ag, Ag-Au (70% Ag), Ag-Zn (1% Zn), Cu-Zn (5–39% Zn), Cu-Sn (1–5% Sn), Cu-Be (0.5% Be), Cu-Cd (0.5% Cd), Cu-P (0.05% P)	Fcc	(113) [211]
Cu-Zn (30% Zn) after severe reduction and high-temperature anneal	Fcc	(110) [112] (Grain growth texture)
Ni, Cu, Au, Al, Fe-Ni (30–100% Ni), Cu-Zn (0-1% Zn), some Ni-Cu and Fe-Ni-Cu alloys	Fcc	(100) [001] (after severe cold rolling)
Cu alloyed with Sb, Mg, or Ni	Fcc	Complex, nearly random
Mg, Zn, Zn-Cd, Zn-Cu	Hcp	Same as cold rolling texture
Fe, low-carbon steel	Bcc	(100) parallel to rolling plane, [011] 15° from rolling direction
Fe-Si, with intermediate anneal and two cold reductions	Bcc	(110) [001]

Forging by the Blacksmith

By William Telfer*

WHEN selecting material of the correct dimensions for a certain part, the blacksmith must first decide how the part is to be forged. One procedure would be to select stock a little larger than the largest dimension and to obtain the smaller dimensions by drawing down. If the forging is to be short, stock comparable with the smaller dimensions could be used, and the larger dimensions could be obtained by upsetting. In either instance it would be correct procedure to figure the approximate cubic contents or weight of the finished forging before selecting the stock, and to allow enough for squaring the end, and for loss caused by scaling. This loss varies with the number of reheatings and with the atmosphere and temperature of heating.

Blacksmith Tools. The tools used at the anvil with hand hammers or sledge hammers are swages, fullers, set hammers, flatters, punches and chisels, with tongs to hold the work. The swages, fullers, set hammers and flatters are usually made of 0.70 to 0.80% C steel, and the hot and cold chisels of 0.80 to 0.90% C steel. A 0.45 to 0.50% C steel could be used for the bottom fuller and swage which fit into the square hole of the anvil. Cast medium-carbon steel or a good gray iron will serve as a swage block.

Fullers. When shoulders are required on both sides, the forging is worked between the top and bottom fullers, the top being struck with a sledge. The top fuller is often used alone to make depressions on one side of the forging as it lies flat on the anvil. The radius of the depression or fillet will determine the size of the fullers to be used. Figure 1 shows a top and bottom fuller.

Swages. These tools (Fig. 2) are used for finishing round or semiround work at the anvil, after the work has been drawn nearly to size by the use of either the hand hammer, the sledge, or the power hammer.

The depth of the impression should be about one-third the diameter of the part of the forging to be swaged, and the edges should be well rounded. If the bottom swage is made to come flush with one or both sides of the anvil, it will have a greater range of usefulness.

* Department of Metal Processing, University of Michigan, Ann Arbor, Mich.

Prepared for the Subcommittee on Forging, with membership as follows: Adam Steever, *Chairman* (Columbia Tool Steel Company), W. W. Criley (The Ajax Manufacturing Co.), A. A. Handler (Deceased), G. R. Houghtaling (Rochester, N. Y.), Waldemar Naujoks (Forging Consultant), William Telfer (University of Michigan) and R. W. Thompson (Transue & Williams Steel Forging Corporation).

Set Hammer and Flatter. Both are used on flat surfaces, but if work is necessary on square shoulders or in depressions too small for the flatter, the set hammer usually answers the purpose. The set hammer and flatter are both shown in Fig. 3.

Cold Chisel. Some steels in the hot or cold worked condition can be notched all or part way around by the use of this chisel and a sledge, and then broken by a sharp blow (Fig. 4).

Hot Chisel. This is much thinner than the cold chisel (Fig. 4), and is used on steel at elevated temperatures. The cut is usually made all the way through.

Hardie. This tool should fit into the square hole in the anvil. It can be used on some steels both hot and cold. The metal is placed on the hardie and struck with a hand hammer (Fig. 4).

When belt, air or steam hammers are used, the tools are somewhat similar to those used for sledge hammering, but are modified to permit their use with power hammers.

Power Hammer Swages. Swages are usually made of 0.45 to 0.50% C steel, and the shape is obtained by sinking hot, through the use of either a round bar or some special shape. Most of the work done by swaging is round in cross section, but special shapes can be produced by using these tools. Where the forgings are of large diameter, the top and bottom swages are ordinarily not attached by spring handles because of the weight to be manipulated by the helper. Figures 5 and 6 show the hammer swages.

Power Hammer Fuller. The hammer fuller, shown in Fig. 7, is used for drawing short sections where the dies are too wide, and also for forging a taper. The rounded side of the fuller is used for breaking down or roughing, and the flat side could be called a "flatter" for finishing.

Power Hammer Cutters. Hot cutters (Fig. 8) usually consist of a straight blade with a handle about 3 to 8 ft long, depending on the size of the forging. Some are made with curved blades and others form an angle of 90 deg. The handle near the blade should be flat so as to act as a spring and prevent injury to the wrists or arms of the blacksmith.

Stocks. These are used for turning and handling the forgings at the hammer (Fig. 9).

When the quantity of forgings of the same kind justifies the making of dies, the blacksmith first makes one forging, taking special care with the shape and dimensions. This sample or master forging then is employed to sink the

die or dies. The die blanks are usually forged with handles drawn out. The next step is to heat the blanks to a high temperature, put the sample in between, and then force them together with heavy blows. Sometimes the dies are partly sunk before using the master forging. These dies or "swages", as they are sometimes called, are held in line by spring handles, guide pins or both, and are held on the bottom hammer die by the helper. The smith has used this method of increasing production for many years. It has been used for some time, on a much larger scale, by the producers of drop forgings.

Forge Fire. A cast-iron hearth with a bowl or depression in the center for the fire, and an opening in the bottom for the tuyeres, will answer the purpose for light work. For heavy work an inexpensive forge can be constructed from ⅛-in. steel plate formed into a square or a cylinder about 4 ft in diam and 2 ft, 6 in. in height. Space below the tuyeres can be filled with broken brick and ashes. The distance between the top of the hearth and the tuyeres should be about 10 in. for heavy work and about 4 in. for light work. Provision should be made for removing ashes from below the tuyeres. The clinkers can be removed from above. After the fire is started, wet coal is banked on both sides. This not only supplies coke for surrounding the metal to be heated, but acts somewhat like the firebrick wall of a furnace.

The object is to heat the steel uniformly to high temperature with as little oxidation as possible. This can be accomplished by keeping a good bed of coke between the tuyeres and the steel, to consume the oxygen in the blast. Also a good covering is necessary. Better control of the atmosphere and the temperature can be maintained in a furnace, but in a forge fire, the heat can be concentrated at some given point of the bar or forging.

In building a forge fire for medium and heavy work, a block of wood corresponding to the size of the fire required is placed on the tuyere, and wet coal is firmly packed around it to the necessary depth. Two boards are then used as forms to build the banks to required dimensions.

The fire is started by shoveling hot coke into the hole left after the wood is removed. The banks usually stand undisturbed for a half to a whole day, and hard coke, broken to a convenient size, is used as a fuel.

The banks of coal coke to a depth of several inches during the day; this coke is used along with the hard coke on the following day, after the fire is rebuilt.

Fine coal is more desirable for forge fires since, when wet, it packs much better than lump coal. The fuel for the forge is usually a good grade of bituminous coal, low in ash and sulfur, high in fixed carbon and having good coking qualities.

Hammer Size. During the forging of the steel, the size will determine the method of applying the force. If the temperature is close to the upper limit of the plastic range, a 1½-lb hammer will supply enough force for ⅝-in. diam low-carbon and ½-in. diam high-carbon steel, and a 14-lb sledge will answer the purpose up to 1¼ in. for low-carbon steel. Of course, the smith will save time by using a power hammer, if he has access to one.

Precautions in Heating and Forging Steel. Too rapid heating will cause uneven expansion of the metal, starting internal cracks. This is especially dangerous in high-carbon and high-alloy steels. When such steels must be heated near the upper limit of the plastic range, it is advisable to use a preheat furnace at temperatures between 1200 and 1400 F, depending on the composition, size and previous treatment.

Forging temperatures too high for the amount of work to be done will result in large grains in the finished forging. If temperatures reach the melting range, voids and oxide inclusions will result when the metal is forged. This is commonly called "burning".

Applying too little force will cause rupture of the steel by working the outer layers more than the inside metal. Sufficient force should be applied to affect the whole cross section, and this should be continued until the dimensions are close to those of the finished forging.

Continuing the forging at temperatures too low will leave the steel in a highly stressed state and, if not followed by some form of heat treatment, will result in short life for the machine part.

When a great reduction in size is necessary, the steel should be forged down on the square or rectangular shape. The stock should be turned so that the sides will form an angle of 90 deg. If the finished cross section is to be round, forging should be continued on the square until close to the finished dimension. The corners can then be forged to produce an octagonal shape, and little rolling is necessary to finish.

If the above procedure is not carried out, the metal may be in shear some of the time, instead of in compression, and if the steel is slightly rigid, because of low temperatures or a hard alloy steel, such as high speed steel, it will be ruptured.

Overlapping of the steel, forming cold shuts, is often caused by using hammer dies and tools with sharp corners.

The above applies both to forging on the anvil with a hand hammer and to forging between the flat dies of a power hammer or press.

Welding at the Forge. When wrought iron or steel is heated to high temperatures, such as are used in welding, and is exposed to the air, the metal oxidizes rapidly. In order to secure a good bond between two pieces, this oxide must be so fluid that it can be squeezed out from between the surfaces. The fusion point of the oxide is lowered by the use of fluxes.

Clean silica sand and borax are two common fluxes used at the forge. Borax, having a comparatively low fusion point, is used on high-carbon steel. After scarfing, it can be placed on the steel at low temperatures, supplying a protective coating. Also, it can be sprinkled on the steel while heating. Borax serves a double purpose, lowering the fusion point of the oxide and preventing further oxidation.

Sand has a high fusion temperature but when combined with iron oxide it becomes fusible at lower temperatures. It is generally sprinkled on when the metal is close to the welding temperature.

Silica sand, cheaper than borax, can be used on the low-carbon steels. Fluxes are not necessary in the forge welding of wrought iron and very low-carbon steel, because it is possible to melt the oxide without "burning" or melting the metal.

The operation of preparing the pieces for welding is known as "scarfing". Figure 10 shows the shape used in lap

welding. Other types of welds are known as: butt, V or split, T, corner, and jump.

Precautions in Forge Welding. Before the scarfs are shaped, the end of the pieces to be welded should be upset sufficiently and far enough back from the scarf to allow for mechanical working during and after welding.

The grain size of the metal in the weld and adjacent to the weld will depend on the amount of work it receives and the finishing temperature.

The scarf surfaces should be well rounded so that contact will be made in the center; the curved surfaces will force the liquid oxide or dirt out from between.

It is important to guard against excessive oxidation on heating, by keeping a good supply of coke in the bottom of the fire, and having the metal well covered with fuel. The scarfed ends should be face down in the fire.

When the work material has reached the welding temperature, enough speed should be used to get the pieces together before the oxide solidifies.

Blows should be heavy enough to work the metal uniformly. A power hammer should be used when necessary.

The metal in and adjacent to the weld may be annealed to produce a more homogeneous structure with greater ductility—a property usually low in forge welds.

The properties of a forge weld will depend on the following factors: (1) the skill of the welder, (2) the weldability of the material, (3) the fuel used (sulfur and ash will interfere), (4) the amount of flux used and the time of application, (5) uniformity of temperatures of pieces to be welded, (6) atmospheric condition of the fire or furnace, (7) amount of oxide or fuel ash trapped between the scarfs, (8) method of working (too much rolling on the anvil or between the dies of a power hammer, when welding round stock, will be detrimental), (9) force of the blow.

Swaging

By W. L. Bowen*

THE term "swaging" as used here refers only to rotary swaging (rotary reduction) and is not to be confused with coining or other types of presswork.

Construction and Operation of Swaging Machines. The modern swaging machine is simply a mechanical means for rapidly opening and closing two dies, or sometimes four dies. The dies are carried in a slot in the face of a revolving spindle and are held between a pair of steel blocks called "backers". Around the spindle is a circular roll cage containing loosely a number of hardened steel rolls.

The revolution of the spindle causes the backers and dies to pass between successive pairs of opposing rolls, thus forcing the dies together. With a spindle rpm of 500 and with 10 rolls, there would be approximately 3000 die blows per min. Actually, this is reduced somewhat because the roll cage rotates slowly, thus lessening the number of blows.

The dies are blocks of hardened steel, having upon their inner faces the impression of the shape or the diameter of the work to be produced. One end of the die groove is flared to allow the unreduced stock to enter (Fig. 1).

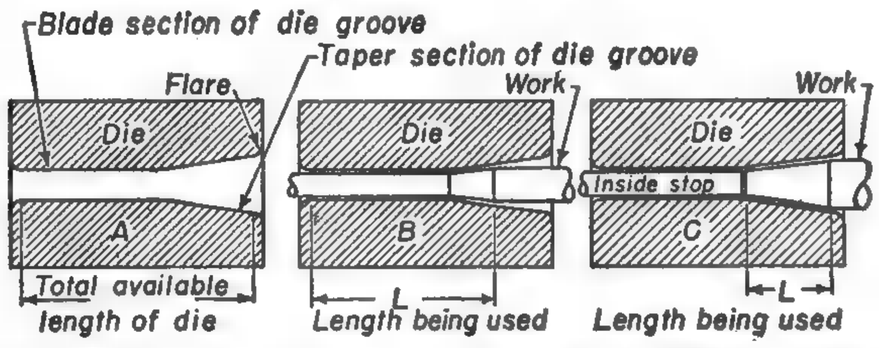

Fig. 1. Three views of the same die, showing different values for *L*. *A* shows the total available length, *L*, of the die. *B* and *C* show two different jobs as swaged with the same die. In *B*, the entire length of the blade section of the groove is used, plus approximately one-half the taper section of the groove. In *C*, only the length of the taper is being used.

Uses of Swaging. Since the dies rotate around the work, the swaged portion must assume a round cross section even though the original work can be of any regular cross section, such as square or hexagonal.

Swaging is the best method for tapering welded or seamless tubes or drawn steels. Rods, bars and wire are also reduced or tapered economically by swaging. Gold-plated wire, for instance, can be swaged with the plate kept intact and evenly distributed all the way to the end of the swaged section.

* Sales Manager, Specialties Division, The Torrington Company, Torrington, Conn.

Prepared for the Subcommittee on Forging, with membership as follows: Adam Steever, *Chairman* (Columbia Tool Steel Company), W. W. Criley (The Ajax Manufacturing Co.), A. A. Handler (Deceased), G. R. Houghtaling (Rochester, N. Y.), Waldemar Naujoks (Forging Consultant), William Telfer (University of Michigan) and R. W. Thompson (Transue & Williams Steel Forging Corporation).

Speed of Swaging. Naturally the speed of swaging depends on many factors, such as the kind of material, angle of taper, amount of reduction, or finish desired. In general, the speed varies from 1 in. per sec up to 4 in. or perhaps 5 in. per sec. Whether the work is fed into the dies automatically or by hand, influences the speed very little, although automatic feeding is always slower than hand feeding unless hydraulic equipment is used.

Physical Effect of Swaging. Swaging is actually performed more by pressure than by blows; hence there is a flow and readjustment of the grains of the swaged material.

Most metals tend to work harden when cold swaged, so annealing may often be necessary after one, two or three swaging passes, depending on the amount of reduction and type of material. This is particularly true of stainless steels.

Some extremely brittle metals, such as a cast or sintered tungsten bar, when hot swaged in a series of passes, are made so ductile that further reductions can be made by drawing.

Since the entire volume of the metal being swaged is not lessened to any appreciable extent, but rather is changed in shape, it follows that solid pieces, when swaged, tend to elongate. In work with tubing, swaging tends to thicken the wall, since a volume equal to only 10% of the cross section goes into elongation. The thickening of the wall is caused by the flowing metal following the line of least resistance.

Amount of Reduction. The amount of reduction in any one pass depends on various factors, such as type of material and angle of taper, but in general the maximum reduction in one swaging pass should not exceed 30% of the cross-sectional area.

Because the die pressure is in a radial direction around the work, steep angles or abrupt tapers are to be avoided. For easy commercial swaging, the included angle of taper should not be more than 10 to 12 deg or less, depending on the force available for feeding.

Swaging Machine Capacities. Various metals have different compressive strengths and therefore require different swaging pressures to obtain a given amount of reduction. For all practical purposes, flowing or swaging pressures may be considered to be 1.75 times the compressive strength of the material being cold swaged. No figures are given for comparative pressures for hot swaging because of the large number of variable factors.

It must be borne in mind that the factor 1.75 given above for swaging pressures does not hold good when the length of swage within the swaging dies exceeds ten times the diameter of the work (this applies to solid pieces only), because of the restriction of endwise flow of the work, resulting from surface friction between the dies and the work, which creates pressures greater than the strength of the dies.

To obtain the maximum capacity of any given swaging machine the following equation may be used:

$$D = \frac{T}{1.75\ (SL)}$$

where D = the diameter of the work, in inches
T = the total capacity of the machine, in pounds
S = the compressive strength of the work material, in pounds per square inch
L = the length of the die being used, in inches (*see* Fig. 1)

The value for S can be obtained from tables elsewhere in this Handbook and the value for T from the swaging machine producer. The value for L depends on the job.

Example. A manufacturer has some material of a certain diameter to be swaged and wants to know whether it can be handled without overloading his swager. The swaging machine has a total capacity of 400,000 lb with a die length of 3 in., all of which length is to be used (Fig. 1).

The material to be swaged has a compressive strength of 150,000 lb, so the example is solved as follows:

$$\frac{400{,}000}{1.75\ (150{,}000)\ (3)} = 0.507 \text{ in. in diam}$$

Hence 0.507-in. diam work could be swaged safely.

From the above equation, it is obvious that as S is reduced, D is increased and vice versa, so the allowable projected area in the swaging die grooves (the length of taper times the average diameter of taper) varies inversely with the compressive strength of the metal being swaged.

Similarly, when only a part of the available length of the swaging die is used, larger diameter work can be safely handled (Fig. 1*C*).

The limiting factor for D is the actual width of the dies. For instance, if it were required to determine the maximum diameter of zinc or a similar material that could be swaged on a certain machine, the value for S, 70,000, might be so low as to cause the value for D (diameter of the work) to be greater than the width of the swaging dies.

Drop Forging

By R. W. Thompson*

DIE forging done under a hammer, in impression dies, is most commonly referred to as "drop forging". It is the operation of forming metal into a desired shape by repeated blows on a hot bar or billet (or on a slug cut therefrom) between a set of dies which have the desired impression of the finished forging shape. Drop forgings, also known as closed-die or impression-die forgings, are produced from carbon and alloy steels and various alloys of copper, aluminum, nickel, and magnesium.

The drop forging hammer has a moving ram, which carries a die operating in a vertical plane, and has also an anvil block in which is keyed a stationary die. The two dies are matched together, with perfect alignment of the impressions in both, so that the impact of the top die striking on the bottom die compels the metal to fill the cavities for the production of the prescribed forging design. The means of lifting the ram determines the name of the hammer.

Steam Drop Hammers. In these, the ram and movable die are actuated by a steam valve which regulates the height of drop and the force of the blow, through the action of a piston rod, operating in a steam cylinder. These hammers are known as double-acting hammers, because the steam is utilized for lifting the die upward, as well as for forcing it downward (Fig. 1). Steam hammers range in capacity from 500 to 50,000 lb and are rated on the basis of the combined falling weight of the ram and piston rod. Because of their great force of impact and rapid operation, steam hammers are generally used for drop forging heavier parts, and also those designs which require numerous hammer blows to complete the various die operations.

R. Houghtaling (Rochester, N. Y.), Waldemar Naujoks (Forging Consultant), William Telfer (University of Michigan) and R. W. Thompson (Transue & Williams Steel Forging Corporation).

Air Drop Hammers. The construction of these hammers is the same as for steam drop hammers, with the exception of the valve clearances and adjustments. Power derived from compressed air instead of from steam enables equally satisfactory operation. Whether air is more practical than steam for power depends on the relative costs.

Fig. 2. Basic elements of a board drop hammer

Board Drop Hammers. In a board drop hammer (Fig. 2), the ram is lifted by means of one or more boards keyed to the ram and passing between two rollers at the top of the hammer. The boards are rolled upward and are then mechanically released, permitting the ram to drop when the desired height is reached. The power for this operation is supplied by direct motor drive or by lineshaft and pulleys.

In the board drop hammer, the force of the impact depends on gravity; for this reason it is sometimes known as a "gravity hammer". These hammers, built to standard specifications, have a falling weight or capacity of 400 to 10,000 lb, and are used in the production of the smaller and lighter forged parts.

Dies and Tools. Drop forgings are commercial duplicates of each other and are produced to meet prescribed dimensional tolerances, as well as chemical and physical specifications. A blueprint or sketch of the forging, showing the necessary draft angles, radii, fillets and amount of finish required, is submitted to the die shop as a guide in sinking the dies.

Forging dies are designed to give the required hot mechanical working to the metal, in order to produce a finished forging shape with a minimum of residual stress. These dies are also designed to keep the grain fibers inherent in the rolled bar continuous and unbroken in the forging and, whenever possible, at right angles to the direction of stress or shock in service. The necessary impressions in a die (Fig. 3) for a certain forging, may be described as follows: fuller or swager, edger or roller, blocker, finisher and cutoff. The fuller reduces the size of the section of the material; the edger conforms the material to the area of the sections of the piece to be forged; the blocker gives the forging its general shape; and the finisher completes the forging design. The cutoff tool, used to cut the forging from the bar, may be a part of the die or may be incorporated in the trimming press.

In addition to the impressions used for the various operations of drop forging production, the dies are also provided with a gutter, which is the portion of the die, around the impression, that has been shaped to provide space for the excess stock.

Some die impression forgings, by nature of their design, provide a lock arrangement in the dies, which helps to maintain match or die alignment of top and bottom dies. When a design has no natural lock and when die alignment is difficult to maintain, shifting of the dies may be prevented by the use of lockpins or counterlocks. The dies in Fig. 3 show such locking methods, as well as the tooling used in the production of die impression forgings. Not all these types of tooling or locks are used for every design.

Standard draft angles of 7 deg are generally used in the dies although quite often, in cases where forgings are designed with deep holes, it is desirable to use 10-deg draft for better forging results. The draft or taper in the side walls of the die impressions is necessary for the removal of the forging from the die, and should be taken into consideration when the forging is designed.

Forging dies for small forgings are often designed with multiple impressions, producing several pieces in one flashing. The use of a larger hammer in producing the forgings in multiples is generally thought more economical, providing the quantities to be made are sufficient to justify the extra die expense.

An illustration of a small forging design produced in multiple impression dies is shown in Fig. 4. This is an example of forging three pieces at a time in one flashing.

Die blocks in most general use are made of forged alloy steel and are heat treated to a hardness governed by the size of the block and the design of the forging for which they are to be used. It is common practice to use dies that have been heat treated before sinking. Tables of standard hardness values, which have been devised by die block manufacturers, apply to the surface area of a given size block. Alloy steel dies, heat treated to ■ Brinell hardness of 444 or about 62 scleroscope, are often cut in the die shop and used for the smaller forging designs. For dies requiring a hardness of more than 62 scleroscope, the hardening of the dies is conducted after the die sinking. (*See also* the article "Heat Treatment of Die Blocks and Hot Die Inserts", in the TOOL STEEL SECTION, page 666.)

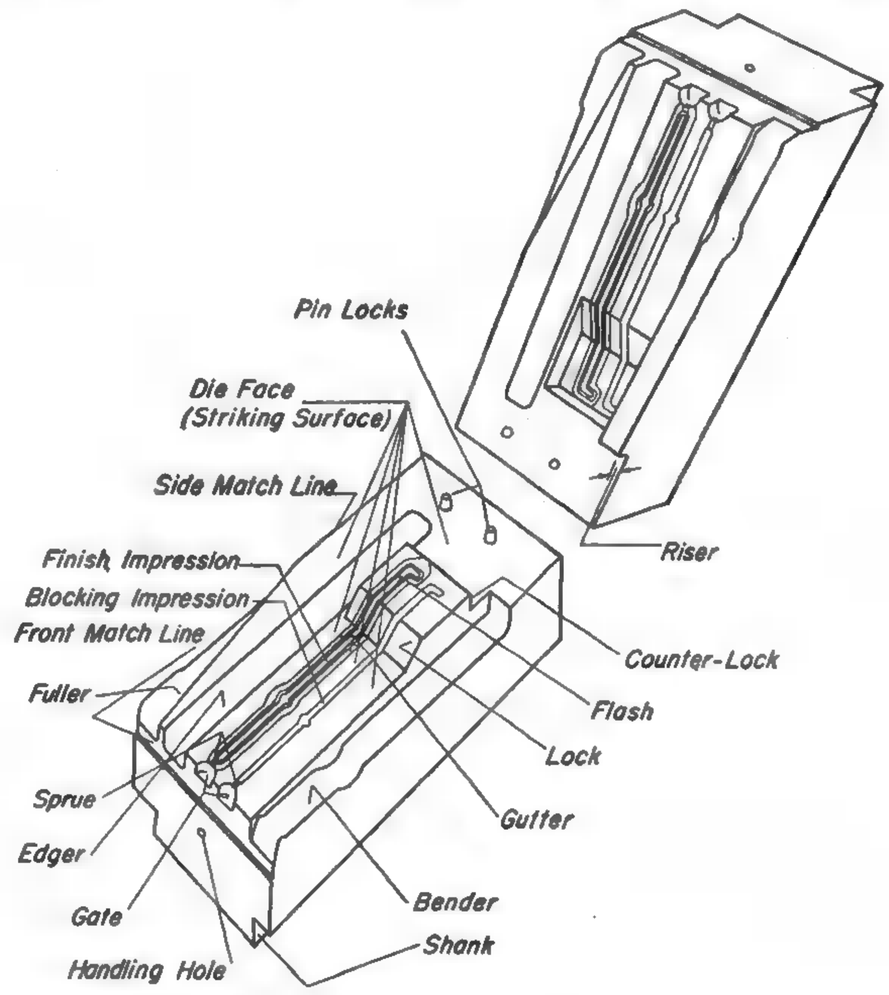

Fig. 3. Drop forging dies showing tool nomenclature

When a set of dies has been completed, the two halves are matched together and a cast of the finishing impression is made by pouring a molten alloy of lead and antimony into the dies. A plasticized sulfur-carbon compound may be used instead, particularly for large impressions, because of its lighter weight. The cast, ■ model of the forging, is measured and checked for die approval before production of forgings in the hammer. All casts are measured with a shrink rule, which compensates for the shrink-

ing of the forging metal. The amount of shrinkage varies with the type of metal forged, as well as with the shape of the forging, but may generally be considered as $\frac{3}{16}$ in. per ft for ferrous forgings.

The flash or excess metal forced out between the dies, in filling the impression to its complete contour, is trimmed from the forging in a mechanical press. Trimming dies are furnished for either hot or cold trimming, depending on the method desired. Hot trimming is done on large forgings and certain alloy steels which would fracture if cold trimmed. This hot trimming is usually performed in a press adjacent to the hammer, at the time of the forging operation. Small forgings are usually trimmed cold. They are trimmed in a press but often in another department.

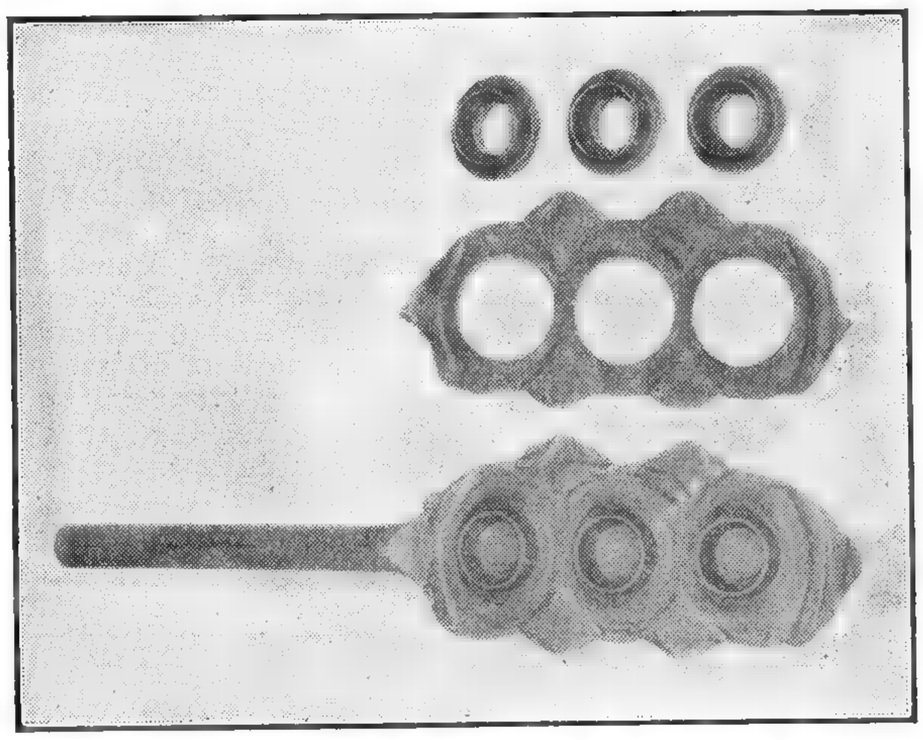

Fig. 4. Example of three pieces produced at one time, showing the trimmed pieces and flashing from the trimmed forging

Trimming dies are made of tool steel and are shaped to fit the outline of the forging at the parting line of the dies. The trimming punch, also of tool steel, is shaped to the contour of the top of the forging to be trimmed. The tools for cold trimming are always quenched and tempered to a hardness that will produce the best wearing and cutting edges for the particular forging design. Hot trimming tools are usually quenched and tempered but are sometimes used in either the annealed or normalized condition. (*See also* "Composition and Heat Treatment of Tools for Hot and Cold Trimming", in the TOOL STEEL SECTION of this Handbook.) A hard facing alloy is often welded to the cutting edge of trimming dies to increase the cutting life. The weld may be applied to the entire cutting edge or localized at points of extreme wear.

The Forging Operation. Drop forging operations are conducted by working from the bar end, cut slug or individual billet. In working from the bar, one or more forgings are made before the end of the bar is reheated. The number of forgings cut off at each heating depends on the size and shape of the forging.

Slugs of the weight necessary for the forging of one piece are cut and forged by the hammer upset method. The slug is placed on end on the die and upset or pancaked to form the forging. This method, affording a particular advantage in the control of grain fibers, is used

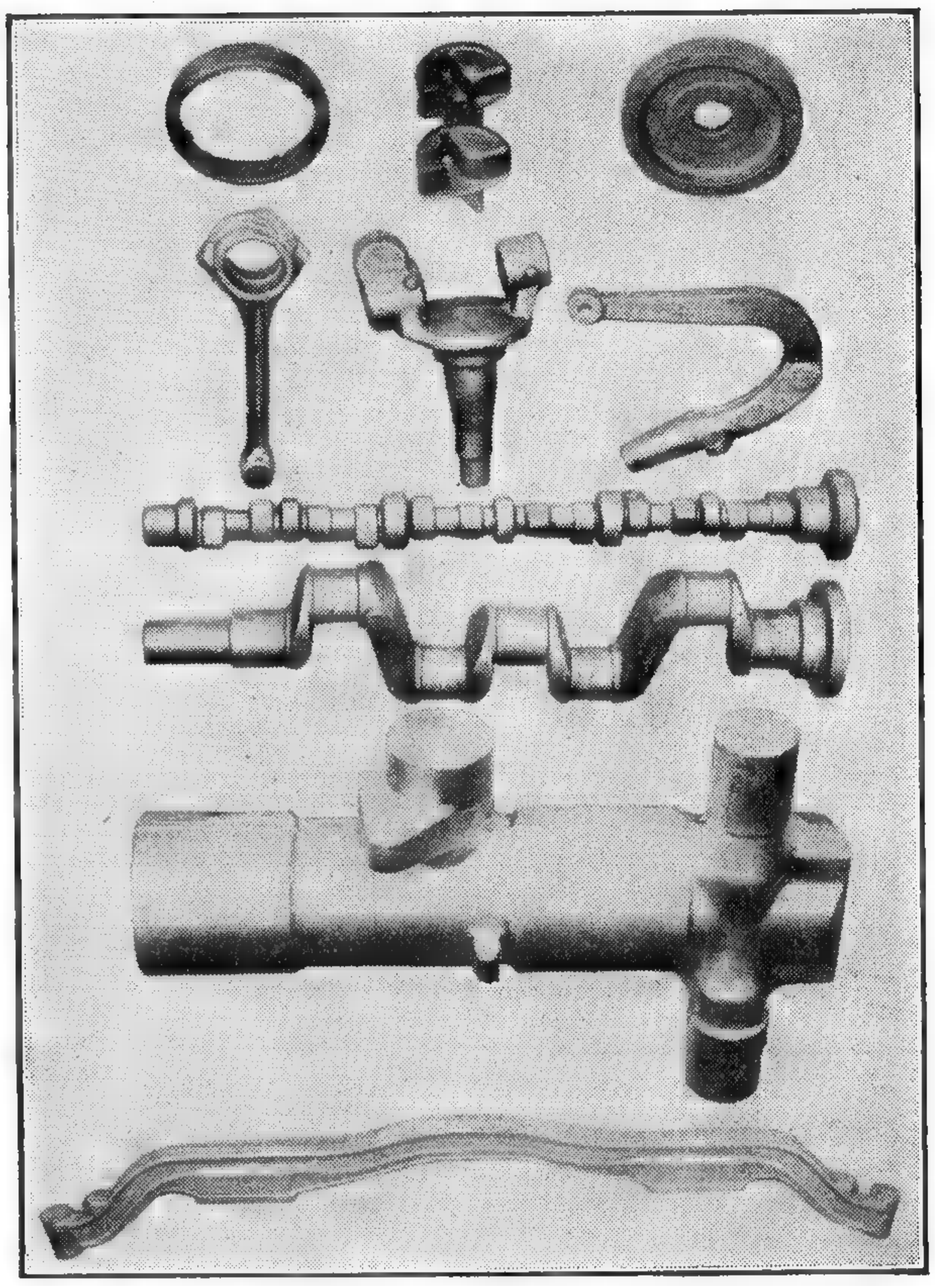

Fig. 5. Miscellaneous drop forgings

generally in the production of gear blanks, hubs, and flange forgings. Figure 5 shows a variety of die impression forgings produced by the drop forging process.

Forgings of medium and larger sizes are made from billets sheared or sawed to the individual length required for the production of one piece. Large and massive forgings often require two or more hammers to effect their completion; each hammer forges progressive steps, with the aid of proper dies and tooling.

While the bar or billet is being forged into a completed drop forging, the metal is further refined into a dense tough fiber structure. This refinement of the forging bar improves the physical properties, increasing the impact, tensile, torsional and compression strength.

Hot Upset Machine Forging

BY W. W. CRILEY*

HOT heading, upset forging or, more broadly, machine forging are terms applied to the hot deformation or plastic flow of steel in forging-machines commonly used for upsetting. Hot upset forging consists primarily of holding a bar of uniform cross section, usually round, between grooved dies and applying pressure on the end in the direction of the axis of the bar by using a heading tool so as to upset or enlarge the end. This method of deformation during compression can be used to forge any of the malleable materials, including wrought iron, alloy steel, copper, bronze, aluminum and others. The forgings thus produced range in weight from a few ounces to several hundred pounds.

* General Manager, The Ajax Manufacturing Co., Cleveland

Prepared for the Subcommittee on Forging, with membership as follows: Adam Steever, *Chairman* (Columbia Tool Steel Company), W. W. Criley (The Ajax Manufacturing Co.), A. A. Handler (Deceased), G. R. Houghtaling (Rochester, N. Y.), Waldemar Naujoks (Forging Consultant), William Telfer (University of Michigan) and R. W. Thompson (Transue & Williams Steel Forging Corporation).

Description of Forging-Machines. Present-day forging-machines, some of which weigh more than 200 tons and are capable of exerting 2000 tons of pressure, are an outgrowth of earlier small machines built mainly for hot

heading bolts. These earlier machines were rated on the basis of the maximum size bolt that they were capable of heading. This method of rating has continued, and has been extended to include even the largest machines.

The machines in general use are mechanically operated from a main shaft, with an eccentric that drives a main or header slide horizontally, and with cams that drive a die slide or grip slide which moves horizontally at right angles to the header slide, usually through a toggle mechanism. Power is supplied to the machine flywheel by an electric motor. A clutch provides for "stop motion" operation, placing the movement of the slide under the control of the operator. (*See* Fig. 1.)

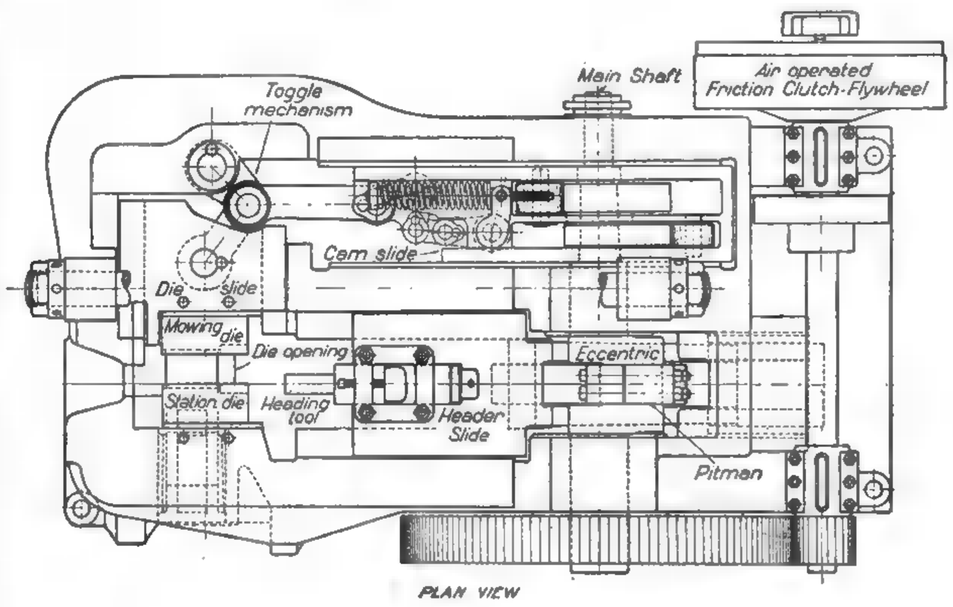

Fig. 1 A plan view of a forging-machine showing arrangement of working parts

Forging takes place in three die elements: two dies or "gripper" dies (one stationary and one moved by the die slide) that have matching faces with horizontal grooves to grip the forging stock and hold it by friction; and "headers" or "heading tools", carried by the header slide in the plane of the die work faces and matching the grooves in the dies. The travel of the moving die is designated as the "die opening", and its timed relation to the movement of the header slide is such that the dies close during the early part of the header-slide stroke. The part of the forward header-slide stroke that takes place after the dies are closed is known as the "stock gather", and the amount that the returning header slide travels before the moving die starts to open is called the "hold on" or simply the "hold".

"Die opening" is the factor determining the maximum diameter of upsets that can be formed on a given machine, transferred between the dies and withdrawn through the throat, without pushing the dies forward and lifting the work piece out over the top. The diameter of the stock, rather than the stock gather, determines the amount of stock that can be upset; however, the stock gather has an important bearing on the depth to which internal displacement can be carried. The height of the die determines the number of progressive operations that can be accommodated in one set of dies.

For forging, the operator places a bar of forging stock heated on the end, in the first groove in the stationary die against a movable stock-gage in order to secure the correct volume of stock in the forging impression. When the clutch is tripped, the moving die closes, grips the stock and holds it, while the heading tool advances and upsets the end of the bar that projects beyond the gripping grooves and is termed "working stock". The operator then transfers the bar to the other die grooves, ordinarily striking it only once in each groove. The number of grooves depends on the steps required in forging.

Forging is not limited to simple gripping and heading operations, since the transverse action of the moving die and the longitudinal action of the heading tool are available for forging in both directions, either separately or simultaneously. In addition to gripping, the die motion can be used for swaging, bending, shearing, slitting, punching and trimming; and in addition to upsetting, the heading tools are used for punching, internal displacement, extrusion, slotting, trimming, bending and other work.

Because the cavities formed by the two dies and the heading tools open in two places at right angles, and because the working stock can frequently be totally confined in these cavities during the forging operation and subjected to a pressure similar to hydrostatic pressure, forcing the stock to fill the impressions completely, a great variety of shapes can be forged and removed from the dies without difficulty, as shown in Fig. 2.

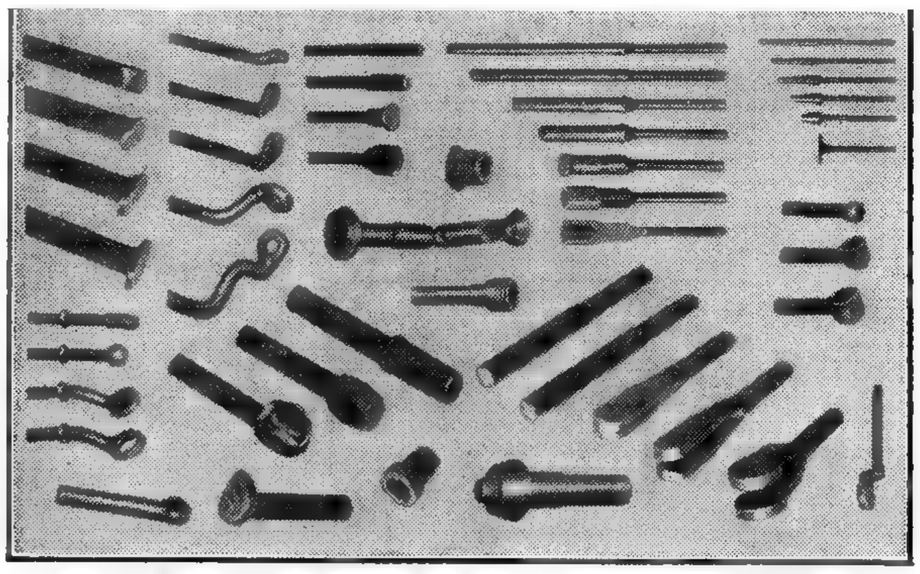

Fig. 2 A group of upset forgings, some of which show the successive forging operations

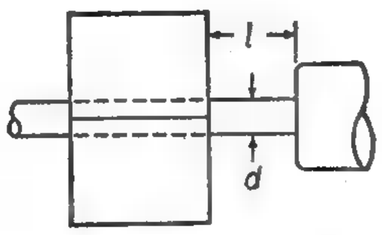
Forging-Machine Requirements. In order to produce forgings accurately filled out, free from defects and conforming to the close standard tolerances drafted by the Drop Forging Association, February 11, 1937, the modern forging-machine must have the following essentials: (1) a rigid frame with minimum transverse and longitudinal distortion under forging pressure; (2) a powerful die grip to hold the stock securely and to prevent the dies from spreading open with resultant formation of flash; (3) accurate die-slide and header-slide alignment to prevent the mismatching of the impressions of the two dies and heading tools, and to produce deep concentric holes; (4) ample heading power to forge to accurate thickness and to drive the stock into remote parts of the die impressions in order to fill them properly; (5) a fast starting clutch, and operating convenience so that the numerous operations required for producing difficult forgings can be performed before the working stock cools appreciably.

Design and Construction of Dies. Proper dies are also essential to the production of sound forgings so that impressions will retain their correct shapes, particularly at the parting line. The dies should be constructed of suitable grades of die steel for hot work with resistance to heat, pressure, and abrasion, and should be selected with reference to the specific properties required, the speed of forging, and the number of forgings to be produced. (*See* "Heat Treatment of Steels for Hot Forging Machine Tools", in the TOOL STEEL SECTION.) The absence of impact in this method of forging makes it possible to build up dies with inserts, thereby utilizing a variety of high-grade steels without prohibitive cost, in order to meet the needs exactly at different locations in the impressions. The use of inserts gives increased durability and makes the more vulnerable points inexpensively renewable. Inserted dies and tools for upsetting gear blanks are shown in Fig. 5.

Grain Flow. In gear forgings particularly, and other highly stressed parts, an effort is made to secure maximum strength through advantageous internal grain flow, as illustrated in Fig. 5. This flow can be controlled by the shape of the preliminary upsets, and re-entering or sharply folded flow lines can be avoided. Each die should be shaped so as to be easily filled by hydrostatic pressure within the hot metal.

Flash. Flash can be avoided best by locating the parting line between the heading tool and the die at the point of the impression that fills last. Differential heating is also helpful in eliminating flash. When upsetting in a groove in the dies (Rule II, Fig. 3), stock should be hottest at the base of the upset and at the lower forging limit at the end. When upsetting in a recessed tool, the natural heating of the stock gives maximum temperature on the end and lowest temperature at the exposed section, discourag-

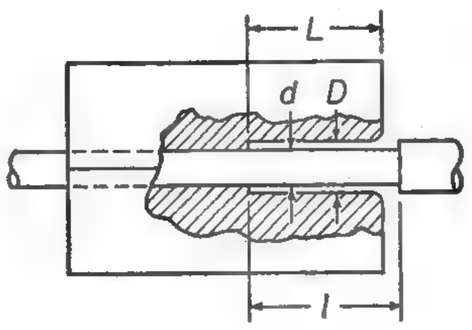


Unsupported Working Stock, One Blow

Rule I. Exposed working stock, up to a maximum length of three diameters, can be upset without support to prevent bending.

Working Recommendation:

$l \leq 2\frac{1}{2}d$



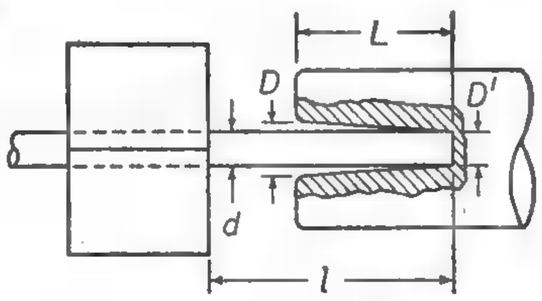
Stock Supported In Die Impression, One Blow

Rule II. Working stock longer than three diameters will be supported against injurious bending, by a die impression of a diameter not greater than 1½ times the diameter of working stock if the length of stock projecting beyond the impression is less than ½ the diameter.

Working Recommendation:

$D \leq 1.4d$

$L > l - \frac{1}{2}d$



Stock Supported In Tool Recess, One Blow

Rule III. Working stock longer than three diameters will be supported against injurious bending, by a heading tool recess of a diameter not greater than 1½ times the diameter of working stock at the mouth and 1⅛ times the diameter of working stock at the bottom and a length of at least two-thirds the length of working stock.

Working Recommendations:

$D \leq 1.4d \quad L \geqq \frac{2}{3}l$

$D' = 1.1d \quad L \geqq l - 2\frac{1}{2}d$

Repeated applications of the second and third rules make possible the upsetting of great lengths of original bar stock. Preference is given to recessed heading tools for stock-gathering because of their durability and because the upsets are free from flash, which tends to form at the die part-line and around the periphery of plungerlike heading tools when upsetting in grooves in the die.

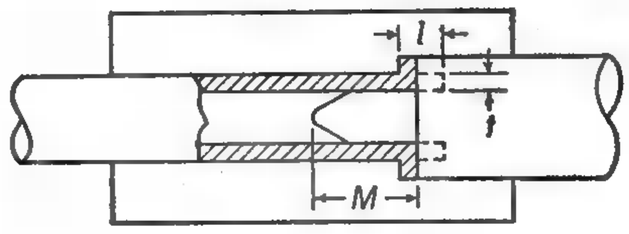
Fig. 3 Rules for upsetting bar stock

ing formation of flash at the parting line between grip dies and header. If flash is unavoidable, it should be located where it can be easily removed by trimming, chipping or grinding.

Factors Governing Upsetting. The number of operations required to produce a forging is determined by the length and diameter of the working stock, the shape of the forging itself, and any special grain flow necessary to produce the desired mechanical properties in the finished forging. Successive upsetting operations should each fill the die cavity completely. Consequently each die cavity in a series should accommodate the same volume of metal, free from defects which would be embedded by subsequent operations. Aside from fins or flash, the most common defects to be avoided are re-entering fiber or internal folds and cold shuts (closed folds in the surface metal).

The rules governing the upsetting or gathering of stock, without injurious bending and resulting cold shuts, are stated in Fig. 3.

Square stock is governed by the same rules as round, using d as the mean of the flat and diagonal dimen-

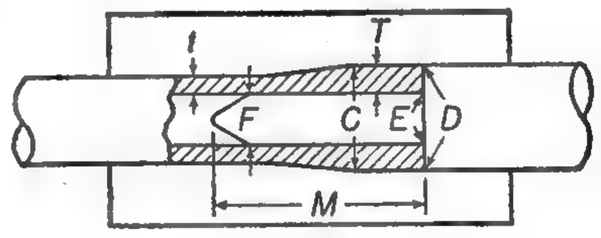


Flanging, One Operation

Rule I. Working stock, up to a maximum length of 2½ times the wall thickness, can be upset in one operation without support to prevent buckling.

Working Recommendation:

$l \leq 2\frac{1}{2}t$



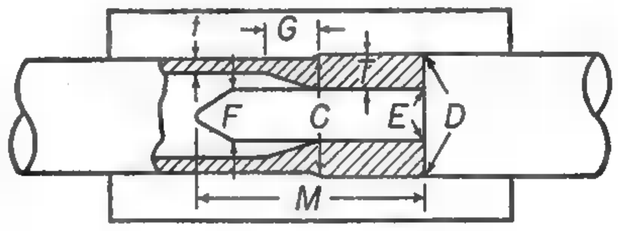
Outside Upsetting, One Operation

Rule II. Wall thickness of working stock can be increased to a maximum of 1½ times its original thickness in one operation, by upsetting to the outside, that is, increasing the outside diameter of the tubing at the upset.

Working Recommendation:

$T \leq 1.4t$

When greater wall thickness is required, successive outside upsets can be made, using the minimum wall thickness of the preceding upset as t in Rule II.



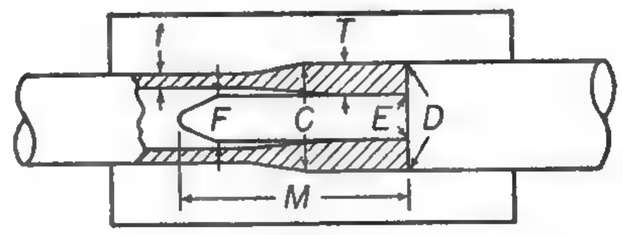
Inside Upsetting, One Operation

Rule III. Wall thickness of working stock can be increased to twice its original thickness, in one operation, by confining the outside diameter and upsetting to the inside, that is, decreasing the inside diameter of the tubing.

Working Recommendation:

$T \leq 2t$

When greater wall thickness is required, successsive upsets can be made, using the minimum wall thickness of the preceding upset as t in Rule III.



Outside and Inside Upsetting

Rule IV. Wall thickness of working stock can be increased up to a maximum of 1½ times its original thickness in one operation, by upsetting to the outside and inside simultaneously, that is, increasing the outside diameter and decreasing the inside diameter in the same operation.

Working Recommendation:

$T \leq 1.4t$

Fig. 4 Rules for upsetting tubing

sions; but rectangular stock bends so easily flatwise that the short rectangular dimension is the one that must be used in the formulas.

Pierced Forgings. Forgings that are internally recessed or deeply pierced are produced most easily by the progressive piercing method, as contrasted with extrusion. In this method, illustrated in Fig. 6, the metal from the interior of the full-length blank is progressively displaced to the outside of the die cavity without excessive pressures or

abrasive flow to cause rapid deterioration of the die elements. The wear on the piercer and the dies is much less than where extrusion or counterflow takes place, as in the piercing operation (*see* article, "Piercing of Steel").

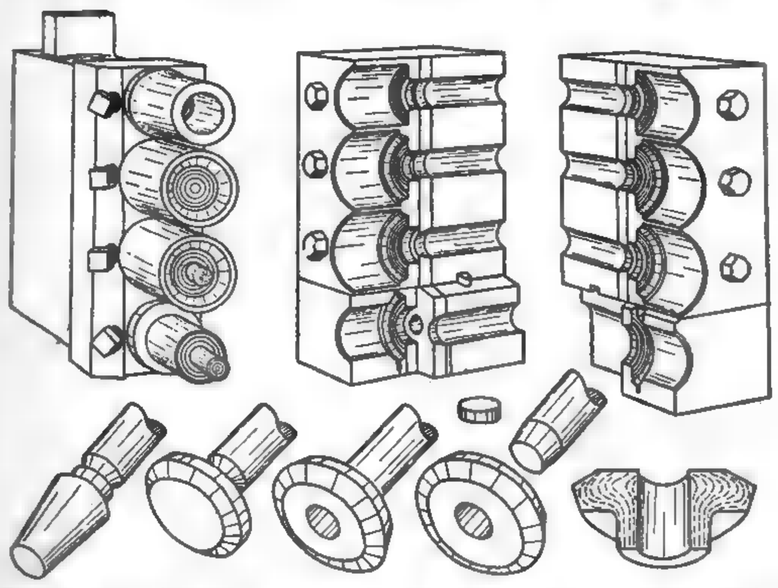


Fig. 5 Inserted dies and tools for upsetting gear blanks with a final combination shearing and punching operation; also the progressive forging steps and a section showing the looping grain flow of the completed forgings

Tubular Upsets. With the extensive use in the oil industry of seamless steel tubing with threaded joints of full body strength, and the use of both seamless and welded tubular structural members where minimum dead weight and maximum strength are required, the upsetting of tubing has assumed importance. Because thin-walled tubing collapses very easily, difficulty is encountered in gripping between the dies to prevent slippage, and the use of a backstop is frequently required. Rapid cooling makes reheating necessary; and the wall thickness limits the extent to which upsetting can be carried in a single operation without injurious folds. Since buckling occurs on the outside, it is possible to gather more wall thickness to the inside, with the outside of the tube closely supported by the walls of the die impression. When it is necessary to upset to the outside, the diameter must be limited so that the walls of the die will keep the amount of buckling short of the point at which wrinkles, folds or cold shuts would be formed. The rules for upsetting tubing are stated in Fig. 4.

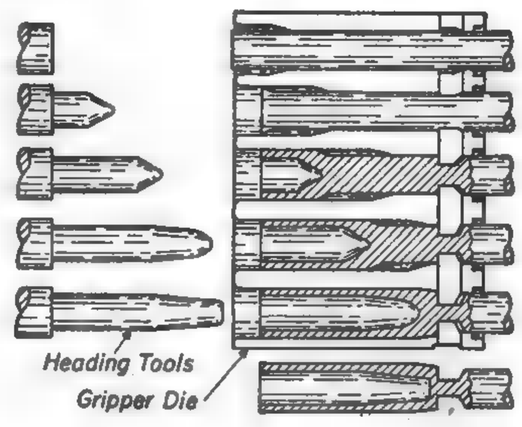

Fig. 6 Progressive steps in deep piercing a shell by internal displacement, showing a cross section of the piercing operation in the die impression, prior to the action of the piercer

When convenient, gaging should be done by a backstop or with the heated portion of the tube projecting as little as possible beyond the mouth of the dies. Mandrel length should be sufficient for the nose to extend beyond the heated portion of the stock. A slight taper on the mandrel and reverse taper in the die cavity beyond the forward position of the tool will facilitate flow of working stock. Highest temperature at the base of the upset, tapering to the lower forging limit at the mouth, decreases resistance of the stock to travel back in the impression, discourages formation of flash around the heading tool, and promotes the filling of the base of the upset.

Mechanical Press Forging

By W. W. Criley*

MECHANICAL forging presses are a distinct type of press designed for forging in impression dies. They are available in capacities up to 6000-tons pressure rating, and are able to produce a wide variety of forgings similar to drop forgings and upset forgings.

Mechanical Requirements. The currently accepted forging presses are upright, driven by a motor and controlled by an air-clutch. They have a full-eccentric type of shaft, imparting constant stroke to a vertically operating ram, carrying the top or moving die with impressions matching those of the bottom or stationary die, which is clamped on the die seat of the main frame. Figure 1 shows a press of about 1600-tons capacity.

To shorten the period of contact between the hot metal and the dies requires great rigidity, reasonably high operating speed and ejectors that act quickly. Good slide alignment is essential, as well as a means for adjusting dies for forging thickness and, because of the positive ram travel, dependable overload protection with facilities for backing off from a stall.

Range of Products. Symmetrical forgings, such as gear blanks, driving flanges and rock drill bits, are produced from blanks of round or round-cornered square stock, sheared to length and placed on end in the die impressions. The number of progressive operations required is governed by the same rules of upsetting as are stated for machine forging, page 40, except that frequently a preliminary operation is introduced for the purpose of breaking off and disposing of scale to avoid trapping it in the die impressions. Ordinarily flash is thrown out at the parting line between the top and bottom dies, as in drop forging; but sometimes flash can be eliminated completely by entering the top die into the bottom impression, with the ejector facilitating removal of the forging.

Automobile valves and cup forgings, like those used in shell case production, can be made by placing a blank in a cylindrical recess in the bottom die and acting upon it with a punch that enters and fits the recess. The stem of the valve is squirted out or extruded, whereas the cup is formed by counterflow up around the punch. In both instances, the metal movement is more rapid than the movement of the punch and slower press speeds are used.

Forging Operations. Forging stock flatwise or transversely is accomplished in die impressions similar to those used in drop forging, with edger or fuller, bender, blocker and finisher impressions, as required. Because of the constant ram stroke, the fuller must have sufficient cross-section to accommodate the original bar stock without flash, in order to avoid folds or cold shuts in subsequent operations. Sometimes when fullering is not required for metal distribution, preliminary flattening is substituted to dispose of scale.

Elimination of scale through induction or controlled-atmosphere heating, hydraulic descaling, or preliminary scale-breaking operations, is of importance since generally the piece is struck only once in each impression. A tong hold is frequently unnecessary, because when the ejectors release the piece from the die impressions, it can be transferred by the flash.

In the absence of variable stroke, the forging press does

R. Houghtaling (Rochester, N. Y.), Waldemar Naujoks (Forging Consultant), William Telfer (University of Michigan) and R. W. Thompson (Transue & Williams Steel Forging Corporation).

not have the ability of the steam drop hammer to draw or fuller blanks with great variation in cross section. For that reason it is desirable to use prerolled blanks or stock that has been previously fullered to the correct shape in trip or steam hammers.

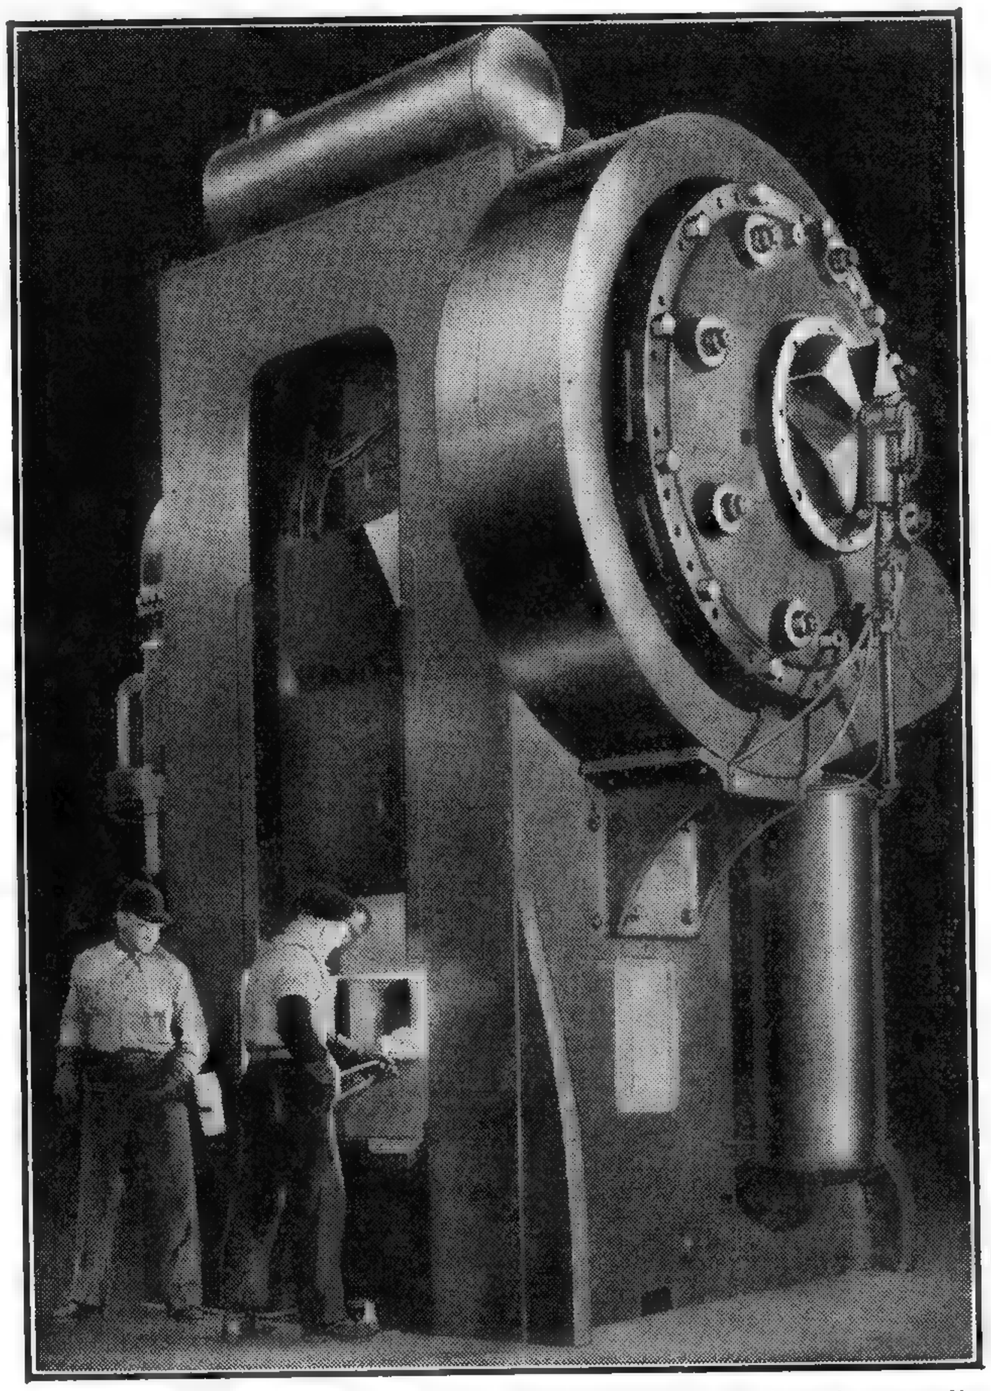

Fig. 1 Mechanical forging press, approximately 1600 tons in capacity

In addition to the usual forging operations, the forging press can be used to hot shear forging blanks of compositions that cannot be sheared cold and to hot trim high-carbon steel forgings that would be damaged by cold trimming.

Die Construction. Although dies can be employed with all impressions sunk in an integral block, identical with those used with drop hammers, the dies need not have the mass called for to absorb impact, since the press displaces the metal by pressure. Consequently, it is preferable and more economical to build up the dies with comparatively small blocks or inserts clamped in holders or bolsters. These can be made of whatever grade of die steel is warranted, and the hardness may be as high as desirable, since there is little danger of cracking from impact.

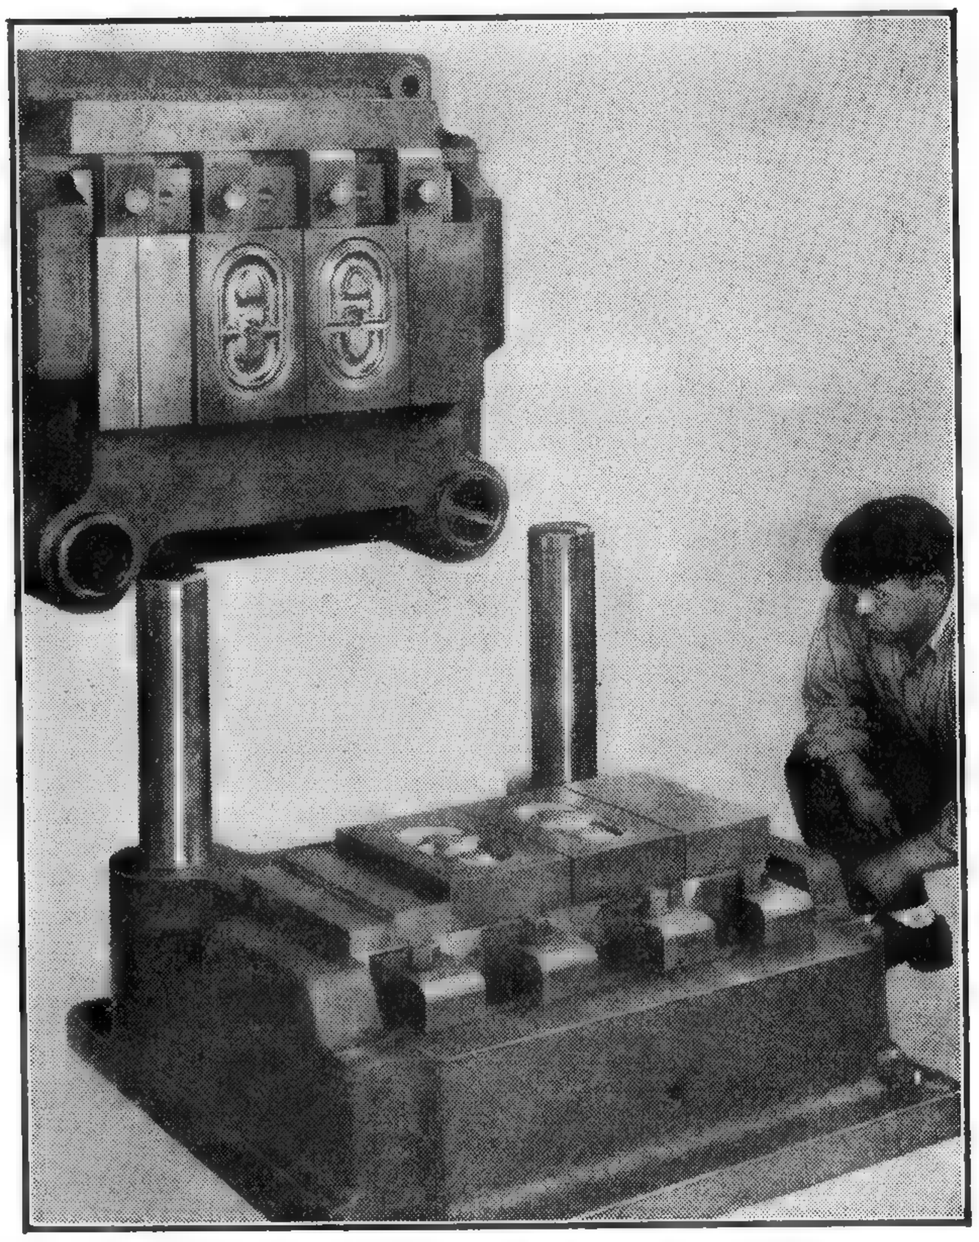

Fig. 2 Bolsters and chain link dies for use in a 2000-ton mechanical forging press

Small rectangular blocks held by toe-clamps are illustrated in Fig. 2.

Coining

By Guy R. Houghtaling*

COINING is a method of cold forming or sizing, by compression, an article of gold, silver, copper, zinc, tin, nickel or other metals. In recent years, iron and steel parts have been subjected to cold sizing for the purpose of imparting smooth finishes and close tolerances, and in numerous instances this coining operation is more economical than the production of a similar finish with cutting tools. A connecting rod for a gasoline engine is an example where coining is used extensively to size the bosses at the ends of crankshafts and wrist pins, within limits of plus or minus 0.001 in. The dies used are ordinarily plain, hardened blocks with stepped parallel surfaces between which the steel forging (about 1/32 in. larger) is squeezed to size.

In coining, it is impossible to suggest a definite percentage of reduction that would be satisfactory for most purposes, since each individual job has its limits, which are usually governed by the ability of the steel in the dies to withstand constant pressure. On work that is confined, a good rule is to use 25% of the ultimate compressive strength of the dies in question. On work that is not confined, 50% of the ultimate compressive strength of the die steel can be used for production runs.

Coining Equipment. *Drop Hammers.* If the pressure is not extreme and if the material will flow readily into the dies, drop hammers can be used to exert instantaneous pressure on the article that is being struck.

Coin Presses. These are usually powerful presses with a slide movement actuated by a toggle between the slides. The toggle is operated by an eccentric or crankshaft.

* Rochester, N. Y. Prepared for the Subcommittee on Forging, with membership as follows: Adam Steever, *Chairman* (Columbia Tool Steel Company), W. W. Criley (The Ajax Manufacturing Co.), A. A. Handler (Deceased), G. R. Houghtaling (Rochester, N. Y.), Waldemar Naujoks (Forging Consultant), William Telfer (University of Michigan) and R. W. Thompson (Transue & Williams Steel Forging Corporation).

Presses of sufficient rigidity may be operated directly by an eccentric.

Screw Presses (percussion). These presses utilize a multiple-thread screw to which is attached a heavy flywheel that stores energy and, on a fast downward movement, exerts a powerful pressure on coin dies.

Hydraulic Presses. These are fast becoming adapted to coining work. The modern, one-unit hydraulic press can be made to operate fast and with high pressures. These presses can be regulated so that only a definite pressure can be exerted on the dies. One distinct advantage is that the action of the hydraulic press permits the metal to take a more definite set because of the length of time in compressive action.

Annealed mild steel, with about 0.20% C, requires approximately 50 tons per sq in. to start plastic flow. This force increases as the article becomes harder and the operation must be stopped before reaching the compressive strength of the die steel.

Hydraulic presses permit using the greatest amount of the operating time cycle in actual squeezing, because the dies can be closed and opened rapidly. Sometimes as much as 3/5 of the time cycle is spent in squeezing, and only 1/5 each in closing and opening the dies.

Coining Dies. These are usually made by sinking a hardened hub into a soft die block. The hub is a faithful reproduction of the article to be coined, and from its impression in the die block comes the article to be manufactured. Most of the details in the actual making of coining dies have resulted from long experience, careful observation and the most painstaking heat treatments. Metals will work harden when squeezed between coining dies; therefore, to get economical production from the dies, it is important to control this condition by annealing.

Coining-Die Steel. The steel selected for the coining dies is largely a matter of personal preference. Carbon steel, formerly selected, is usually shallow hardening, and although it becomes very hard on the surface, it will not withstand intense pressures. Tool steel manufacturers supply a Cr-Ni-Mo drop-forge die block steel that has about 0.65 to 0.70% C and is pack hardened and oil quenched. This steel has a high compressive strength, holds its shape well during heat treatment and, after proper tempering, gives a coining die of long life. Many other steels are suitable, and where simple finishing can be done by machining and grinding, the high-carbon, high-chromium steel is excellent. Modern high production schedules require coining dies to withstand tremendous pressures repeatedly and only steel able to be heat treated for deep hardness is suitable.

Methods of Coining. Usually money is coined in a hardened ring, inside of which are upper and lower dies. Just enough metal is used in the blank to size the coin accurately. Spectacle frames are made from "found blanks" (blanks with proper dimensions and just enough metal to fill the dies). Spectacle parts and jewelry items made of gold-filled metal must come from the coining dies with the surface gold unbroken.

Because of the large amount of flow required on numerous articles that are coined (for example, finger rings), the metal work-hardens before it is possible to fill the die completely. It is then necessary to anneal the blank and sometimes to restrike a number of times, with an anneal before each strike. Since the work-hardened metal requires such enormous pressure to make it flow, the coining dies do not have sufficient compressive strength to resist sinking, so it is most important to anneal the blanks whenever necessary.

It is essential to have clean blanks at the start of the coining operation and perfectly clean blanks after annealing and before restriking. Most copper-base alloys require a red heat to anneal and, unless a protective atmosphere is used during heating, the parts will have to be pickled and washed. Coining dies must be kept clean. Degreasing solvents are recommended as well as frequent use of bristle brushes. Small particles are bound to be removed from blanks during coining and a die can easily be split because of such particles. Another important precaution is to keep even the smallest drop of moisture (water or oil) from entering deep cavities, since metal will not flow into cavities containing moisture.

Numerous pieces of jewelry are made purposely with a surplus of metal called "flash-selvage". These dies are economical to make where it is not necessary to hold thickness to exact dimensions. Therefore, any surplus not needed to fill either upper or lower dies is flowed over the edges of both dies. This surplus or flash must be carefully controlled. Generally, a good rule is to limit the width of the flash to no more than three times its thickness. Where flash must be thicker, flash gutters can be cut in one half of the die, next to the die line.

Coining is usually done by compressing an article into a die. The reverse operation, compressing a soft annealed article onto or around a shaped hardened mandrel or arbor by forcing the article through a compressing die or taper ring, compresses the soft article onto the mandrel or arbor.

The Army Ordnance Department has successfully compressed a machine-gun barrel onto a hardened spiral-fluted mandrel, thereby giving the gun barrel a series of rifled grooves. It had always been considered necessary to machine this spiral groove by cutting tools or broaches.

Numerous difficulties are involved in this external compression of metals, such as unequal cross sections of the part to be compressed and the problem of removing the shaped mandrel after the compressing is done. Plastic molding dies have been made in which a small deep blind hole of irregular shape has been compressed onto ■ hardened mandrel, solving the difficult problems encountered in producing such a blind hole in any other manner.

One method of freeing the mandrel is to force it slightly into the article after the compression die has been removed, which tends to expand the outer member. Another method is to hammer or roll the article externally to expand it enough to free the mandrel. *See also* Novel Methods of M3 Submachine Gun, American Machinist, May 11, 1944, page 109.

Cold Heading

BY THE SUBCOMMITTEE ON BOLTS*

COLD heading consists in forcing metal to flow cold into dies to form thicker sections and more or less intricate shapes. The operation is performed in specialized machines where the metal, in the form of wire or bar stock, may be upset or headed in certain sections to a larger size and, if desired, may be extruded in other sections to a smaller diameter than the stock wire. Although cold heading was developed for the production of bolts, screws, and rivets and is used largely for these parts, the process is applicable to a wide variety of special parts that have somewhat similar form.

* The members of this subcommittee are H. B. Pulsifer, *Chairman* (Deceased), C. L. Harvey (The Lamson & Sessions Co.), H. L. Hopkins (The National Screw & Manufacturing Co.), E. O. Mann (Chevrolet Motor Company) and W. C. Stewart (American Institute of Bolt, Nut and Rivet Manufacturers).

Size and Shape. Because of the high forming pressure necessary and the consequent heavy machinery involved, cold heading is applied only to small and medium-sized parts, generally to those that can be produced from wire no larger than ¾ in. in diam, though facilities are available for upsetting from wire as large as 1 in. in diam.

The extrusion which may accompany cold heading is applied principally to the production of cylindrical sections, less than the stock wire size. This reduction in cross-sectional area may be as much as 30%.

The upsetting or heading by cold forging can be used to produce a great variety of bulbous shapes which are usually

symmetrical about the longitudinal axis but may be offset (Fig. 1). The upset may be at one end of the part or at some intermediate position. The volume limit of such upsetting is expressed in terms of length of stock, in diameters required to fill out the upset. The usual limit of upsetting is a volume of 4½ diam of stock, although there are methods by which larger upsets can be obtained.

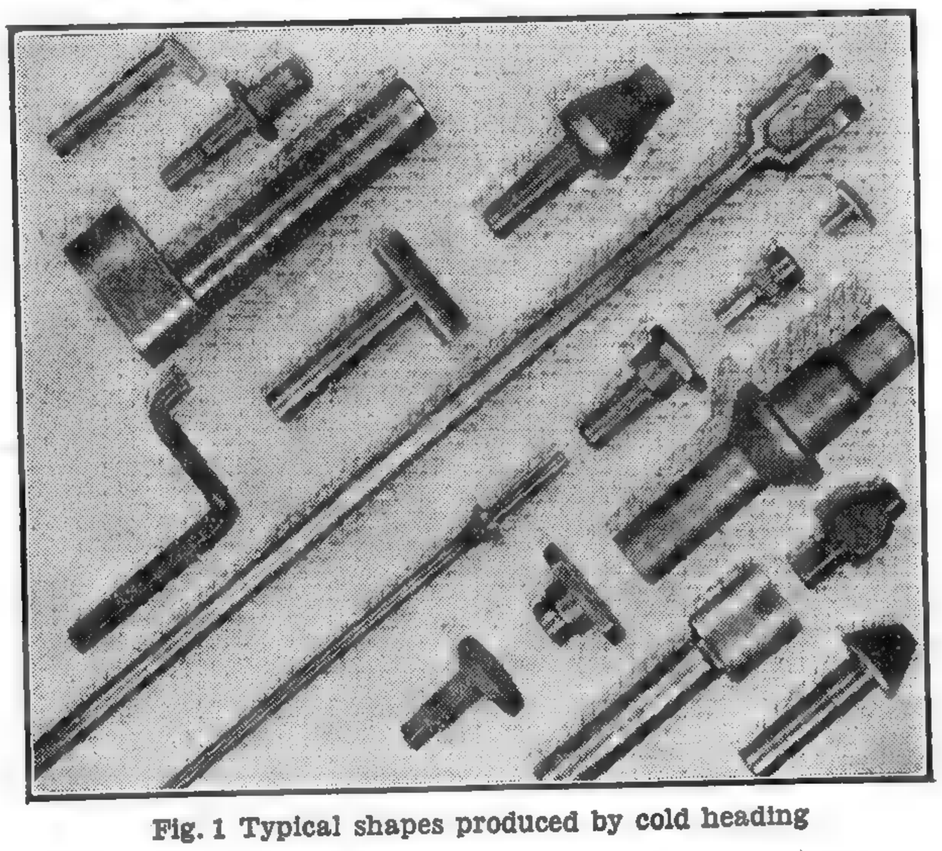

Fig. 1 Typical shapes produced by cold heading

Materials and Treatments. Virtually any material that is malleable when cold can be used for cold heading. Such materials include carbon and alloy steel, stainless steel, copper and its alloys, aluminum and its alloys, monel metal and others, providing a selection of material for almost any service. A little stiffness of material from cold work is desirable in most cold heading stock; otherwise buckling and folding may result. On the other hand, on the hard side, the upper limit may be set by the practical limit of die life, shearing, or bursts from imperfections that would not affect softer stocks. Special-purpose materials, such as screw stocks designed for use in other processes, are not ordinarily cold headed. Similar materials without the free-machining elements, such as high sulfur content in steel, are used with improved properties and reliability.

Although a large proportion of cold headed parts are given no heat treatment, they may be quenched and tempered provided suitable steels are used, thereby enhancing the mechanical properties. Also, in certain low-carbon steels where extreme upsets are made, the parts may be stress relieved at 900 F or higher.

Finish and Secondary Operations. The finish of cold headed parts gives a bright, smooth and burnished appearance where heat treatments are not applied. Also, dimensional tolerances can be held very closely. For these reasons, often cold headed parts can be used in the as-formed condition. However, any of the usual secondary finishing operations, such as machining, grinding, trimming, shaving and drilling, may be applied where unusually close tolerances are desired or where alterations of the cold formed shape are required.

Quality. Cold headed parts have unusually high and reliable quality. In the first place, material of special quality suitable for cold heading is ordinarily used, which has had special care in the steel mill. Then the shaping operation itself is a 100% check, since any serious defects in the material will become apparent visually during the upsetting operation.

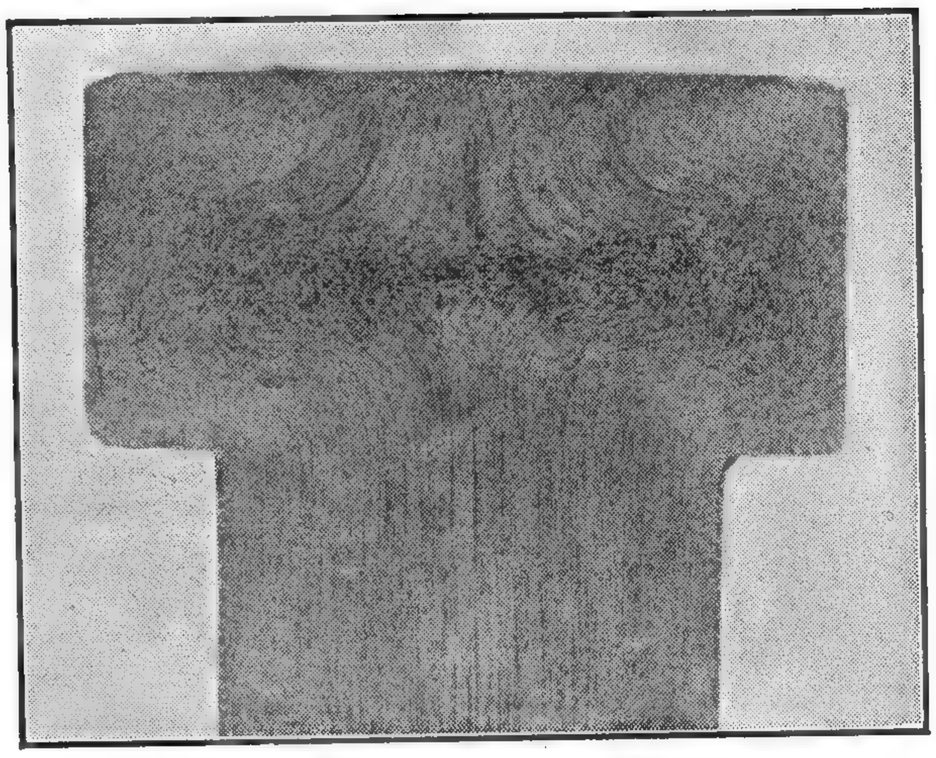

Fig. 2 Flow lines in cold upset bolt head

The strength of cold headed parts is enhanced by the cold working of the metal unless subsequent heat treatments are applied. Even when heat treatments are applied, the cold headed part is superior by reason of the directional flow of the metal. During the upsetting operation the grain flow of the metal conforms to the contour of the part, resulting in the highest degree of reliability and resistance to shock and vibration. This directional flow of the metal can be shown by etching a section of the upset. (*See* Fig. 2.)

Economy. There is little if any waste of material in cold heading. In the as-formed condition waste may be virtually zero compared with the very high losses incident to cutting parts of varying section from the solid. Further, parts are produced at a very high speed—from possibly 50 per minute for large sizes to several hundred per minute in small sizes—all of which tends to make cold heading processes well suited to mass production.

Dies. For information about the heat treatment of cold heading dies, see the TOOL STEEL SECTION, page 672.

Roll Threading and Knurling

BY L. A. WARD*

ROLL threading and knurling are processes for impressing a design into a metal object by means of suitable revolving rolls or dies that are forced against it while it is being rotated. The rolls or dies have a female impression of the desired pattern embossed on their periphery. In roll threading, the design is a helical groove or grooves of the desired contour and pitch. In knurling, the design may be of any desired shape that lends itself to the process.

Little has been published about the history of roll threading and knurling. As early as 1888, socket shells were roll threaded by the Edison Lamp Works; in fact, standard specifications had been formulated there for this work. Knurling was undoubtedly performed some years before this, particularly on solid objects in the lathes that were available. Since knurling is frequently done in combination with spinning, it is probable that knurling hollow objects was also standard practice at an early date.

The advantages of knurling are apparent, particularly as applied to hollow objects where, as compared with machining, there is a considerable saving in cost, because of the reduction in labor, the possible reduction in thickness, and the increased rate of production. The advantages of roll threading are much the same; namely, a reduction in cost, a decrease in time necessary to perform the opera-

* Technical Service Engineer, Chase Brass & Copper Co., Waterbury, Conn.

tion, and in addition, improvement of mechanical properties because of the cold working.

Knurling. Since knurling is generally somewhat simpler than roll threading, this will be discussed first. Three different types of equipment are commonly used in knurling: lathes, automatic screw machines, or special machines.

Lathes. Knurling in lathes is ordinarily done only on small runs of work or in combination with spinning operations. It can be performed by using a hand tool of the kind commonly used by a spinner or by using a tool clamped in the tool post and moved against the work in the usual method. The knurling roll or die used in this type of equipment is of any convenient diameter (usually about 2 in.) and is made of hardened steel. In use, the die is pressed against the article to be knurled and sufficient pressure is exerted to produce the desired depth while the article rotates.

Automatic Screw Machines. In automatic screw machines, the knurling tool may be mounted either on the turret, or on one of the cross-feed attachments, or as a swing tool. Detailed description of the tools or cam layouts are available in standard instruction books. The feed and speed will vary with the particular machine and the material being knurled. A table of feeds and speeds would be too long to include here. This information may be obtained from instruction books or by consultation with the machine manufacturers and vendors of the particular material being knurled.

Special Machines. For large-volume production it is frequently more economical to perform the knurling operation in a separate machine specifically designed for the operation. A number of such machines are available for use on either solid or hollow parts. In these special machines the design of the arbor and rolls is extremely important, although somewhat less important for automatic screw machines and simple lathes than for special high-speed machines. In lathe knurling, the operator can readily watch the operation and see that the pattern matches as the work piece revolves; but with an automatic machine this is impossible and the design will be neither uniform nor properly impressed if the size of the roll is incorrect in relation to the work. For hollow parts, an arbor is used to support the work. The arbor and roll are geared together so that they will mate properly at all times. The arbor, embossed with the male impression of the design, is as large as will permit entry and removal from the work. The design embossed on the roll is a female impression of the design to be impressed on the object. In such machines the work material is usually fed into the machine through some device enabling the entire operation to be done automatically. Details should be worked out in consultation with the machine manufacturers.

Roll Threading. Roll threading may be carried on in the three types of equipment listed for knurling; namely, lathes, automatic screw machines and special machines. Roll threading is seldom done in ordinary lathes and then only where it would be either impractical or uneconomical to set up a special machine; for example, where it is desired to roll thread an article that is much longer than would normally be handled in the available automatic equipment.

Lathes. If a rod is to be roll threaded, a roll is fastened in a suitable fixture on the tool post, set at an angle corresponding to the desired pitch, and the feed is set accordingly. A back rest is commonly used to support the rod and it is frequently necessary to go over the thread a number of times to obtain the desired depth.

Automatic Screw Machines. Considerable roll threading is done in automatic screw machines; the tools used are generally similar to those described for knurling. However, instead of ■ design, the roll has a thread cut on the surface in the direction opposite to that to be produced on the work piece. For instance, if it is desired to produce a right-hand thread on the piece, the roll will have a left-hand thread. The diameter of the blank to be threaded is approximately the pitch diameter of the final thread. The outside diameter of the threading roll should be larger than the work piece and is calculated from the following formula taken from the Brown and Sharpe Automatic Screw Machine Handbook.

$$\left.\begin{matrix}\text{Outside}\\ \text{diameter}\end{matrix}\right\} = \left\{\begin{matrix}\text{Pitch}\\ \text{diameter}\\ \text{of piece to}\\ \text{be rolled}\end{matrix}\right\} \text{minus} \left\{\begin{matrix}\text{½ single}\\ \text{depth of}\\ \text{thread}\end{matrix}\right\} \text{times} \left\{\begin{matrix}\text{Multiple}\\ \text{used}\end{matrix}\right.$$

It is impossible to give any fixed multiple which will be suitable for all work, but the threading roll should be made as large as possible. If there are questions concerning the proper multiple, the machine manufacturers should be consulted as well as about the proper feeds and speeds to be used for the particular material being threaded. In many instances, it will be found that the vendors of the metal being threaded can be of material assistance in working out the necessary details.

Special Machines. A number of special machines are used for roll threading a great variety of work; for instance, there are special machines for the roll threading of bolts and screws, as well as machines designed specifically for the roll threading of tubular objects.

In the special machines for roll threading bolts and screws, the operation is carried out by using two suitable dies that have impressions of the thread projected on the work faces. One of these dies is held stationary and the other moves in a plane parallel to the axis of the work material and in a direction normal to that axis. These dies are commonly made of hardened tool steel (*see* the TOOL STEEL SECTION) and the thread is projected on them. The blank used has approximately the same pitch diameter as the bolt or screw being made. This method of threading bolts and screws is probably the most commonly used and is a very rapid, economical one where the volume of production is large enough to warrant the special equipment and tools. The speed used in this type of roll threading ordinarily varies inversely with the size of the bolt being threaded, but common practice is to hold within the range of 30 to 100 pieces per minute.

In the roll threading of sheet metal caps and tubular products, the design of thread is less standard than in bolts, screws and the like. Several different systems of threads are commonly used. Probably the most standard is that used in the manufacture of shells for electric light bulb sockets as well as similar articles; this is called the Uno system. It is difficult to give exact information about the relation of the size of shell to either the outside or pitch diameter of the threaded part. Also there is considerably more variation in this respect than there is with solid objects because of alloy and temper. This results from the wide variation in mechanical properties both between one alloy and another and with variation in temper in any single alloy.

In general, the shell diameter will be slightly larger than the pitch diameter. The arbor size used is as close to the blank diameter as possible, consistent with fitting the shell over the arbor. The roll size is found by subtracting the single depth of thread from the pitch diameter and multiplying by a factor, in a manner similar to that used in calculating roll size for use in automatic screw machines. On special machines for the roll threading of tubular objects, it is found that multiples as high as 12 are occasionally used, but more commonly the multiple is 4. The arbor and roll are mated through gears as for knurling. Depending on the multiple used, the roll will have a single, double, triple or quadruple thread. For instance, when the multiple used is 2, there will be a double thread cut on the roller. In use, the shell or tubular part is ordinarily fed into the machine, the operation is carried out and the threaded shell is discharged automatically. Speeds vary so greatly that it is impossible to give any definite figures.

Although no exact formulas for blank diameters are given for the various types of roll threads, still finding and maintaining the correct one is extremely important. Frequently the success or failure of roll threading of tubular objects hinges on how accurately this size can be maintained. In general, a blank too small produces ■ poorly developed thread which is usually undersize, while a blank too large ordinarily produces an oversize thread which is frequently rough.

Straightening Bars, Shapes and Tubing

By J. D. Armour*

MANY types of straightening devices have been developed for straightening bars, shapes and tubes, from simple hand straightening to very complicated straightening machines. However, the fundamental principle involved in all these straightening methods is the same except in twisting and straightening by stretching. This principle may be explained by referring to Fig. 3. The bar is supported at points *A* and *B* with the convex side of the bow or kink toward point *C*. Sufficient pressure is applied at *C* to cause the bar to become bowed in the opposite direction. The pressure must be sufficient to exceed the elastic limit of the material and to set up just enough strain in the bar to allow it to return to the straight position but no farther, when the pressure is released. The greater the bow in the bar and the higher its elastic limit, the greater the pressure required to produce the correct amount of strain. To straighten a bar by this method, the material must possess the property of resilience, it must be capable of cold deformation, and it must strain harden. In the diagrams of Fig. 2 to 10 inclusive, the arrows show the location of the points corresponding to points *A*, *B* and *C* of Fig 3.

In straightening to remove twist, the bar is twisted in the opposite direction until the elastic limit is exceeded and just enough strain is set up to allow the bar to return to the straight position but no farther.

In straightening by stretching, the bar must be stretched until the elastic limit is exceeded and sufficient strain is set up to prevent the bar from returning to its original position. The bar must be permanently elongated and reduced in cross section to remain straight after the load is removed.

Hand Straightening. Although many mechanical methods have been developed for straightening bars and shapes, the original method of hand straightening is still used extensively on jobs where great accuracy and precision are required or where odd shapes make mechanical straightening impracticable.

For accuracy and precision, surface tables and wooden mallets are used; grooved wooden blocks are used for odd shapes (Fig. 1 and 2). Hand straightening requires great skill on the part of the operator. Sometimes an operator needs several years to develop sufficient skill to do certain jobs of hand straightening.

Punch and Press Straightening. Punch and press straightening are semimechanical methods, the principle of which is illustrated in Fig. 3. The operator usually locates a kink or bow in round bars by holding a piece of chalk close to the surface of the bar and then rotating the bar so that any high spots will be marked by the chalk. The high spot is then brought under the ram of the straightening press and sufficient pressure is applied to take out the kink or bow. In shapes other than rounds, the out-of-straight condition must be detected by eye or with the aid of a straight edge. This type of straightening requires considerable skill on the part of the operator. A straightening press is sometimes referred to as a "gag press" and the straightening operation as "gagging".

Rotary Straightening. In rotary straighteners the bar is rotated while it is being fed into the straightening machine, so this equipment will necessarily straighten only round bars. The simplest form of rotary straightener is illustrated in Fig. 4. The top roll, which can be set at any desired angle, controls the speed of the bar. The top roll can also be adjusted up and down to control the pressure of the bar. Reference to Fig. 4 will show clearly that the same principle of straightening is involved here as for punch or press straightening.

Other popular types of rotary straightening machines are shown diagrammatically in Fig. 5, 6 and 7. Although they are more complicated in design than the simple rotary straightener, in order to obtain such features as speed or polishing effect, these machines involve the same straightening principle, as may be seen in the illustration.

The principle of a straightening machine used for flats, squares and hexagons is illustrated in Fig. 8. It will be seen that, as the bar passes through the machine, it is subjected to a double-straightening action similar to that employed in Fig. 3. In some straighteners for these shapes, both horizontal and vertical rolls are used, making a setup similar to that shown in Fig. 10 for wire.

Wire Straightening. Figure 9 shows the type of straightening machine used for straightening coiled round wire into straight bars. In this process, the wire does not rotate as it feeds through the machine. A cylinder with adjustable dies rotates around the wire and produces the straightening action. Some straightening is provided also by the feed rolls on the entering end, as will be seen from the illustration.

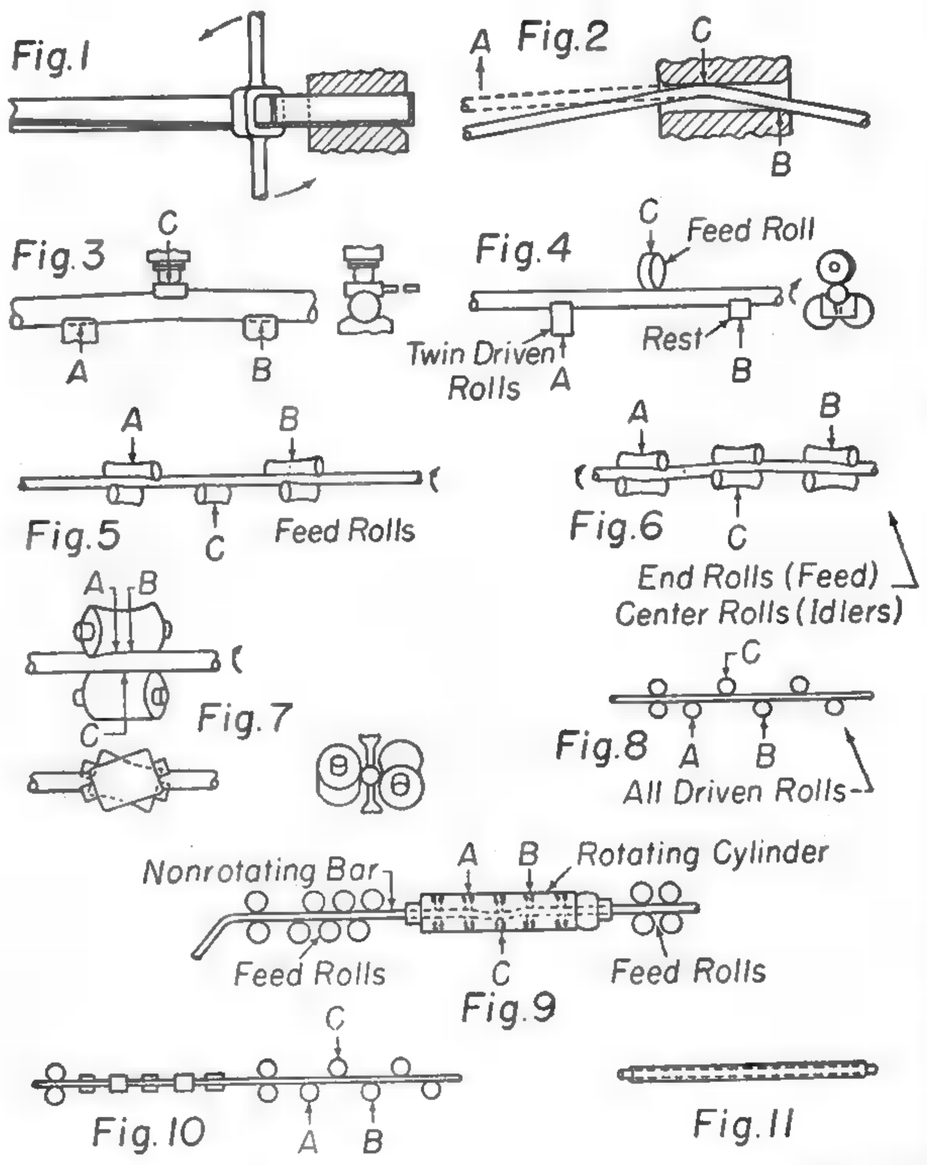

Fig. 1 Hand twist straightener. Fig. 2 Hand straightener. Fig. 3 Punch straightener. Fig. 4 Rotary straightener. Fig. 5 Five-roll rotary-type straightener. Fig. 6 Six-roll rotary-type straightener. Fig. 7 Two-roll rotary-type straightener. Fig. 8 Straightener for flat, square, and hexagonal bars. Fig. 9 Wire straightener. Fig. 10 Horizontal and vertical straightener for flat, square and hexagonal wire and bars. Fig. 11 Straightening by stretching.

Figure 10 illustrates the setup of a wire straightener for shapes other than rounds. It amounts to a double setup similar to Fig. 8, one horizontal and one vertical, so that the wire will be straightened in both directions during a single pass through the machine.

Stretching. Figure 11 shows how a bar must be changed in size to be straightened by stretching. The change in shape is necessarily exaggerated in the illustration. The increase in length and decrease in cross section need actually to be very slight to produce the required effect. This method is well adapted to straightening odd shapes.

Powder Metallurgy

By C. H. Samans*

POWDER metallurgy is the art of producing metal powders and utilizing them to make serviceable objects. The processes involve the heating (termed "sintering") of a compact formed by compression. No fusion takes place, or, at most, fusion of a minor constituent only. Occasionally either the compression or the sintering may be omitted. These processes may be applied to individual, mixed, or alloyed metal powders, either with or without the inclusion of nonmetallic constituents. The methods of powder metallurgy have permitted the attainment of compositions and properties not possible by the conventional methods of melting or casting.

Typical Products. Powder metallurgical products include:

1 The refractory metals, including tungsten, molybdenum and tantalum, for which the method is a necessary one because of their high melting points and the undesirable coarse grain structure produced by fusion.

2 The superhard materials, including the cemented carbides and diamond-impregnated tools, for which the method is also necessary to produce the structures desired.

3 Bearings and porous metallic parts, in which controlled porosity, the possibility of oil impregnation and the use of nonmetallic additions are required.

4 Electrical and magnetic parts, such as contacts, motor brushes, commutator segments, permanent magnets, and cores for inductance coils, in which characteristics or combinations of materials, impossible to secure by other methods, can be produced.

5 Machine parts, in which the mechanical properties may be somewhat inferior to those of wrought metals, but in which the necessary tolerances and shapes can be attained at a reduced cost, by the elimination of machining operations.

6 Clad and duplexed parts, either all metallic, as in thermostatic bimetal, or both metallic and nonmetallic, as in friction materials.

Typical Processes. The characteristics required in each part are secured by varying certain steps in the manufacturing process. This can be seen from the typical flow sheets shown in Fig. 1.

1 In the manufacture of refractory metals, the powders are pressed into bar form with or without the addition of nonmetallic materials to control grain size or grain shape. Such bars, made from tungsten or molybdenum, are presintered in hydrogen to develop added strength. Tantalum and columbium bars are not preheated. The bars are then heated by their own resistance, by passing an electric current through them, until the core has nearly reached the melting temperature. With tungsten or molybdenum the heating is done in hydrogen; with tantalum or columbium it is done in a vacuum. After this sintering operation, tungsten and molybdenum are worked hot, by swaging or rolling, until they are compacted sufficiently to permit drawing into wire. With tantalum and columbium, working can be carried out at room temperature.

2 In the production of cemented carbides, the refractory carbide powders must be ball-milled with the binder (usually cobalt) for long periods of time, both to produce fineness and to coat the carbide particles thoroughly with the binder. In their final form cemented carbides are difficult to shape, except by grinding or lapping. Hence, they are either pressed to their final form, with proper allowance for shrinkage, or else formed into slabs and given a relatively low presintering heat treatment. In this condition the material can be cut, machined or ground to the desired shape. The final step is a high-temperature sintering operation. Large carbide parts are often hot pressed.

3 Oil impregnation is the unique step in the production of bearings. Blanks are first formed and sintered in such a way as to produce a controlled porosity. After all sizing and machining operations have been completed, the parts are given a special treatment to fill these pores with oil.

4 In the production of porous metal parts, such as filters, the shape and size distribution of the powder particles is all-important, since the parts are sintered from shapes formed either without pressure or with very light pressure.

5 The manufacture of machine parts may involve the use of a re-pressing operation, after sintering, to produce the necessary accuracy in size and to improve mechanical properties. However, parts may be used as-sintered or machining may be the finishing operation.

Advantages and Limitations of Powder Metallurgical Methods. Basically, powder metallurgical methods are used in preference to conventional methods for only two reasons: to secure properties not otherwise obtainable, or to eliminate machining and subsequent operations. As with every industrial process, the economic factors are the determining ones. If specific impurities must be controlled, if chemical composition limits must be held accurately, if certain specific types of shapes or special characteristics must be secured, powder metallurgy offers a convenient method; but the advantages are real only if the alloys, shapes or properties produced cannot be secured as cheaply by other methods. High production rates with close tolerances and a minimum of material waste can be maintained on many parts which, if designed to conventional methods of production, would require numerous machining operations. But these very factors also require that suitable designs be used and that the volume of production be large in order to justify die costs and setup time. As a rule, the smaller the piece, the greater the volume required for an economical run. However, since the real determining factor is the ratio of raw material cost to total processing cost, small pieces can sometimes be run economically by powder metallurgical methods, even though larger pieces of the same shape and characteristics cannot, simply because the raw material cost per pound of powder is usually considerably higher than that of the same material in cast or bar form.

In general, the principal limitations of the process are those imposed by the size and shape of the part, the compacting pressure required, and the materials used. Physical limitations are imposed by the dies required to hold the powders and by the presses available for compacting them sufficiently.

An additional shape limitation results from the necessity of supplying pressures from the top and bottom rather than from the sides. There is almost no lateral flow in the powder mass, so possible shapes are limited by this factor also. Holes parallel to the axis of compression can be readily made by use of a core rod, but holes normal to this axis must be machined after compacting and sintering. Likewise, threaded and other surfaces in which undercutting or re-entrant angles are involved, cannot be molded, but must be formed by machining after the part has been sintered.

Although in time many of these limitations may decrease in importance, the economic balance, which is the determining factor, may still show that costs are too high to compete with conventional methods for many parts.

Metal powders themselves are inherently susceptible to two faults. First, because of their high surface area, they tend to be attacked by and to absorb both air and moisture. Although this can often be minimized by proper storage and pretreatment and by the use of air conditioned press rooms and sintering atmospheres that have a low dew point, costs may thereby become excessive. Second, powders under pressure do not flow like fluids. The problems involved are more nearly those of soil mechanics than those of hydraulics. Powders do not tend to flow, for example, from a region of high compression to one of low compression and, as a consequence, the depth-width ratio is extremely important in the dies used.

* Research Metallurgist, American Optical Company, Southbridge, Mass.

Prepared for the Subcommittee on Powder Metallurgy, with membership as follows: F. N. Rhines, *Chairman* (Carnegie Institute of Technology); C. W. Balke (Fansteel Metallurgical Corporation); J. J. Cordiano (Hardy Metallurgical Company); R. P. Koehring (Moraine Products Division, General Motors Corporation); C. H. Samans; Alexander Squire (Westinghouse Electric Corporation); N. E. Woldman (Upper Montclair, N. J.); F. E. Wormser (Metal Powder Association); L. L. Wyman (General Electric Company).

There is a distinct tendency for the powders to cling to the sides of the die and thereby encourage unequal pressures throughout the mass. For this reason parts compressed from the top tend to have a region of low density at the bottom, whereas those compressed from both top and bottom are usually less dense in the middle. Too little is known concerning the welding and adhesion characteristics of various shaped powders of different metals and alloys. Considerable experimentation is still required in all phases of the art.

Of necessity, additional limitations imposed by the die design influence the shapes which can be made, the tolerances which can be maintained economically, and the dimensional changes resulting both from normal shrinkage and from the unequal heating of the compacted parts during sintering. Shapes that require a weak design must be avoided, because the pressures needed for compacting will result in excessive breakage, both of the dies and of the compact. Because of die wear, lack of cold deformation of the individual particles of many powders, springback after compression, and dimensional changes during sintering, extremely close tolerances can be maintained only by costly individual gaging. However, if the fairly liberal commercial tolerances are allowed, the parts will, usually be sufficiently accurate, particularly when a sizing operation follows the sintering. For example, radial tolerances of 0.003 in. per in. in unsized bearings, 0.001 in. per in. in sized bearings, and axial tolerances of 0.010 in. per in. can be maintained commercially. At an added cost even closer limits are possible.

mented carbides, in which theoretical densities are secured either by hot working or by using very high sintering temperatures. Structural and machine parts made by powder metallurgical methods usually have lower tensile properties than wrought materials of the same or similar compositions. This can be seen from Tables IA and IB. In addition, low ductilities and impact strengths accompany the low tensile strengths. These inferior properties are a direct consequence of the porosity which is unavoidable in the powder method of manufacture. Material of theoretical density can be made, but only by resorting to repressing and resintering, which is rarely feasible, or by using sintering times that are too long to be economical. This is one limitation with which the designing engineer must be thoroughly familiar before specifying machine parts made by powder metallurgical methods.

A final limitation is imposed upon engineers and designers by the relatively small amount of technical information available. Standard tests on metal powders and on finished parts are still not accepted generally, so the ultimate user has no exact method for checking the products used. The widespread interest in and importance of the process, however, indicate that this limitation will probably be of relatively short duration.

Metal Powders. The selection of materials in powder metallurgy is determined by two factors: (1) the alloy required in the finished part and (2) the physical characteristics needed in the powder. Except for the specialized refractory metals and cemented carbides, the most widely used alloys are copper-base or iron-base, and the most

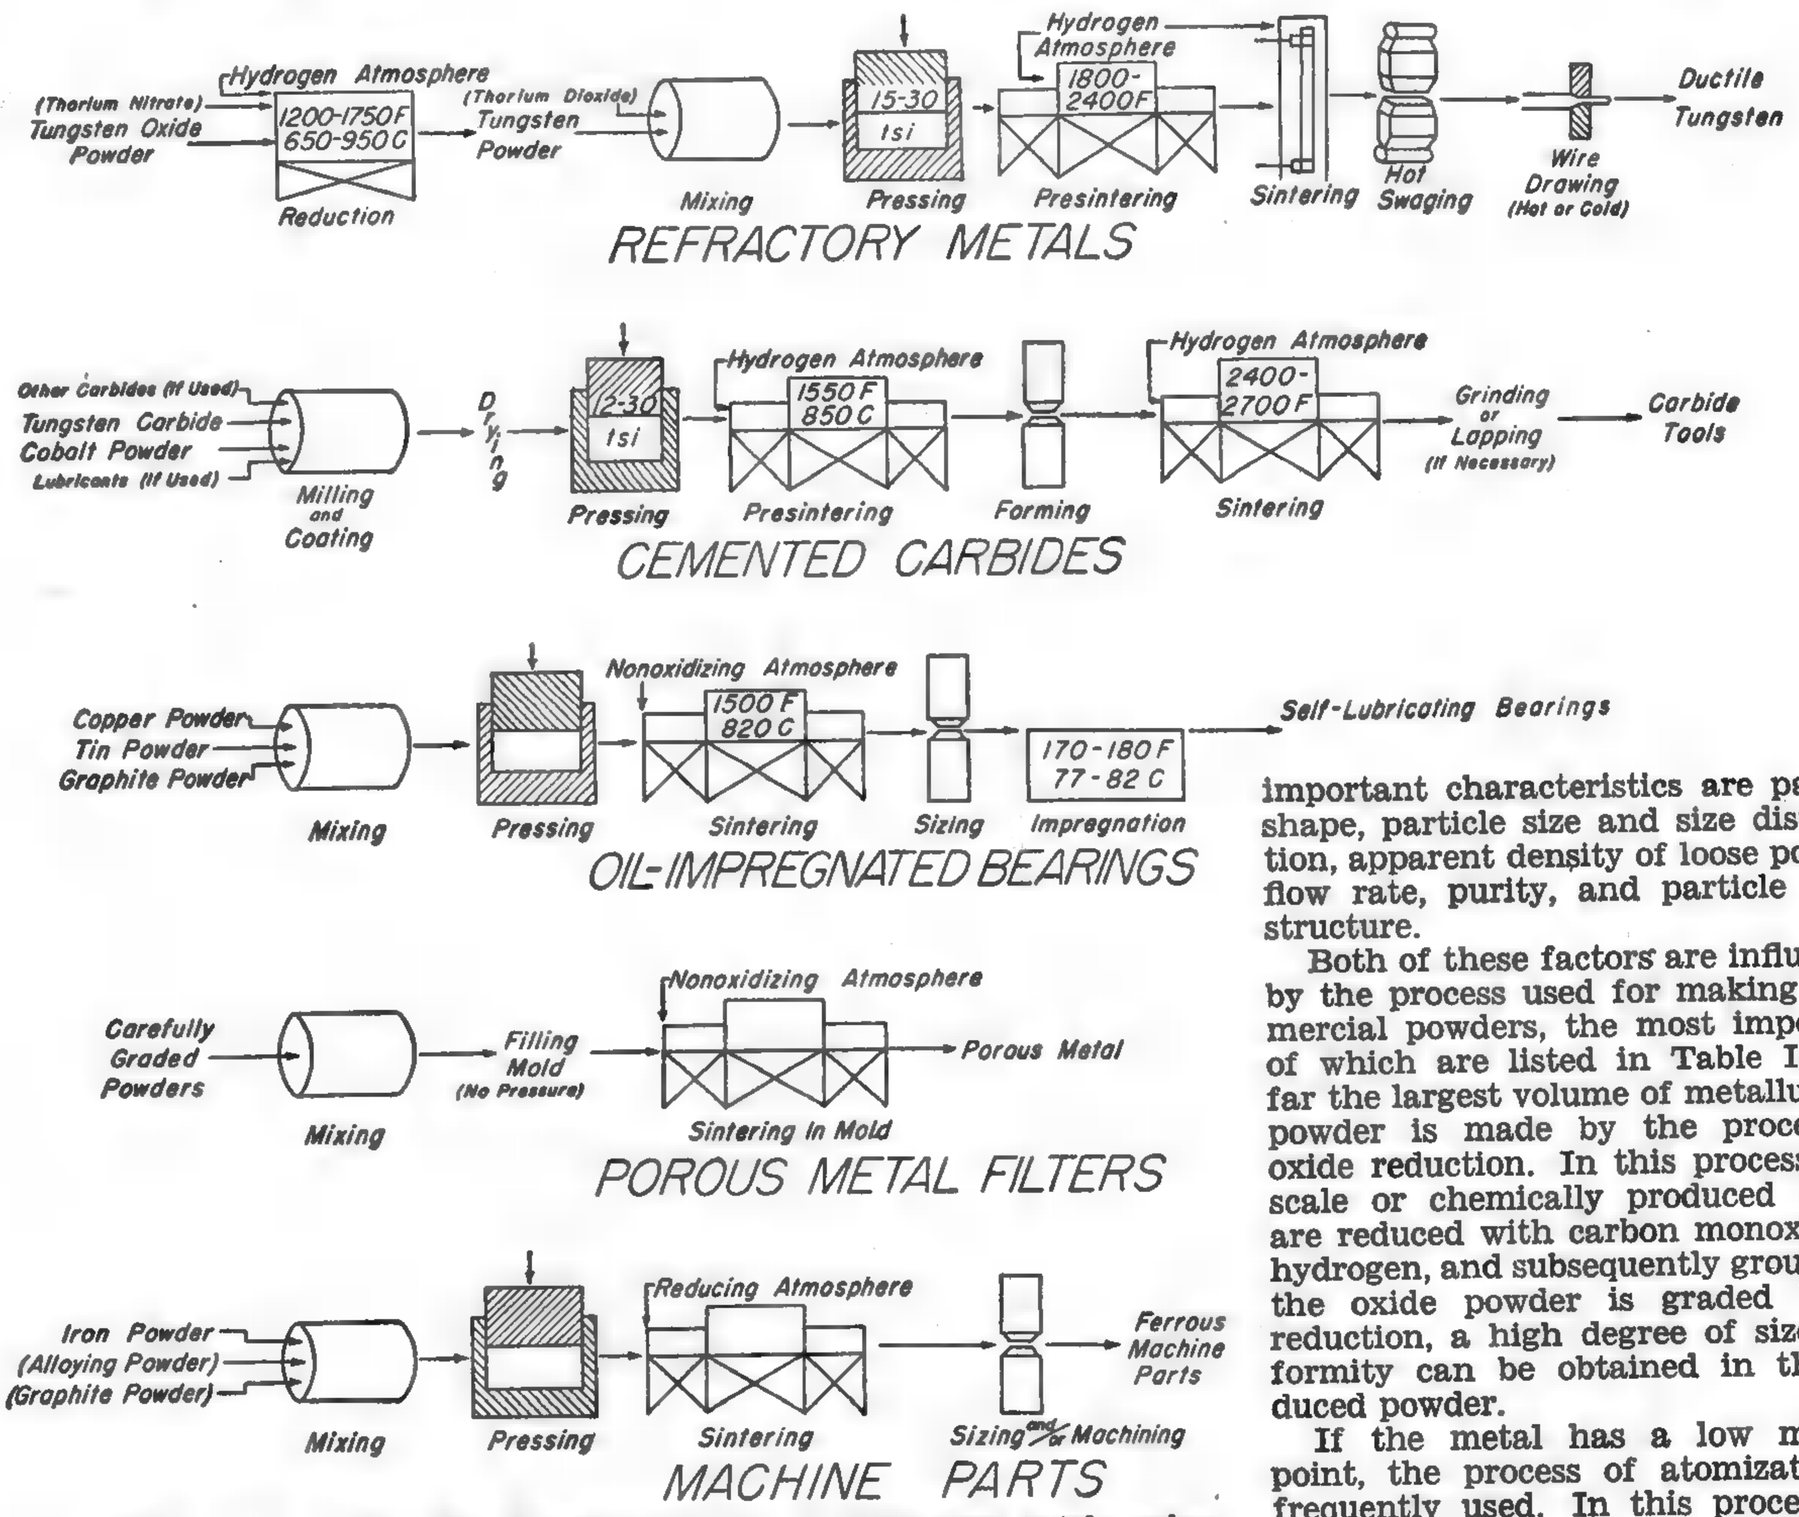

Fig. 1 Typical flow sheets showing steps in the manufacture of articles from metal powders

In structural and machine parts it is desirable to maintain as high mechanical properties as possible. This does not apply to self-lubricating bearings and filters, which are made porous purposely, or to refractory metals and ce-

important characteristics are particle shape, particle size and size distribution, apparent density of loose powder, flow rate, purity, and particle grain structure.

Both of these factors are influenced by the process used for making commercial powders, the most important of which are listed in Table II. By far the largest volume of metallurgical powder is made by the process of oxide reduction. In this process, mill scale or chemically produced oxides are reduced with carbon monoxide or hydrogen, and subsequently ground. If the oxide powder is graded before reduction, a high degree of size uniformity can be obtained in the reduced powder.

If the metal has a low melting point, the process of atomization is frequently used. In this process the molten metal is forced through a small nozzle orifice and broken up by a stream of compressed air, steam or inert gas.

By varying plating conditions properly, either the metal powders can be deposited directly electrolytically, or else a

hard, brittle and easily powdered codeposit of hydrogen and metal can be secured. This can be given a low-temperature bake after it is powdered, to drive off the hydrogen and restore ductility. Electrodeposited powders are frequently dendritic in shape, and may be milled or ground to improve their molding characteristics. They are, relatively, more nearly pure and more expensive than oxide-reduced powders.

Milling by various methods is also used to produce metal powders directly from either friable or malleable metals. The friable metals yield angular, jagged particles of irregular shape. Except with a few special mills, malleable powders tend to produce flakes, provided a lubricant is used to keep the flakes from welding together. The metallic stearates; and any volatilizing agents used to give a desired type of porosity, such as salicylic acid. If segregation occurs, the type of powder, particle size or size distribution, mixing time, or method of mixing must be modified by trial and error to eliminate it. This is likely to be particularly troublesome when powders with fundamentally different specific gravities are involved.

Overmixing may be as bad as undermixing, for it tends to increase the apparent density and to work-harden the particles, and may also decrease the particle size. Overmixing may also result in deterioration of the powder because of air or moisture attack, unless sealed containers are used. Even then, it is becoming common practice in the larger plants to minimize this deterioration factor as much as possible by mixing in atmospheres of controlled humidity. During mixing, reducing gas atmospheres are seldom, if ever, used commercially.

Table IA. Bearing Materials

Material	Tensile Strength, psi	Elongation, per cent	Yield Strength in Compression (0.1% offset), psi	Compressive Strength, psi	Brinell Hardness Number	Porosity, per cent	Density, g per cu cm
90% Cu, 10% Sn, with up to 1½ parts graphite...	12,500	2.0	11,000	70,000	30	25	6.3
5 to 25% Cu, remainder Fe	28,000	0.5	25,000	140,000	50	23	6.0
Iron	12,000	1.0	22,000	130,000	40	25	5.9
99% Fe, 1% C.....	28,000	0.5	22,000	160,000	60	20	5.9

Table IB. Materials for Structural Parts

Material	Yield Strength in Tension, psi	Tensile Strength, psi	Elongation, per cent	Brinell Hardness Number	Density, g per cu cm
Tin bronze with 5 to 10% Sn, remainder Cu (medium density)	12,500	20,000	10	40	7.0
Tin bronze with 5 to 10% Sn, remainder Cu (high density)	20,000	35,000	15	55	8.0
Iron with up to 0.3% C (medium density)	22,000	32,000	6	50	6.6
Iron with up to 0.3% C (high density)	28,000	38,000	8	60	7.0
Fe-Cu alloy with 25% Cu.....	.....	40,000	2	70	7.0

The above table gives the mechanical properties of test pieces pressed and sintered under the same conditions as production items of the same material. Variation in density between the test pieces and standard metal powder parts will invariably produce corresponding differences in the mechanical properties. The mechanical properties of metal powder parts are often not a good criterion of the value of the material, since many metal powder materials find application because of characteristics, such as porosity, which reduce the mechanical properties but impart other properties that can be obtained in no other way. This applies particularly to the first group of materials, Table IA, which are designated as "bearing materials". They are used not only for self-lubricating bearings but also in other applications (gears and cams, for instance) where either self-lubrication is important or the mechanical stresses are low. The figures in the table were derived from the published literature of the manufacturers and are meant only to give an indication of the strength and ductility of average powder material. Much higher values for any of the materials can be obtained by special treatment, but treatments of this type are frequently too costly.

combination of the lubricant and the flake shape makes these powders almost useless in powder metallurgy, but they are readily used in paints and pigments.

Both nickel and iron, under suitable conditions of temperature and pressure, will react with carbon monoxide to form gaseous metal carbonyls. These can be decomposed to yield a metal powder of high purity, but also rather expensive, which has almost spherical particles.

Metal hydride powders are made either for direct addition to other powder mixtures, or for the production of alloy powders by adding the hydride powders to properly mixed and proportioned oxide powders; heating them together under controlled conditions to accomplish reduction and alloying; and subsequently leaching out the inert oxide produced. This rather expensive hydride process is used largely for specialty products.

The ordinary methods of machining, the process of shotting (that is, dropping the molten metal from a small opening through air or an inert atmosphere into water), vapor condensation, chemical precipitation or cementing, and granulation accomplished by stirring rapidly during solidification, are also used but not for high production.

Characteristics of Metal Powders. Characteristics of the various types of metal powders most commonly used commercially are listed in Table II. The data given are intended only as an indication of what might be secured in these materials and should not be used for design or direct manufacturing purposes.

Processing. *Mixing.* Homogeneity of mixing is essential to successful powder metallurgy. This is controlled largely by the particle size and size distribution of the powders and by the duration of mixing. A satisfactory particle size distribution should be secured in advance by proper blending of each major type of powder used. With these blended powders are mixed the alloying powders, either metallic or nonmetallic; lubricants, such as stearic acid or

The time required for mixing may vary from a few minutes to as much as 24 hours, depending entirely on experience and the results desired. In the production of metal carbides, periods of several days are used to coat the carbide powders with the cementing agent, usually cobalt, and to reduce the particle size, rather than merely to mix the two together.

Pressing. Compacting or pressing is the most important operation in powder metallurgy because the practicability of making a given part from metal powder is determined largely by the attainment and maintenance of a satisfactory pressed density.

Pressing is usually done at room temperature, but there are a few applications in which compacts are hot pressed, using much lower pressures. In these, the powders are introduced into a cold graphite die and heated by resistance through the mold and the compact. Many so-called hot pressing operations are actually sintering under pressure.

Although both mechanical and hydraulic presses have been designed for this type of work, the mechanical types are preferred for mass production. Pressure ratings for the mechanical presses may range from 10 tons to as high as 500 tons, for a straight side and knuckle joint single-acting press. Speeds range from 6 to 60 strokes per min, and may be as high as 400 strokes per min for some types of rotary presses. Classification according to depth of die fill is sometimes used, with ratings from 1⅝ to 8 in. Hydraulic presses, as a rule, have higher capacities, as great as 1000 or even 3000 tons. Stroke speeds are much slower, generally less than 20 per min and as slow as 20 per hr for the largest presses, although these speeds can be increased greatly by use of accumulators.

The size of the part that can be made depends to a great extent on the pressure rating of the presses available, since pressures required by powder metallurgical processes usually range from 10 to 50 tons per sq in. and may approach 100 tons per sq in. for some applications.

The usual dies consist of a die body which, for many parts, is filled volumetrically from a hopper; an upper punch, sometimes hollow, but corresponding to the shape of the part to be produced; a lower punch, which forms the bottom of the die body and serves as a stripper to eject the compressed parts; and either a movable or a stationary core rod, which determines the inside diameter.

Dies are usually made of tool steel, machined to a close tolerance, and hardened, ground and lapped to a mirror finish. However, when parts are made from highly abrasive particles, hard carbides may be used for the dies or for liners in them. Replaceable liners, which are discarded when worn, are also used sometimes to reduce the cost of

Table II. Properties of Metal Powders

Metal or Alloy	Type of Powder	Purity of Composition,[a] [b] per cent	Particle Shape or Character	Particle Size Distribution,[b] mesh	Range of Apparent[b] Densities, g per cu cm	Hydrogen Loss, per cent
Aluminum	Atomized	99% Al	Irregular & nodular	— 30 to —325	0.40 to 1.15	Not applicable
Antimony	Milled	99% Sb	Angular	—100 to —200	2.30 to 3.00	Not applicable
Beryllium	Milled	99.5% Be	Irregular	—100 to —200	....	Not applicable

(b) The range of values represents a compilation of the specifications of various manufacturers and not necessarily the specification of any one manufacturer's grades of powder.

die upkeep. It is common practice to maintain initial clearances at 0.0003 to 0.0005 in., although, with use, these will undoubtedly increase. The permissible die clearances depend to a large extent on the part being made and the materials used. If they are too close, either air will be entrapped in the die, leading to poor compacting and excessive porosity, or the die parts may "freeze" together. If they are too loose, powder will tend to be forced between the die body and the punches, forming a flash burr and favoring breakage of the compact during stripping. A slight taper is ordinarily designed in the upper part of the die body to facilitate ejection of the compacted part and to assist the escape of air during the early part of the stroke. Die depth depends on the compression ratio, that is, the ratio of the apparent density and the pressed density of the powder being pressed. It is usually from about 2:1 to 3:1 for iron and copper powders but may be as high as 6:1 or 8:1 for some materials and particle sizes. Information such as this must be determined accurately for each specific part before production is attempted, because only in this way can accurate size tolerances be maintained. With powders of very low density, the greater die depth introduces complications because of uneven pressures and additional friction, both within the powder mass and against the die walls.

The unsintered part is sometimes referred to as a "green compact". Although it is relatively weak, it can be handled safely if ordinary precautions are taken.

Parts in which the axial variations are less than one-fourth their length are ideally suited for compacting. In such parts the compression ratio and the resulting density will be sufficiently uniform without requiring multiple punches. Since the pressure is applied axially, any radial projections or contours that do not require variations in axial length (such as those of gears, cams, and similar parts in which the design of the die body and punch are mated in the desired shape) can be compacted without introducing any additional problems, unless the projections or splines are excessively deep and narrow. When the axial variations of parts are greater than one-fourth their length, as for flanged or winged parts, proper compensation is accomplished most simply by compacting from both the top and the bottom. This may or may not require two compacting movements, depending on the exact shape; but flanged or winged parts always require two movements. The direction of compacting should be chosen in such a way that the cross section perpendicular to the direction of pressing is as simple as possible. If there are several changes of section, like axial projections, multiple punches, which require complicated and expensive die construction, will be necessary.

Sintering. The maintenance of uniform dimensions and a reproducible product require an accurate control of the sintering cycle. Sintering furnaces are frequently of the electric resistance type, but gas or oil heating is often used, particularly when some special atmosphere is needed or when the temperature required does not exceed the limiting temperature for muffles—about 1800 F (1000 C). High temperatures are secured by the use of nickel-chromium alloy elements up to about 2000 F (1100 C), silicon carbide units up to about 2500 F (1370 C), and either molybdenum or tungsten elements operating in hydrogen, or the electrical resistance of the part itself for higher temperatures. High-frequency methods of heating have not proved very satisfactory because of the difficulties of temperature uniformity and control; and molten salts have been tried without much success, largely because of salt impregnation. The residual salt, which cannot be removed after sintering, will cause corrosion.

Most modern sintering furnaces are either continuous or semicontinuous, frequently using mesh-belt or roller-hearth conveyers for temperatures below 2100 F (1150 C). These furnaces are generally constructed with entrance or purging chambers (in which preheating is possible and volatile constituents that are not desired in the main furnace atmosphere can be removed) and with cooling chambers, so that the parts can be cooled to room temperatures before exposure to the outside atmosphere.

The great majority of electrically heated (nickel-chromium alloy, silicon carbide, and molybdenum rod) furnaces do not use a muffle but have the heating elements radiating directly on the work in the heating chamber. Under these conditions the outside steel shell of the furnace must be gas-tight to contain the protective atmosphere. Muffle-type resistance furnaces are also made with a heat-resisting steel or a refractory muffle, unless the operating temperatures exceed about 2100 F (1150 C), in which case silicon carbide muffles must be substituted. Most frequently, heat-resisting steel muffles are used only in gas-heated furnaces; and refractory muffles, only in the molybdenum-wound furnaces, which are becoming obsolete.

Atmospheres* are restricted somewhat because of production difficulties or expense. Tank hydrogen is commonly considered too costly, but some are using it and also hydrogen made by the electrolysis of water. Gas from either of these sources must have the oxygen removed and be dried if "dry" hydrogen is needed.

Drying can usually be effected to a plus 40 F dew point by refrigeration; and, once this is done as a preliminary step, moisture can be further removed to at least a minus 40 F dew point by dryers that use activated alumina. However, some concerns are still using the more complicated treatment of first passing the gas over heated copper turnings to remove oxygen, and then passing it over calcium turnings to remove the water vapor formed.

Commercially, the so-called "hydrogen atmospheres" are usually secured by dissociating ammonia to a mixture of

* For more detailed information concerning protective furnace atmospheres, see the article on page 294 of this Handbook.

Table III. Sintering Conditions for Various Materials

Material	Atmosphere	Temperature, deg Cent	Temperature, deg Fahr	Time, minutes	Remarks
Bronze	Combusted gas	700 to 870	1300 to 1600	10 to 15	
Iron	Combusted gas	800 to 1100	1475 to 2000	45	Atmosphere controlled to prevent decarburization.
Friction materials	Combusted gas	800 to 1100	1475 to 2000	90	Sintered and brazed to backing simultaneously.
Noble metals	Air	1000 to 1200	1825 to 2200	45	
Permanent magnets	Hydrogen	1200 to 1300	2200 to 2375	150	Very dry atmosphere necessary.
Refractory metals	Hydrogen or vacuum	2500 to 3200	4500 to 5800	15	Frequently given low-temperature presintering.
Refractory carbides	Hydrogen	1300 to 1500	2400 to 2700	90	Occasionally sintered in vacuum and sometimes pressed and sintered simultaneously in carbon mold.
Brass	Hydrogen	850 to 900	1550 to 1650	45	Care must be taken to prevent zinc loss by vaporization.
Electrical contacts	Hydrogen	900 to 1200	1650 to 2200	10	Sometimes sintered and solder-backed simultaneously.

The times and temperatures listed are typical but many processes call for appreciable variations from the conditions given. In some applications it is possible to use any protective atmosphere and the final decision concerning which is most desirable may be based entirely on economic considerations. In some instances, dissociated ammonia may be used in place of hydrogen, whereas in others, such as permanent magnets, only the driest form of purified hydrogen is satisfactory. Carboniferous compacts require an atmosphere with the correct ratio of carbon monoxide to carbon dioxide to prevent decarburization; certain other materials must be sintered in a carbon-free atmosphere.

75% H, 25% N. The ammonia has the additional advantages over pure hydrogen of being relatively inexpensive and of being readily produced free from oxygen and water vapor. Generally, it is not dried further. Dissociated ammonia cannot be substituted for hydrogen when the nitrogen will react with either the material being sintered or with the heating elements. Most other commercial sintering atmospheres are produced by the partial combustion of various hydrocarbons. In localities where natural gas is available, it is commonly used for this purpose; otherwise bottled propane is often used in preference to city gas, because of its greater purity. Carbon monoxide atmospheres are secured by heating in a closed container, such as a belt-type furnace, in the presence of a carbonaceous material.

Dry hydrogen is required to secure satisfactory sintering of refractory metals, cemented carbides and alnico magnets. Most iron-base and copper-base alloys are sintered in partially combusted hydrocarbon gas atmospheres, particularly those made with a lean air: gas ratio and refrigerated to a plus 40 F dew point.

However, if decarburization must be avoided in iron-base alloys, a gas must be used that is very low in water vapor and that has a low ratio of carbon dioxide to carbon monoxide. This can be readily secured, either by using a rich air: gas ratio in a generator that is externally heated and contains a special catalyst, or by absorbing carbon dioxide and water vapor from the lean air:gas ratio gas. Vacuum is used with some materials, such as tantalum, which reacts with all the common gases.

The time of sintering depends entirely on the characteristics and homogeneity desired in the sintered part, since intermetallic diffusion, which determines the approach to essential equilibrium, is a rate process. The capacity of a furnace will be dependent on its dimensions and the sintering time required.

An appreciation of the order of magnitude of the three sintering variables—atmosphere, temperature and time—can be secured from the data listed in Table III. These are intended to give a starting point rather than to furnish specific sintering information. The large numbers of sizes, shapes and compositions used commercially make this the only feasible procedure to follow.

Subsequent Operations. Operations following sintering involve sizing, resintering, machining, or impregnation.

It is sometimes necessary to add a few machining operations to take care of shapes that cannot be molded or to maintain extremely close tolerances. Screw threads, undercuts, and holes, grooves or flanges normal to the direction of pressing, are typical examples of the former. With porous bearings the bearing surface is usually not machined, because this tends to close the pores. When impregnation is to follow, the use of a coolant during machining is not advisable. Mechanical properties can often be improved materially by re-pressing, because of the cold deformation so produced; and more accurate dimensional tolerances can be maintained, without the expense of individual gaging, by coining, sizing or re-pressing the finished part in a die of suitable size and shape. These operations are also used sometimes to increase the density of the sintered compact.

Impregnation is the means used to fill the internal pores in the sintered compact. This can be done with oil, as in oil-impregnated bearings, either by a vacuum process or by immersion, for a suitable period of time, in the lubricant held at a temperature of 170 to 180 F (77 to 82 C). Sintered compacts can also be impregnated with alloys that have a low melting point, such as solders, for example, when stiffening or antifriction properties are desired.

Testing Finished Parts. In general only two types of tests are used for powder metallurgical products—density and chemical analysis. Hardness and tensile strength are sometimes determined, but they are useful chiefly for the purpose of comparing the properties of different parts made from similar compositions. Additional special tests have been devised, such as crushing tests for bearings, transverse strength tests for cemented carbides, and various electrical and magnetic tests; but they are used only for special products, depending on the application. Density is commonly determined because other mechanical properties are frequently proportional to it. Standard test procedures have been developed and issued in Army Ordnance Specifications AXS-1396.

In determining the density by this method a modification of the Archimedes method is required, because of the porosity of the sample. The weight of the lubricant-free sample in air is first secured. The sample is next impregnated with oil by a definite procedure, and, after the excess oil is removed, it is again weighed in air. The oil-impregnated specimen is then reweighed while it is immersed in water, and its volume is determined by the usual method. Since two bodies cannot occupy the same space at the same time the water cannot enter the pores because they have previously been impregnated with oil. From these three weights the density can be calculated.

The hardness of a sintered powder metal compact is a much more complex characteristic than that of even a solid metal. Basically, it is a composite of two parts, one resulting from the matrix and one from the porosity. Because of the importance of the porosity factor, hardness values comparable with those of solid metal are seldom produced. Hardness tests are, therefore, usually not suitable for the purpose of specification, except in nonporous materials like cemented carbides, although they are widely used for purposes of production control.

The parts made by powder metallurgical methods are usually of such a size and shape that it would be clearly impossible to cut from them a standard tension test specimen of the type commonly used for solid metals. Tension tests are, therefore, not suitable for specification purposes. In order to determine the strength properties of powder metallurgy materials, small test specimens are compacted and sintered. No standard tension test specimen has been widely accepted thus far, but a flat bar having a test section ¼ in. square is in fairly common use. In any such test, it is advisable to refer specifically to the type of specimen used, in order that better comparisons may result.

The Explosion Hazard of Metal Powders, and Preventive Measures

By Irving Hartmann*

WHEN a layer or pile of dust is ignited, if left undisturbed it usually burns quietly at a rate that depends on ease of oxidation and availability of oxygen. However, if this dust is thrown into suspension in the air, a violent explosion may result.

Thirty years ago it was believed that a dust explosion could occur only if the atmosphere surrounding the dust contained some flammable gas. This view was proved incorrect by tests in the experimental coal mine of the Bureau of Mines and elsewhere. Today it is known that nearly every combustible solid in finely divided form can produce an explosion under the right conditions.

The necessary conditions for an explosion are a dust cloud of sufficient concentration in air or other gas that will support combustion, and a source of ignition sufficiently intense to raise the temperature of a portion of the suspended dust to the ignition point. If, after the initial ignition, the combustion progresses through the dust cloud at such a rate that heat is developed more rapidly than it is dissipated to the surroundings, the phenomenon is termed a dust explosion. When this occurs in a closed or partly closed space, a rapid rise of pressure results. During explosions of many carbonaceous dusts, the pressure results partly from the generation of gaseous combustion products greater in volume than the original air in the space; and partly from the heating and expansion of the gases by the heat of combustion. When dust clouds of metal powders explode in air, the final volume of gas, mostly nitrogen, is usually smaller than the initial volume of air, and the rise in pressure is caused entirely by heating and expansion of the nitrogen.

* Supervising Physicist, Experimental Coal Mine and Dust Explosions Section, Explosives Division, Bureau of Mines, Pittsburgh

Published by permission of the Director, Bureau of Mines, U. S. Department of the Interior.

Dust explosions in industrial plants have been started by various sources of ignition. These include electric sparks and arcs in motors, fuses, and other equipment; static electrical discharges; frictional or metallic sparks; overheated bearings and other hot surfaces; open lights; glowing particles entering grinding mills and dust collectors; spontaneous ignition of dust; disturbance of burning dust by use of a water hose; chemical reactions between constituents of dust mixtures, as between oxidizing and reducing agents; and other common incendiary agents.

Explosibility Factors. The ignition temperature and the minimum energy required for ignition of a dust cloud have an important bearing on the probability of a dust explosion; however, these two factors appear to have little relation to each other. The ignition temperatures of metal powders range from about 200 to above 1000 C; the minimum energies necessary to ignite metal powders, as determined by experiments with condenser discharge sparks, range from a few millionths of a joule to several joules. The rate of oxidation of several metal powders, including powders of the noble metals, is so small that their suspensions in air are incapable of propagating a dust explosion. While some metal powders can be ignited most readily by direct heat source, other powders, notably atomized aluminum, are ignited more readily by electric sparks.

The nature and violence of a dust explosion are influenced principally by the following factors:

Chemical and Physical Properties of the Dust. Important properties that have a bearing on explosibility include: the ease of oxidation, oxygen requirement for complete combustion, heat of combustion, specific heat, purity, presence of oxide film on surface, shape, size and porosity of particles, and affinity for nitrogen. As might be expected, in general the explosibility increases with decrease in the particle size (increase in surface area) of the dust. For magnesium powders it was found experimentally that stamped or flaked powders are more explosive than milled powders, and these are in turn more explosive than atomized powders.

Concentration and Homogeneity of Dust Cloud. The concentration of dust in the air must be between certain lower and upper limits, in order that ignition of one portion of the cloud should propagate through the mixture and develop into an explosion. Other conditions being equal, the strongest explosions will be produced at concentrations approximating the stoichiometric mixtures.

Composition of Atmosphere. In general, decrease in the oxygen content of the gaseous atmosphere containing a dust reduces the ease of ignition and the violence of a dust explosion. For most dusts there exists a critical oxygen content below which they will not ignite and propagate an explosion.

Ignition Source. The ignition temperature, lower explosive limit, and the violence of explosions produced by dust clouds, are affected in some measure by the type of source initiating the explosion. Generally, a large source is more effective than a point source or a short spark; a source of some duration is more hazardous than an instantaneous one.

Characteristics of Explosion Space. The volume, shape, tightness and construction of the enclosure in which a dust explosion occurs determine to a large degree the damage that may result from it. Of special importance is the presence of vents through which the pressure developed by an explosion might be quickly released to the outside.

Classification of Metal Powders. During the last few years several industrial explosions have occurred, which were caused by dust clouds of magnesium, aluminum, magnesium-aluminum alloys, zirconium, zinc, pure iron powders, and mixtures of metal powders with other dusts. On the basis of this experience and of extensive experimental test data accumulated by the Bureau of Mines,[1] the metal powders currently manufactured can be grouped approximately in the three classes given below. In the experiments the following factors were determined: ignition temperature, lower explosive limit, minimum energy required for ignition, relative flammability, maximum pressures and rates of pressure rise developed by explosions of dust clouds of several concentrations, and limiting oxygen content to prevent ignition and propagation. The three classes of powders are:

1 Powders of High Explosibility. These include zirconium, magnesium, aluminum, titanium, and certain magnesium-aluminum alloys. Dust clouds of these powders can be ignited readily by weak electric sparks and by hot surfaces of comparatively low temperatures (less than 650 C). The lower explosive limits of these powders range from 0.020 to 0.050 oz per cu ft. The powders can all be ignited by spark in an atmosphere of commercial carbon dioxide; and zirconium, magnesium, and some magnesium-aluminum alloys can be ignited by spark in air-nitrogen mixtures containing less than 3% oxygen. Ignition can be prevented by processing the powders in helium. Highest pressures (more than 70 psi) are produced by explosions of magnesium powder dispersions. Zirconium powder can be ignited by weaker electric sparks than can any other dust tested; when it is dispersed into air at ordinary temperatures, the dust clouds ignite under certain conditions without application of any external ignition source, apparently because of static discharge within the cloud.

2 Powders of Moderate Explosibility. The metal powders in this class present almost the same dust explosion hazard as pulverized bituminous coal. They include vanadium, pure iron (carbonyl, hydrogen reduced, electrolytic, sponge), manganese, silicon, tin, zinc, antimony, tellurium, cadmium, ferrovanadium, ferrotitanium, ferrosilicon, and ferrochromium. Ignition temperatures of dust clouds range from about 315 to 850 C, and lower explosive limits from 0.100 to more than 0.500 oz per cu ft. Dust explosions of silicon powder produced higher pressures (over 60 psi) than any of the others in this class. Atmospheres of air-carbon dioxide and of air-nitrogen mixtures, with sufficiently low oxygen content, are effective in preventing explosions of these powders.

3 Powders of Little or No Explosibility. These include lead, chromium, copper, nickel, impure iron, molybdenum, tungsten, cobalt, selenium, and probably all noble metals. (The latter have not been tested.) These powders, having ignition temperatures above 700 C, could not be ignited by the electric sparks used in the tests.

Preventive Measures. The two principal ways to guard against dust explosions are to prevent the formation of dust clouds of explosive concentration and to eliminate all possible sources of ignition in areas where dust is present. The first measure calls for good housekeeping throughout a plant. It requires that dust processing equipment be dust-tight; that suitable dust collectors be installed where necessary; and that dust accumulations on ledges, beams, floors and other exposed surfaces be removed periodically, preferably by vacuum cleaners and soft push brooms. To eliminate the ignition sources, all electrical equipment and wiring should conform to the requirements of the National Electrical Code for hazardous and dusty locations; all open lights and smoking should be prohibited in the affected areas; repair work requiring the use of torches and welding equipment should be performed during shutdowns after removal of all dust; bearings and other moving parts of machinery should be dust-tight and in good working order to prevent overheating; all dust-processing equipment should be properly grounded to prevent accumulation of static charge; if possible, only nonsparking tools should be used, although little is known at present about the incendiary hazards of frictional sparks; and finally, the entrance of foreign matter into grinding mills and fans should be prevented. The heating and ventilating system in the plant should be of a type that will keep the air dry and at fairly even temperature, and will not raise dust into suspension. Where particularly hazardous dust is handled, it is advisable to segregate the dusty operations in separate buildings detached from the main plant. If considered necessary and practicable, inert gas may be provided instead of air in closed equipment. Finally, whenever possible, equipment and rooms in which a potential explosion hazard exists should be provided with relief vents through which the pressure of an incipient dust explosion can be released quickly.[2]

In order to reduce the fire hazard, care should be taken to prevent spontaneous heating of metal powders in storage, particularly shortly after grinding. It should be remembered that some metal powders, including magnesium, aluminum, and zinc, have a tendency to heat in the pres-

ence of moisture. First-aid fire protective equipment, suitable for extinguishing small fires in powdered metals, should be provided and workmen should be trained to use it properly. Small fires in magnesium and aluminum powder can be extinguished by surrounding and gently covering the fire with sand, talc, or other dry inert materials, or by using hard pitch that completely seals the fire.[3] Spray or fog nozzles can be used without danger to control fires in metal powders, although the application may increase the rate of burning of some powders—for example, magnesium. However, streams of water should be used only with great caution in fires where combustible dusts are involved, and the water should never be directed into the burning pile, since this may produce dust clouds and an explosion. Employees and the fire department should be advised of this in advance. Also, water from buckets must never be applied to burning dust.

For further recommendations on the prevention of explosions and fire in metal powder plants, the codes of the National Fire Protection Association[4] for aluminum bronze powder and for magnesium powder plants are important.

Precision Casting

By F. S. Badger* and A. W. Merrick*

THE application of precision casting to industrial purposes has received a great deal of attention because of its success in wartime production of parts difficult to fabricate by other methods. This process of casting, also known as the "lost wax" or "investment casting" process, is an old one used for many years in the casting of dental inlays, dentures and jewelry. New techniques and materials were devised to make it applicable to high-melting-point alloys used in superchargers and gas turbines.

Process. The process is described below with the major variations used for quantity production of industrial castings. Patterns for the precision casting process must be made of materials such as waxes and plastics that will melt, vaporize or burn completely leaving no residue. These patterns are made by the injection of the pattern material into metal dies. Suitable cast alloy dies are generally used for making wax patterns. The dies are prepared by casting two halves in strong metal shoes around metal master patterns with proper allowance for shrinkage of both wax and metal. The dies may have either single or multiple cavities, according to the size of the patterns and the quantities required.

Machined and hardened steel dies are usually necessary for plastic patterns. These may also be used for wax injection, but they involve more time and much greater expense than cast metal dies, particularly if production is not great, if designs and other details are not definitely established, or if the desired intricate detail is easier to produce in a positive master pattern than in a negative die impression.

The single or multiple patterns are assembled with wax gates and risers for convenient mounting and proper feeding of metal into the mold. In order to produce the fine surface finish desired on precision castings, the pattern assemblies may be dipped or sprayed with a slurry of fine refractory powder. After eventual transfer to the investment mold, this powder serves as a mold-facing material. If very fine investments are used or if the casting surface does not require a high degree of smoothness, the coating step is sometimes omitted.

The coated patterns are attached to a flat plate by molten wax, and a heat-resisting metal flask lined with waterproof paper is sealed to the plate, making a liquid-tight space around the pattern. This space is then filled with an investment slurry of which many types are used. For the casting of nonferrous alloys that have melting points not exceeding approximately 2000 F, plaster of Paris is adequate as the binding medium for silica or other refractory materials. For alloys with higher melting points, silica generally forms the base of the mold and the binding agent is frequently "organic" silica formed by hydrolysis of ethyl silicate.

A number of other types of investment binders are being used industrially, such as phosphoric acid in water or in alcohol, reacting with magnesium oxide or carbonate, or colloidal silica in water. The filled mold assembly is vibrated to pack the solids and remove air bubbles, which may also be eliminated by vacuum treatment.

Complete setup and curing time for the investment molds varies from ½ hr to 24 hr, according to whether plaster is used or a binder with a vehicle of alcohol or water. Time can be saved by early removal of the plate to which the wax patterns and flasks are sealed.

After the mold has been adequately cured, wax patterns are sometimes melted out in a low-temperature oven. The molds, either dewaxed or with pattern material intact, are charged into a mold-heating furnace and heated to temperatures as high as 2000 F, depending on the type of investment and the character of both material and casting. This heat melts and burns wax or vaporizes and burns plastic patterns, leaving clean cavities in the mold. When the mold has been thoroughly soaked at the desired temperature, it is ready to receive the molten metal charge.

The metal charge is melted in small indirect-arc or induction furnaces; every precaution is taken to obtain clean melts and sound castings. Gas melting is often used for alloys that have a low melting point. Castings may be poured statically or centrifugally, either from a ladle, or directly from the melting crucible, or by pressure casting directly from certain patented melting furnaces, using air pressure to insure that all details in the mold are filled Careful attention to details is even more essential in this method of casting than in normal foundry practice, because of the smooth surface required for most of these castings. There are no particular limitations concerning the type of alloys that can be cast, but investments frequently vary according to the characteristics of the alloys to be used. Ordinarily, castings are slowly cooled in the mold, then knocked out and separated from the investment material when cold. Gates may be removed by sawing or by cutting off with abrasive disks. The castings are then cleaned by shot-blasting or sandblasting, and the gated areas are ground to the surface required on the finished castings. The castings are then submitted to whatever inspection is specified for dimensions and quality, such as visual, radiographic, magnetic particle, and fluorescent penetrant inspection.

Applications. The most important use of the precision casting process is in the casting of alloys and shapes that are difficult or impossible to forge and machine. The process is also useful with forgeable and machinable alloys in order to eliminate expensive machining operations. Precision casting may be used to replace die casting where production quantities are relatively low. It is particularly applicable in development work to avoid expensive machine setups or costly forging dies for trial runs, to permit intricate designs and to test various cast alloys for particular parts. The mass production of stationary and moving

* Haynes Stellite Company, Kokomo, Ind.
* Austenal Laboratories, New York

blading for gas turbines has been an outstanding application of precision casting and promises the eventual extensive use of the process in making parts for steam turbines.

Advantages. The precision casting process produces a smooth surface far superior to ordinary cast surfaces. The dimensional accuracy is ordinarily about plus or minus 0.005 in. per in., and is occasionally closer than plus or minus 0.003 in. on small dimensions. Considerable intricacy of design and detail is obtainable, including thin airfoil sections. Difficultly cored holes not obtainable by any other process can usually be cast by this process. There is no parting line in the mold, but there is one in the die for wax or plastic pattern injection. A minimum of finishing operations is necessary. Alloys with improved physical and corrosion properties may be substituted for less desirable alloys at little extra expense, since the metal is seldom the major part of the total cost.

Limitations. Smoothness and accuracy become increasingly difficult to obtain as the size of the casting increases. Small castings weighing less than 1 lb are the most practical to produce, although castings as heavy as 5 lb have been made successfully on a production basis.

Maximum accuracy is usually not obtainable on a part until some production experience has been gained. In general, dimensional tolerances should be left as wide as possible to avoid excessive and unnecessary rejection of castings for dimensional reasons. The precision casting process, while much more accurate than sand casting, does not compete with machining or grinding for accuracy in producing simple shapes.

There are some limitations when complicated internal coring is involved, particularly concerning blind holes and long internal threads. Threads must be chased or finished by grinding where very close fits are required.

Because of the many steps involved, the cost of the process is high and it cannot compete with screw machining or other methods of mass production of readily machinable metals, particularly where large runs absorb high setup costs.

Further information on the precision casting of particular alloys will be found elsewhere in this Handbook.

Rolls for the Metal Industry

BY THE SUBCOMMITTEE ON ROLLS*

ROLLS are used in the metal industry for reducing the cross section of plastic metal or changing its shape, or both. As a rule two rolls are used, running in opposite directions, as shown in Fig. 1. The metal to be rolled, which will be called the "bar" hereafter regardless of its shape, passes between the rolls and is thereby reduced in cross section. In cross rolling (Fig. 2), used in the making of seamless tubing and straightening rounds, the rolls rotate in the same direction and set a piece of metal in rotation as it passes between them longitudinally.

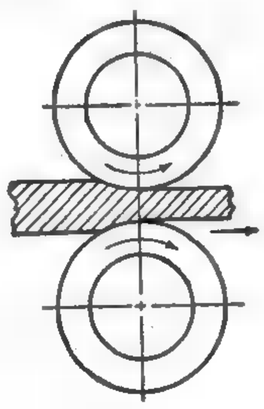

Fig. 1

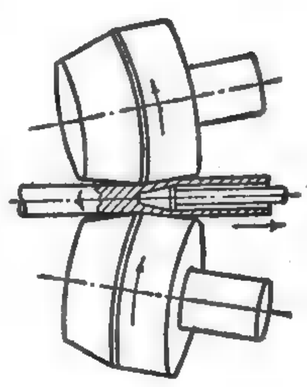

Fig. 2

Fig. 1 Typical rolling process
Fig. 2 Cross rolling

Roll Parts. A plain-bodied roll for rolling flat products is shown in Fig 3. The roll body or roll face is the working part in contact with the bar to be rolled. A grooved roll for rolling shapes is shown in Fig. 4. The metal is reduced by passing it through the grooves or passes. The parts of the roll separating the passes are called the "collars". Some rolls may be combinations of those shown in Fig. 3 and Fig. 4; for example, blooming mill rolls, which may have a portion of the body plain for rolling slabs and another portion grooved for rolling blooms and billets. The roll "neck" is the part that lies in the bearing or journal box. The "wabbler" is the part that receives the torque from the outside source of power. Instead of wabblers, some rolls are equipped with universal joints (Fig. 5), which make contact on surfaces rather than lines or points and thereby minimize wear.

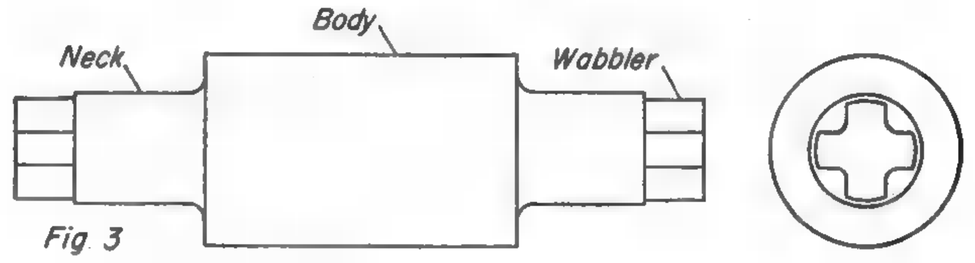

Fig. 3

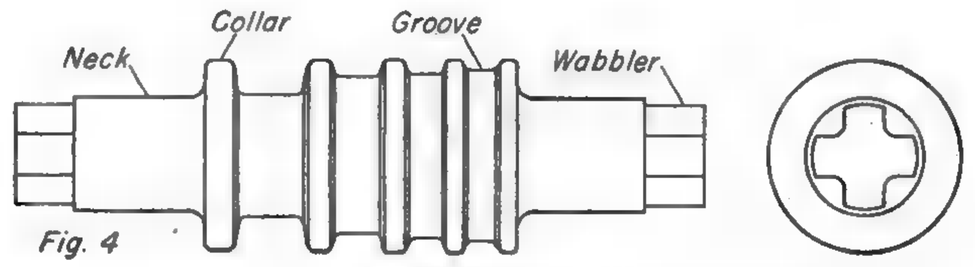

Fig. 4

Fig. 3 Plain roll
Fig. 4 Grooved roll

Roll Types and Arrangement in Roll Housing. "Blooming mill" rolls and "slabbing mill" rolls convert ingots into blooms and slabs.

"Roughing" rolls are used in the early stages of reducing billets and blooms into various shapes.

"Intermediate" rolls (also known as "second roughing", "pony roughing" or "strand" rolls) work on the bar after it comes from the roughing rolls.

"Leader" rolls are those preceding the finishing stand.

* The members of this subcommittee are S. C. Spalding, *Chairman* (The American Brass Company), J. R. Adams (The Midvale Company), F. H. Allison, Jr. (United Engineering and Foundry Company), R. S. Barnes (Bethlehem Steel Company), E. H. Berges (Farrel-Birmingham Company, Inc.), F. C. T. Daniels (Mackintosh-Hemphill Co.), B. C. McFadden (Aluminum Company of America), V. M. Surerus (Inland Steel Company) and W. Trinks (Pittsburgh).

"Finishing" rolls are used to give the bar its final shape. When used for rolling flat products these are sometimes called "planishing" rolls.

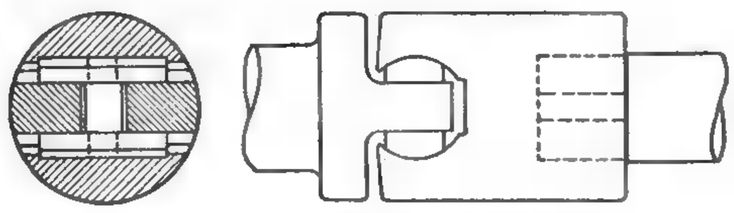

Fig. 5 Universal joint for rolls

If only two rolls are used in a mill, the mill is called a 2-high mill. If three rolls are used (usually on top of one another) the mill is called 3-high, and so on. Not all rolls are in contact with the metal to be deformed. Some rolls act as stiffening or supporting rolls for smaller rolls that are in contact with the work. The smaller rolls are then called "working rolls" and the supporting rolls are called "backing rolls". Figure ■ shows the arrangements of rolls on 3-high, 4-high and cluster mills.

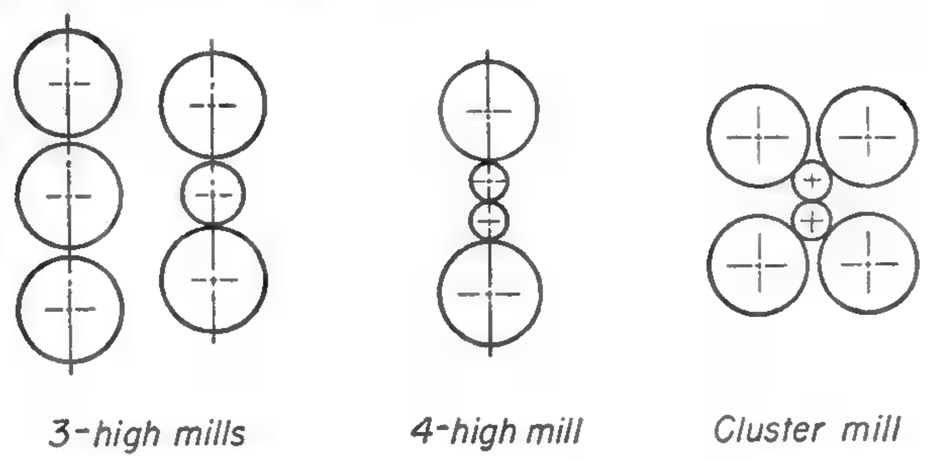

Fig. 6 Arrangement of rolls in 3-high, 4-high, and cluster mills

Roll Requirements. *Resistance to Wear.* This is the first requirement for rolls, since rapid wear impairs the surface or enlarges the section beyond the tolerance that can be used. Wear is caused by the relative motion between the bar and the roll surface. In all rolling there is relative motion between rolls and bar while they are pressed against each other at enormous pressures, which, in severe operations, reach several hundred thousand pounds per square inch. There is no general index for resistance to wear of rolls. For lack of something better, hardness is ordinarily used as an indication. The hardness of the roll is usually determined by the Shore scleroscope because of its portability and because the test involves a minimum marking of roll surfaces. Hardness of a roll is limited by the requirements for strength, since ductility and shock resistance decrease as the hardness increases.

Strength. This property is necessary in the rolls because they must withstand fracture from bending, torsional and shearing stresses to which they are subjected in operation. Sufficient strength for any application depends on the chemical composition of the roll, the heat treatment, and the freedom from residual stress and internal defects. Residual stress is present to some extent in every roll. Size, thermal treatment, design, and casting conditions play an important part in these stresses. Under service conditions, rolls that have unfavorable high residual stresses may rupture easily by uneven or rapid heating on the mill. This is particularly true of chilled iron rolls for flat products. Subsurface strength is necessary to resist spalling, which frequently originates below the surface and progresses outward until the part breaks loose.

Bite. For grabbing the metal and starting it through the roll, bite is necessary, particularly in taking large reductions. Bite depends partly on the roughness of the roll surface. In many blooming or roughing mills, this roughness is artificially increased by ragging or knurling; that is, by cutting longitudinal grooves or welding ridges on the roll surface. Ragging must be done carefully or it will show in the finished bar. Where reductions are small, as in the leader and finishing pass, a smoother roll can be used.

Surface Perfection. The roll surface must be of high quality to obtain a good bar. In that type of cold rolling where a high surface finish is important in the product, the roll surface must be ground to a high finish and must be exceptionally free from defects. Only the highest hardness will preserve such a surface for a sufficiently long commercial operation. In hot rolling, the roll surface is subject to fire cracking, caused by alternate heating and cooling. Fire cracking is greater in the early passes where the hotter metal and larger reductions prevail.

The surface must be metallurgically correct. If the bar material has too great an affinity for the roll metal, it will stick to the roll and "load" it. The solution of this problem is not always easy. A change of roll material helps in some instances; application of a lubricant between roll and bar helps in others; insertion of another metal between roll and bar has become necessary in ■ few instances.

Rigidity. This property in a roll is essential to reduce the deflection or roll spring across the roll length. This is particularly important in rolling flat products, such as plate, sheet or strip. If the rolls spring, the edge of the section is wavy and thinner than the center. For a given diameter, a steel roll is more rigid than a cast-iron roll, but the hardness of the steel roll has no effect on its rigidity since deflections depend solely on the modulus of elasticity, which is the same for hard steel and for soft steel. Leader and finishing rolls are made relatively short for the purpose of reducing roll spring and giving accurate finished dimensions. Crowning the roll, by making the diameter slightly larger at the middle than at the ends, will produce a flatter section, but crowning is a limited remedy since a given crown can be correct for only one thickness, hardness, and width of section.

Size and Design of Rolls. The size of a roll is specified by the diameter and the length in the order named, such as 24 by 48 in. Rolls for shapes are often designated by the nominal roll or pitch diameter, which equals the distance between the centers of the mill-driving pinions. The diameter of the rolls is usually smaller than the pitch diameter because there must be room for the bar to pass between them. Occasionally the roll diameter is larger than the pitch diameter when the rolls are new. Plain rolls used for plate and strip may sometimes be designated by the length of the roll body. Rolls of the smallest possible diameter are used as far as is consistent with strength, bite, and rigidity, because rolls of relatively larger diameter spread the bar, exert greater roll pressure or separating force, and use more power for a given reduction. Rolls are made as long as is consistent with freedom from excessive deflection or breaking by bending. The deeper grooves of grooved rolls are placed as far as possible from the center, in a location where the bending moment is smaller.

For grooved rolls, the safe ratio of body length to diameter depends on the material being rolled and on the temperature of the bar.

Fairly sharp limitations exist as to the largest section that can be rolled on any mill, because on material larger than ■ certain size the rolls do not bite, or they break in bending, the wabblers twist off, the necks overheat, or the mill is stalled.

Table I. Minimum Safe Ratios of Neck Diameter to Body Diameter for Rolls Used on Various Types of Mills

Type of Mill	Ratio of Neck Diameter to Body Diameter
Blooming mills	0.50 to 0.55
Sheet mills and tin mills	0.76 to 0.80
Strip mill, backing rolls	0.55 to 0.65
Strip mill, working rolls	0.60 to 0.65
Merchant bar mill	0.60 to 0.67
Plate mill, middle roll	0.60 to 0.70
Plate mill, top and bottom rolls	0.65 to 0.72
Structural mill	0.57 to 0.65
Continuous bar mill	0.70
Universal mill, vertical rolls	0.57
Cold rolling brass, heavy reduction	0.775
Cold rolling brass, finishing reduction	0.72 to 0.75

The sudden change of diameter from roll body to roll neck intensifies the bending and torsional stress at this location. The neck diameter should not be smaller than a certain safe fraction of the body diameter, which with plain bearings will approximate the ratios given in Table I.

Misuse. Rolls can be broken or damaged easily by misuse. In hot rolling, the entering bar may be too cold or may be heated unevenly. Fire cracking usually occurs if the mill is stopped while the hot metal is between the rolls. If the bar runs between the collars instead of entering the groove, the roll pressure becomes excessive. By accident, strips or bars may wrap around the roll, forming collars and inducing excessive stresses in the rolls. Lubrication may stop in cold rolling. Other mishaps may occur on the mills, overstressing the rolls and contributing to failure some time later. Among the avoidable mistakes are local heating, too rapid heating, too rapid cooling, bruises, and nonuniform cooling. The results of these abuses may not become apparent for a considerable period of time. In the original grinding of rolls, or in regrinding, improper technique can cause serious damage, especially on hardened steel rolls. For precautions in grinding hard steel rolls, see page 59 of this article.

Roll Materials. There are three large classes of roll materials—cast iron, cast steel and forged steel. Cemented carbides have been used for some small rolls.

Cast-Iron Rolls

In American practice, cast-iron rolls are classified as (1) chilled iron rolls, (2) grain rolls, (3) composite rolls, and (4) sand iron rolls.

Chilled Iron Rolls. Chilled iron rolls (scleroscope hardness, 50 to 90) have a definitely formed, clear homogeneous chilled white iron surface on the body, and have a fairly sharp line of demarcation between the chilled surface and the gray iron central portion of the body. The depth of chill is measured as the distance between the finished diameter of the body and the depth at which the first graphitic specks appear. Below this, there is an area consisting of a mixture of white and gray iron known as mottle, which gradually becomes more gray and more graphitic, until it merges with the gray iron structure of the main part of the roll. The mottled area should equal that of the primary chill or be somewhat smaller.

The chilled rolls are subdivided into plain carbon and alloy rolls. Plain carbon rolls, having a hardness of 50 to 72 scleroscope, were the standard rolls in use for both hot and cold rolling until the introduction of the alloy chilled roll. The approximate composition of carbon chilled rolls is as follows:

	C	Si, min	Mn, max	P, max	S, max
Soft	3.00	0.75	0.25	0.50	0.125
Hard	3.50	0.50	0.20	0.50	0.150

The alloy chilled rolls have a hardness range from 60 to 90 scleroscope, controlled by the carbon and alloy content. Their composition is essentially that of the carbon roll plus one or more special alloying elements. The customary maximum percentages of elements used are 1.25% Mo, 1.00% Cr, 5.5% Ni. Many varying combinations produce the properties desired. Rolls of this type, particularly in the harder grades, are used chiefly for rolling flat work, both hot and cold. The softer, machinable grades are used for small shapes and rod mill work.

Grain Rolls. Grain rolls are "indefinite chilled" iron rolls (scleroscope hardness, 40 to 90) .that have an outer chilled face on the body but no definitely formed chilled structure. At the surface there is finely divided graphite, which gradually increases in amount and in flake size, with a corresponding decrease in hardness as the distance from the surface increases. This diminution of properties is gradual and these rolls have high resistance to wear and good finishing qualities to considerable depths. The harder grades are used for hot and cold flat finishing work and the milder grades for deep sections, even with small rolls. The basis of the composition of grain rolls is low-phosphorus pig iron, together with 0.75 to 2.50% Cr. Other alloying elements such as nickel and molybdenum are usually added, singly or in combination, to develop specific properties of hardness and toughness similar to those of chilled iron rolls.

Composite Rolls. Composite rolls (scleroscope hardness: bodies 70 to 90, necks 40 to 50) are rolls in which the body surface is a richly alloyed, hard cast iron, resistant to wear; while the necks, wabblers and body centers are of a different material that is softer and tougher. Both metals are bonded firmly together to form an integral structure that permits the attainment of a wearing surface of high hardness along with a tougher body and neck. Composite rolls are thus better able to withstand impact and thermal stresses. The rolls may be of either the chill or the grain type. The chief application in the rolling of steel has been for work rolls on 4-high hot and cold strip mills and on plate mills; in the rolling of nonferrous metals the chief application has been for the hot breakdown and cold running down of sheet and strip.

Sand Iron Rolls. Sand iron rolls (scleroscope hardness, 35 to 45) are cast in sand molds in contrast with chilled iron rolls and grain rolls, the bodies of which are cast in chilled molds. In sand iron rolls, the metal in the grooves of the body is mildly hardened by the use of cast-iron rings set in the sand mold. Sand iron rolls are used chiefly for intermediate and finishing stands on mills that roll shapes. Since these rolls are comparatively soft, their use is justified only when there is not enough metal being rolled to warrant the use of more expensive rolls.

Manufacture. In the manufacture of chilled iron rolls, pig iron and scrap are used. Low-phosphorus pig iron and grain roll scrap are the basis of grain rolls. Both types are usually melted in a reverberatory or air furnace similar to that used for the melting of iron for malleable castings (*see* "Malleable Iron", page 520); though the chilled type is sometimes made in a cupola.

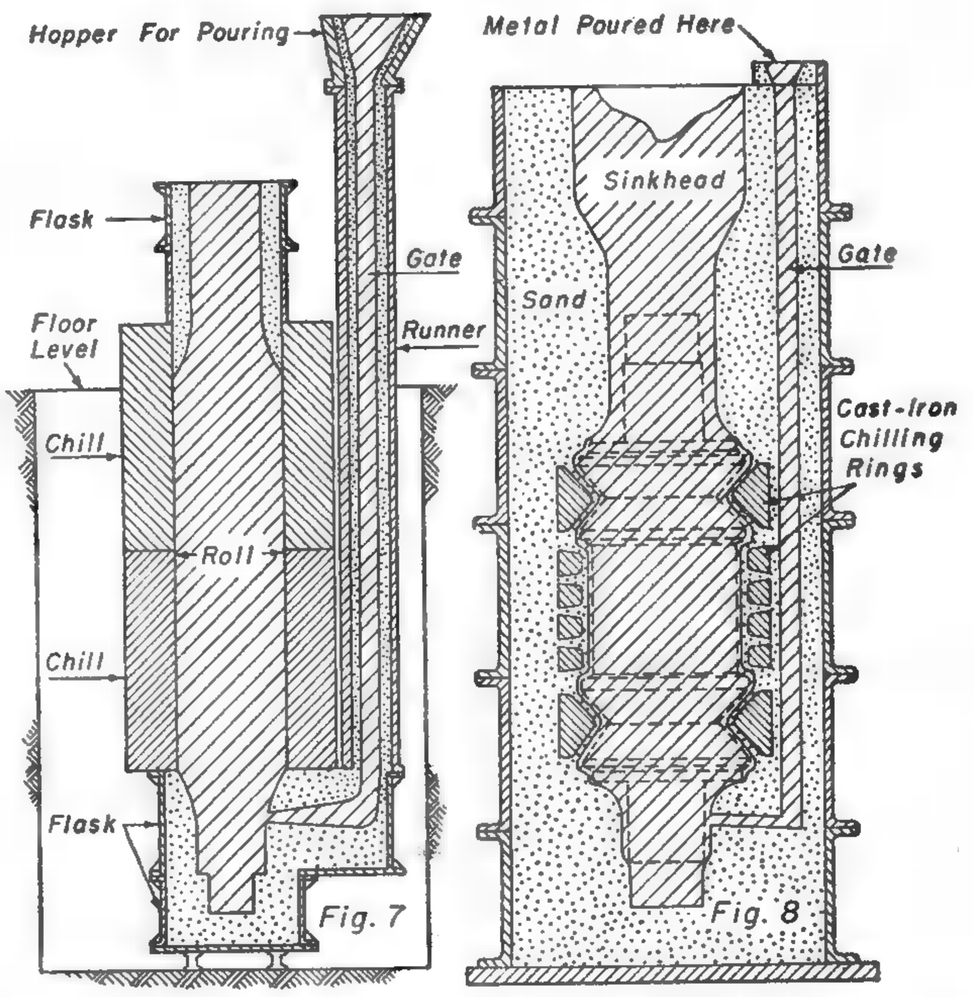

Fig. 7 Typical mold for manufacture of iron roll
Fig. 8 Typical mold for manufacture of alloy steel roll

The mold for casting the roll is erected in a perpendicular position. A typical design of a mold is shown in Fig. 7. When the metal is poured, a rapid centrifugal motion or swirl is produced by the tangentially located gate. The heavy cast-iron cylinder that comprises the body of the mold conducts heat rapidly from the molten metal, causing the formation of a hard white or chilled iron surface layer on the body of the roll. The depth of this chill is controlled by the composition of the iron and is varied to suit the requirements of the roll. The roll casting is allowed to remain in the mold for a period of 12 hr to 6 days, depending on the size. Some special alloy castings are taken from the mold while still quite hot and transferred to an annealing furnace to cool at a controlled rate, or reheated for certain mechanical properties.

Application. The principal use of plain cast-iron rolls is for hot rolling, such as is done on 2-high mills for the rolling of sheet and tin plate. The applications of plain cast-iron rolls, as well as of alloy cast-iron rolls, vary with mill practice and the finish requirements. The applications of these rolls are listed in a general way in Table II.

Table II. Applications of Cast-Iron Rolls

Grade	Hardness, Scleroscope	Application
Definite chill ..... (carbon or molybdenum chill)	50 to 72	Hot and cold rolls for sheet and tin mills, 2-high and 3-high plate mill rolls, jobbing mill rolls, wet and dry work rolls, 4-high hot strip mills, intermediate and finishing stands, rod, merchant, sheet, bar, skelp mills.
Definite chill ..... (alloy iron)	60 to 90	Hot rolls for nonferrous sheet and strip, 2-high and 3-high plate mill rolls, universal mill rolls, work rolls for 4-high hot strip mills, cold rolls for finishing nonferrous and steel sheet.
Definite chill ..... (nickel alloy)	65 to 90	Finishing stands, sheet bar, skelp, strip and merchant mills. Work rolls for 4-high hot strip mills. Cold finishing nonferrous sheet and strip.
Grain ..... (indefinite chill)	40 to 90	*Mild Hard* Light-duty roughing for small merchant and bar mills. *Medium Hard* Intermediate rolls for merchant and bar and large structural mills. *Hard Grade* Finishing rolls for merchant, bar and structural mills, also for flat finishing on sheet bar and skelp mills; sizing, high mill, reeler and welding rolls for tube mills.
Sand iron ..... (no chill)	35 to 45	Mild-duty small mill roughing to large structural finishing.

The harder, richly alloyed chilled rolls are nearly as hard as forged and hardened steel rolls and are competitive with them in the cold finishing of flat work.

Cast Steel Rolls

The differentiation between cast-iron rolls and cast steel rolls cannot be made strictly on the basis of carbon content. Iron rolls are of such compositions that free graphite is apparent in the unchilled portions; steel rolls do not show graphite.

The harder cast alloy steel rolls have hardness equivalent to that of the softer cast-iron rolls, and the superior strength of cast steel rolls often demands their use.

Composition. A few rolls are made from carbon steel, particularly for blooming and billet mills. The carbon range is usually from 0.40 to 0.80% for roughing, and from 0.85 to 1.25% for finishing rolls.

Alloy steel rolls have almost entirely superseded the carbon steel rolls. The majority of alloy steel rolls are within the following range of compositions: 0.40 to 2.60% C; less than 0.12% S, usually 0.06% max; less than 0.12% P, usually 0.06% max; as much as 1.25% Mn; as much as 1.50% Cr; as much as 1.50% Ni; and as much as 0.60% Mo. Lower carbon content gives greater ductility and shock resistance; higher carbon content affords increased hardness and resistance to wear.

A small number of rolls are made with alloy content higher than any indicated above, but these are usually rolls for special purposes.

Manufacture. Steel rolls are generally cast from acid open hearth metal, although basic open hearth steel and electric furnace steel are sometimes used. The steel is cast in a dry sand mold in which suitable metal chills may be placed for more rapid solidification in certain portions of the roll (*see* Fig. 8). The mold is cast in a vertical position and the metal enters the bottom neck at an angle to the circumference, so as to set up a swirling motion. A fairly large head and cope neck are necessary to feed the casting and avoid shrink holes. The cope neck is generally weaker than the drag neck because of the greater segregation at the upper portions of the casting and because of the removal of more of the condensed surface metal in the enlarged area to reach finished size. After casting, the gates and heads are removed from the rolls, which are then annealed or otherwise heat treated, and turned or ground to finished size.

Heat Treatment. According to the service required, the hardness, and the composition, cast steel rolls are generally given one of the following heat treatments:

Single Annealing. This treatment involves heating the steel to just above the A_3 transformation temperature, and then cooling it in the furnace. Single annealing refines the as-cast structure and removes casting strains.

Double Annealing. This treatment involves heating the steel to several hundred degrees above the A_3 transformation temperature, cooling in the furnace to below the A_1 temperature, reheating to slightly above the A_3 temperature, and then cooling in the furnace. The first heating refines the as-cast structure and homogenizes the steel. The resulting coarse structure is refined by reheating.

Normalizing. This treatment involves heating the steel to somewhat above the A_3 transformation temperature in order to refine the structure, and then cooling in air. Normalizing may decrease the ductility of the steel, but the treatment is used under special circumstances to increase hardness and resistance to wear.

Application. Cast steel rolls are graded according to the range of carbon content. The general applications of these rolls are listed in Table III.

Table III. Applications of Cast Steel Rolls

Carbon, percentage	Application
0.50 to 0.65	Where strength is the prime and only requirement
0.70 to 0.85	Blooming mills, jobbing mill, plate mill and sheet mill roughers, muck mills
0.90 to 1.05	Blooming mills, continuous bar mill roughers, backing-up rolls
1.10 to 1.25	Blooming mills where breakage is not great, piercing mills. billet, bar, rail and structural mill roughers
1.35 to 1.55	Intermediate stands for rail mills, structural, continuous billet and continuous bar mills
1.60 to 1.80	Intermediate stands for continuous bar and billet mills, middle rolls for 3-high mills
1.85 to 2.05	Middle rolls for rail and structural mills, finishing mills where housing design is too limited for iron rolls
2.10 to 2.60	Finishing rolls to meet unusual conditions

The applications listed in Table III are not a rigid classification because of the wide variation of conditions from mill to mill. Adjustments in carbon and alloy content are generally made to suit individual conditions.

Forged Steel Rolls

The principal application for forged steel rolls is cold rolling. The forged rolls are generally of a standardized composition. The average composition is, as follows: 0.85% C, 0.30% Si, 0.30% Mn, 2.00% Cr. Nickel, vanadium or molybdenum may be added either singly or in combination. Special types of forged rolls are available for certain special applications.

Manufacture. Forged steel rolls are made from acid open hearth or electric furnace steel, cast in ingot molds of suitable size and shape to afford the required reduction in forging, in order to produce the necessary structure and grain refinement. After being forged, the rolls are put through suitable normalizing and annealing processes and are then rough machined, bored and heat treated. Thereafter the rolls are machined for hardening and are hardened by heating to a suitable temperature and quenching in water or brine. Special fixtures and devices are used in order to insure uniform and extreme hardness on the working face, as well as to prevent or retard hardening of necks, shoulders, fillets and so forth. After the roll has been hardened, it is tempered to relieve stresses and to obtain the desired hardness. The next step is machining and grinding to finished dimensions and desired surface finish. Forged steel rolls are capable of a high surface finish. For special purposes a so-called "mirror finish" may be put on the rolls.

Application. Rolls of this type are used for cold rolling and for the finishing of thin metal where a high-grade

finish is desired. The hardness is varied with the service for which the roll is intended. For extreme hardness and fine finishing of thin metals a hardness greater than 95 scleroscope is commonly used. For soft and thicker metal, and for operations such as running down or semifinishing, a hardness of 80 ot 90 scleroscope may be used. For heavy roughing and special purposes hardnesses less than 80 scleroscope are used.

When forged rolls are used as backing-up rolls in 4-high mills, the scleroscope hardness depends on the size of the roll and character of the mill. For the small strip or band mill, the hardness should be 75 to 90 scleroscope. For the forged backing-up rolls, larger in diameter and used in either hot or cold strip mills, the hardness should be from 55 to 80, in order to insure maximum service. Forged rolls are applied as backing-up rolls when high pressures are used and high strength is required. Forged steel rolls of various hardnesses—such as leveler rolls, pinch rolls, coiling rolls and carrier rolls—are used for many auxiliary purposes around mills.

The extremely hard rolls must be handled with great care, and precautions should be taken to prevent their being subjected to rapid changes in temperature while in use. Before rolls are put into service, they should be preheated to approximately rolling temperature, preferably by means of heated water or low-pressure steam in the bore. Preheating of rolls by means of a gas flame is dangerous and should never be attempted unless the rolls are rotating. Rolls should never be warmed by running them in contact with one another; also, idling the rolls in contact with one another is dangerous. This practice may cause minute surface, or subsurface, fractures that result later in a spall. When not rolling, the rolls should be separated from one another and the cooling water should be turned off immediately whether they are rotating or not. Rapid and excessive heating of roll journals as a result of defective bearings or improper lubrication, causes rapid local expansion or subsequent rapid contraction, and will result in a broken or spalled roll or fire-cracked journal.

Bruises on the faces of rolls frequently bring about spalling. Such bruises often result when the ends of the strip are harder than the rest of the strip. Other factors that account for bruises are badly sheared ends, turned over or broken edges, pinches caused when the shape of the roll is unsuited to the type of rolling or when the mill is set up wrong, nonuniform thickness of strip or sheet, passage of foreign material such as micrometers, and small spalls from back-up rolls. Whenever a roll is bruised it should be ground until no trace of the spall remains after polishing and etching with a solution of ethyl alcohol containing 7% of nitric acid.

Forged steel rolls can be damaged readily by improper grinding. For roughing down and rough grinding, coarse free-cutting wheels are essential. Fineness of grit for finish grinding and polishing depends on the finish required. It is necessary to select a grinding wheel of the proper bond and hardness and to use the correct speeds for roll and wheel; otherwise the face of the roll will be injured. The manufacturers of grinding wheels should be consulted when selecting the wheels for specific shop conditions.

During periods of storage, hardened steel rolls should be well covered with a rust-preventive compound and should be placed in a dry room kept at a reasonably constant temperature. They are best supported on their journals. Manufacturers of forged steel rolls ordinarily furnish instructions for the care and use of their rolls.

Worn or damaged forged rolls can sometimes be rehardened for use in the same mill or can be made into smaller rolls for use in other mills.

Miscellaneous Rolls

Sleeve Rolls. The sleeving of back-up rolls has become a common practice in recent years and, as a result, a definite increase in tonnage and service has been obtained in comparison with that obtained with solid cast back-up rolls. In general, sleeves are manufactured from an oil-quenching grade of forged steel, heat treated to a hardness of 50 to 75 scleroscope, finished and accurately ground on the inside diameter to match a spindle or mandrel, and applied by means of a shrink fit.

The mandrel may be obtained from a solid worn-out cast roll cut down to suit, or from a casting made of alloy steel ground smooth on the outside diameter to fit the sleeve. The shrink fit for this assembly depends on the accuracy and smoothness of the two ground surfaces and is satisfactory only when a minimum is allowed for expansion to avoid possible longitudinal cracking while in service.

The best results obtained from sleeved back-up rolls are in cold reduction mills where the rolling temperatures are held constant, and also in many of the larger hot mills where the surface or frictional heating of the roll can be eliminated.

Carbide Rolls. Since about 1936, small-diameter rolls of sintered tungsten carbide have been used on some small rolling mills for flat work. Rolls 3 in. in diam and 15 in. long are now in use, but they can be made as large as in. in diam and 30 in. long with the present manufacturing equipment.

Carbide rolls impart a better finish to the product than steel rolls and it has been asserted that when steel rolled on carbide rolls is plated, a much better finish is obtained and less plating material is needed to coat the sheets than when the steel sheets have been rolled on steel rolls. At one time it was believed that carbide rolls could be used only on tension mills. However, they have been used on driven mills. Rolls made of tungsten carbide or of tungsten-titanium carbide are used to roll steel for razor blades.

Cemented or Sintered Carbides

By L. J. Hull* and D. L. Schwartz*

COMMERCIAL cemented carbides are products of powder metallurgy, made of very finely divided carbide particles of the refractory metals, cemented together by a metal or alloy of the iron group, forming a body of great hardness and high compressive strength.

Cemented carbides were first used for wire-drawing dies, from which the application expanded to include all types of drawing dies for round and irregular shapes, and cutting tools for machining all kinds of materials. In addition, cemented carbides have been used for machine and instrument parts and for a wide variety of products where high rigidity and resistance to wear are important.

In general, cemented carbides come under the two broad classifications that follow, depending on their uses.

* Metallurgists, Engineering and Research Department, Carboloy Company, Inc., Detroit

1 The straight tungsten carbide with cobalt binder is used in tools for cutting cast iron, nonferrous metals and nonmetallic materials; and in dies for drawing wire, bar, tube and sheet metal, and for blanking; as well as for machine parts where resistance to wear is important.
2 The steel-cutting grades consist largely of tungsten carbide with additions of titanium carbide or tantalum carbide or both, or of columbium carbide. These added constituents produce a material that resists cratering better than the straight tungsten carbide grades. ("Cratering", caused by the hot steel chip, is the formation of a cavity in the top surface of the carbide blank, slightly behind the cutting edge.)

Basically, the process consists of preparing the powder carbides of tungsten, titanium or tantalum; mixing one or more of these carbides with a binder, such as cobalt powder; pressing the blended powder into compacts of desired form; and sintering molded shapes to achieve consolidation.

Preparation of Powders. *Tungsten Carbide.* Of the two tungsten carbides, only the monocarbide is used for manufacturing cemented carbides. Tungsten monocarbide can be prepared by any one of the three methods that follow:

1 Heating a mixture of tungsten powder or tungsten oxide with a calculated amount of carbon powder in a hydrogen atmosphere containing carbon. The carbon powder may be lampblack or sugar carbon; either will give good results if processed properly.
2 Heating tungsten powder or tungsten oxide in a carburizing atmosphere.
3 Forming tungsten carbide by reaction of the constituents in a molten metal that does not form a stable carbide.

Tantalum and Titanium Monocarbides. These carbides can be prepared by the methods mentioned for tungsten monocarbide. To avoid difficulties otherwise likely to occur, the metal powders are usually prepared by heating the oxide with carbon to a high temperature. The carbides may also be prepared in either an inert atmosphere or a vacuum.

Cobalt. The cobalt powder is obtained by reduction of either the oxide or the oxalate in a hydrogen atmosphere, at a temperature not high enough to cause appreciable coarsening of the particles through sintering. Mechanical means may be used to reduce the particle size further.

Milling and Blending. After the carbide has been formed, it is carefully crushed, milled and screened. Compositions of the various commercial grades are prepared by selecting measured quantities of the binder metal and the carbide or carbides and blending the mixture by ball milling, which can be done either wet or dry. There are indications that the hard particles are coated by a film of the binder metals during this blending operation. Where the lining of the mill or the balls used for milling are of the same material as the binder metal, the binder can be obtained from the lining or balls through erosion, by regulation of the time of milling. The duration of ball milling varies from a period of hours to a period of days, depending on the properties required in the final sintered product and on the amount of binder metal.

Compacting and Sintering. The prepared powders are formed into shapes for commercial use by (1) cold pressing, followed by sintering or (2) by hot pressing, during which the pressing and sintering are done simultaneously.

Cold Pressing. For cold pressing, a small quantity of a lubricant, such as paraffin, is added to the powders before they are placed in the mold. This practice facilitates pressing and handling of the compacts.

The material is pressed in either hard steel molds or molds lined with cemented carbides, at pressures that vary between 5 and 30 tons per sq in., depending on the size and shape of the compact. Equipment for pressing is similar to that employed for pressing other kinds of powders—hydraulic machines for the higher pressures, and tablet machines for the lower pressures. The fragile compact may then be given a presintering treatment at a temperature high enough to drive off the lubricant, and to cause partial sintering. After presintering, the material has the consistency of ordinary chalk. In this condition, if extreme care is used in handling, the still-fragile compacts can be ground, turned, bored, faced or otherwise machined into regular or irregular shapes.

Dimensional allowances must be made in the shaping or forming operations to compensate for the shrinkage that takes place during the final sintering operation. This shrinkage may amount to 40% by volume or 15% linearly.

Sintering is performed at a temperature of 1400 to 1500 C from 30 to 60 min either in a protective atmosphere of hydrogen, containing sufficient carbon to prevent decarburization, or in a vacuum. Sintering in a vacuum is often desired for grades that contain titanium and tantalum.

During the sintering operation, the material goes through a plastic stage, as a result of the formation of a eutectic between the cobalt and the carbides at approximately 1350 C. This eutectic becomes the cementing material, wetting the carbide particles that do not dissolve, and the surface tension draws the particles together. The carbide grains are always larger than before sintering, a result of solution and reprecipitation of the carbides on particles that were not dissolved by the cementing material.

After cooling, the sintered compact has its final properties. For a given composition, the physical and mechanical properties can be altered by changing the sintering practice.

Hot Pressing. In the hot press method, the pressing and sintering are combined in a single operation. The prepared powders are placed in a graphite mold, closed at the ends by plungers that transmit pressure during the heating and cooling cycles. The heating can be accomplished by passing the current through the mold assembly, which acts as a resistance, or by placing the assembly in a suitably designed furnace that can be heated electrically by resistance or induction. Also the two methods may be combined.

Sufficient pressure must be applied to fill out the mold completely, and to eliminate gases entrapped during the insertion of the metal powders into the mold, as well as the gases that are generated during the sintering cycle.

Extrusion. The extrusion method of forming cemented carbides is an important development, since by this method, rods, tubes, spiral blanks, twist-drill sections with or without an oil hole, triangular, half-round and many other shapes can be produced in lengths of approximately two feet, or in even greater lengths if warranted.

In this process, the prepared powders are mixed with a suitable plasticizer in controlled amounts. The plastic material is then extruded through an appropriately designed die. Next, the extruded shape is baked at a low temperature, and is finally presintered and sintered, as outlined for the cold pressing method.

From a given composition, the final products obtained by employing any of the various methods of manufacture described above, can have the same qualities, depending on the control of processing. For a given method, raw material and composition, the final sintering practice determines the properties of the product.

Control of Quality. Careful control of the size and shape of the particles and of the distribution of the particle sizes, requires periodic examination during the manufacturing of this material. Variations of grain size and distribution of the particles are detected by metallographic examination. A further guide for the constancy of production operations is provided through determinations of density, hardness and strength.

Density is determined by the usual method, involving displacement of liquid. This test serves as a control of constituents and porosity, against previous standards or theoretical densities.

The measurement of hardness is ordinarily made as a Rockwell-A reading, using a 60-kg load and a diamond brale. It is more common to use a Rockwell-A reading because of the short life of the diamond brale when using the 160-kg load required for Rockwell-C readings. For checking the extremely hard grades, the Superficial Rockwell Tester is occasionally preferred in order to reduce brale failures to a minimum. In addition to the approved procedure for taking Rockwell hardness measurements, extreme care should be taken to support the specimen well.

The cemented carbides show very little permanent deformation or ductility under tension or compression loading. For control of production, the simplest method of estimating the strength of these materials is the transverse rupture test, in which a breaking load is applied to a test bar midway between supports.* The distance between supports should be such that the bar does not fail in shear.

* For additional information concerning such tests, the reader may refer to the article "Bend Tests for Hard and Brittle Metals", page 125.

The fracture test also is utilized for estimating quality. Fractured surface is ordinarily examined at low magnifications for surface skin effects, dark areas that may be graphite flakes or segregation of carbides, bright areas that may be inclusions or lakes of binder metal, voids and other characteristics of the break, which may indicate the toughness and strength.

The technique of applying these tests varies among the various manufacturers of cemented carbides. No standards for conducting the tests have been generally accepted.

Metallographic Examination. Cemented carbides may be readily polished and etched for microscopic examination. Specimens can be cut from large pieces of cemented carbide material by using a diamond cutoff wheel. The surface to be examined is rough ground with a diamond or silicon carbide wheel. The lapping is done with diamond dust on a metal lap. An oil, such as kerosene, may be used as a medium for holding the diamond dust. For rough and intermediate lapping, boron carbide can be substituted for diamond dust; however, it gives less satisfactory results. The three following stages are ordinarily used for lapping:

1 Rough lapping can be accomplished with diamond dust that has particles in the size range of 10 to 30 μ.
2 Intermediate lapping is performed best with diamond dust that has a maximum particle size of 10 μ.
3 Final lapping is performed on a paper lap, glued to a metal polishing wheel, using diamond dust that has a maximum particle size of 1 μ or less.

For estimating porosity and voids in the material, the as-polished surface is usually examined at relatively low magnification. The structural details, grain boundaries and phases are resolved at a magnification of 1000 to 2000 diam, after etching with one of the following solutions, which may be used for either a chemical or an electrolytic etch:

1 One to one mixture of 10% potassium hydroxide and 10% potassium ferricyanide at room temperature
2 A solution of 10% sodium hydroxide for compositions high in titanium carbide (an electrolytic etch)
3 Three parts of 30% hydrofluoric acid and one part of nitric acid
4 Phosphoric acid containing a small amount of nitric acid.

Properties. The combination of high hardness and compressive strength is among the most valuable properties of this material. The effect of temperature on the values of indentation hardness in cemented carbides at elevated temperatures is illustrated in Fig. 1. The abrasive or scratch hardness is also high, in a class with hard substances such as corundum, silicon carbide and boron carbide (*see* Table I). The relative Knoop hardness values of these hard substances are compared in Table II. The combination of high indentation and abrasive hardness in conjunction with high compressive strength, modulus of elasticity and fatigue endurance (comparable with that of hardened tool steel) makes this material versatile for many unique applications. The load that this material will sustain in tension is substantially less than in compression. Before fracture, very little permanent deformation takes place in either tension or compression; nevertheless, indentation by dynamic impact can be produced. Values of physical and mechanical properties are listed in Table III.

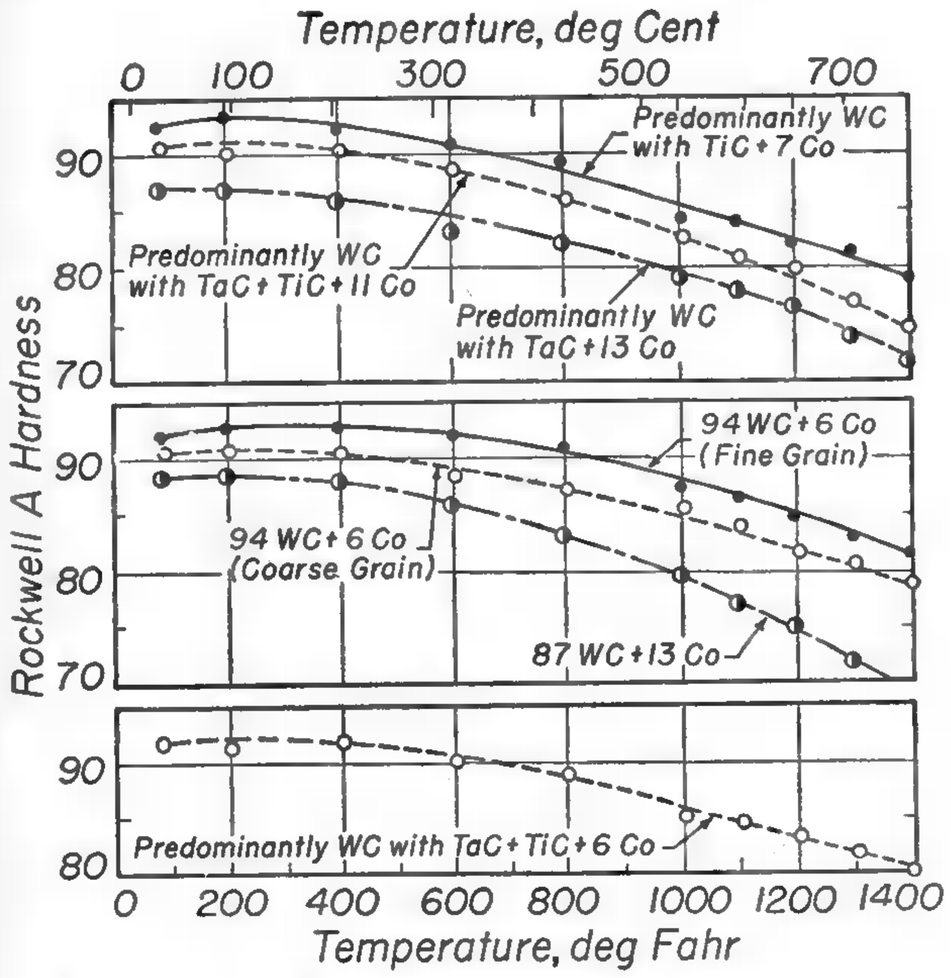

Fig. 1 Rockwell A hardness for commercial compositions of cemented carbide at elevated temperatures. Rockwell A readings (diamond indenter and 60-kg load) were taken on a standard Rockwell machine fitted with extensions for penetrator and anvil, and a heating furnace with hydrogen atmosphere. (Engle[1])

Table I. Relative Abrasive Action of Diamond and Similar Substances on Sintered Carbide[a]

Diamond dust on sintered carbide	1000
Boron carbide on sintered carbide	600
Boron on sintered carbide	480
Silicon carbide on sintered carbide	220
Aluminum oxide on sintered carbide	40

Commercial grades of cemented carbides are not considered resistant to chemical corrosion. However, they have been used under corrosive conditions in certain applications, but usually where a material of high abrasive resistance and indentation hardness was required. The carbide constituents of cemented carbides resist acid corrosive attack, but the binder retains most of its basic chemical properties, with the result that corrosion occurs intergranularly between the carbide particles. Many of the alkalies readily attack the carbide particles. Cemented carbides are subject to oxidation at elevated temperatures.

Applications. *Tools.* Grades of commercial cemented carbides are available to meet almost any machining requirement. Ordinarily the work speed used with carbide tools is considerably greater in number of feet per minute than that employed with tools of other materials. This increased speed of cutting results in removing a greater volume of material per minute, for any given depth of cut and feed. The depth of cut and feed per revolution is regulated by the horsepower available, the strength of the work piece and the quality of finish required. For details concerning specific applications, the reader may refer to the tool manuals, which are readily available.

Ordinarily where cemented carbides are used in the construction of tools, a small piece of the carbide material is brazed or fastened mechanically to a steel shank that provides a rigid support under the cutting edge. The three methods commonly used for brazing employ induction heating, an oxyacetylene torch, adjusted to give a nonoxidizing flame, and an electric furnace with a hydrogen atmosphere.

Cemented carbide tools can be ground or sharpened as safely and rapidly as any other type of tool. Silicon carbide and diamond-impregnated grinding wheels are used to grind the carbide, but the grinding of the steel shanks to which the carbide is attached, is done best with an aluminum oxide wheel. The customary procedure is to grind the portion of the steel shank that is not close to the carbide tip, with an aluminum oxide wheel, and then to grind the carbide with the silicon carbide or diamond wheel.

Cemented carbides may be used for cutting operations ranging from light finishing cuts at high speeds and light feeds, to heavy cuts with coarse feeds and slower speeds. Interrupted cuts on steel and other materials are common with tools designed for the purpose.

Cemented carbides are used in the following tools:

Single-point lathe tools	Solid twist drills for nonferrous materials
Reamers	Hi-Brinell drills
Counterbores	Small solid circular saws and large carbide-tipped circular saws
Spot facers	Milling cutters of all shapes, sizes and kinds
Countersinks	Shear blades
Facing tools	Files, flat and rotary
Boring tools	Dental burrs
Turning tools	Planer tools
Threading tools	Bending tools
Fly cutters	Gage contact points
Form tools	Spinning tools
Broaches	Hand scrapers
Core drills	Brinell balls
Boring bars	

Dies. The first commercial application of carbide dies was for the hot drawing of tungsten and molybdenum wire. The usage expanded rapidly and within a few years, carbide dies were generally employed for the cold drawing of wire made of steel, copper, aluminum and other materials. Today a large percentage of wire, rod and tubing smaller than 3½ in. in diam is produced through these dies. In addition, considerable high speed steel wire is drawn hot, using carbide dies.

Besides the application in the wire, bar and tubing field, cemented carbides are employed largely for the cold extrusion and heading of parts such as bolts and nails, and for the cold forming of heavy-walled steel parts, such as the nosing of shell forgings.

Cemented carbides are used extensively in the blanking of steel, aluminum, and like metals and in the cupping, drawing and redrawing of sheet metal parts in sizes from small eyelets to cylinders 10 in. in diam.

Carbide-tipped mandrels for sizing the inside diameter of all types of tubing, produce tubes with a fine finish inside and hold the wall thickness and dimensions of the hole within close tolerances.

Wear. The practical application of cemented carbide for purposes of shaping materials both with and without cutting, is attributed to the properties of high hardness and great compressive strength required of a material to resist wear. During these operations for changing the form of materials, very high pressures are involved, and high temperatures are reached at the mating surfaces between work and tool. At elevated temperatures, cemented carbides retain their indentation hardness better than other metals and alloys. The resistance of this material to abrasion is compared in Table I with the resistance of other known substances of great hardness. After final sintering, the cemented carbides are so hard that they can be shaped only by such operations as grinding, lapping and polishing with the hardest of abrasives, and boring, turning and facing with a diamond tool. Cemented carbides are being used where wear occurs from the loss of dimensions by rubbing, fretting of assembled parts under high stresses without visible motion, and scoring from foreign abrasive particles between mating surfaces.

Although data concerning coefficients of friction for cemented carbides are lacking in the technical literature, information is limited also for many of the other metals and alloys selected by the engineer and designer for parts expected to resist wear. For instance, the coefficient of friction for one shaft and bearing combination can be different from that for another combination, depending on surface finish, irrespective of the many other variables present in every application. As a result, this coefficient cannot be relied on for the selection of a wear-resistant material. However, where the coefficient of friction is low, an improvement in performance is noted. Material for resistance to wear is commonly selected on the basis of two factors—ability to support the load and ability to resist scoring.

Both of these factors are satisfied by the properties of cemented carbides. Shoes for grinding camshafts, centerless grinder rests, and steady rest pads are made to carry heavy loads and resist scoring, even in the presence of abrasive materials and carriers, such as lubricants and coolants that tend to carry the abrasives between the work piece and the rest. Cemented carbides are used also as material for pads inserted in metal forming dies; seals or glands for sump pumps; guides used in the textile industry and in wire fabrication; guides, arbors and the like in spring-forming machines; and various gages for inspection.

The following are additional applications:

Centers for grinders and lathes	Knurling wheel shafts
Steady rest pads and rollers	Spring coiling arbors, pitch tools, guides and the like
Centerless grinder rests	Ways and gibs for machine tools
Gagematic gages	Thread and wire guides
Sizematic machines

(a) The values given in this table are representative of properties obtained in good production practice for the particular method of manufacture. They are not necessarily the highest values obtainable, nor do they represent the lowest that are of practical use.

(b) Most of the values for compressive strengths are given through the courtesy of P. W. Bridgman of Harvard University.

(c) The proportional limit in compression is the load per unit area at which the increase in strain ceases to be directly proportional to the increase in stress. (Bridgman data)

(d) Many values for the modulus of elasticity were obtained by W. H. Davenport of the Norton Co., who used the musical pitch method.

(e) Calculated from formula $G = \frac{E}{2(1 + \mu)}$ where G and E are determined values for modulus of rigidity and Young's modulus, respectively, and μ is Poisson's ratio.

(f) Impact values are from unnotched specimens in sections approximately ¼ in. sq. A Charpy machine was used.

(g) Values for endurance limits are based on 20,000,000 cycles, for specimens of the R. R. Moore rotating-beam type.

(h) Average coefficient of expansion per deg Cent for the range 20 to 700 C (68 to 1290 F)

Swaging dies
Dies and plungers for molding powders
Collets
Ball mill slugs
Rolls
Balls for ball valves
Spinning and burnishing tools
Liners for brick molds
Chill plates for hardening thin steel
Valve seats

Cobalt-Chromium-Tungsten-Molybdenum Alloy Tools

By W. A. Wissler*

USEFUL alloys of cobalt and chromium, with tungsten or molybdenum or both, were developed and patented by Elwood Haynes. Alloys of this basic composition are now made by a number of manufacturers, and in a number of grades that cover a considerable range of hardness and other properties. The softer and tougher compositions discussed in the article "Heat-Resistant Castings" (page 570) are used for high-temperature applications, such as cast gas-turbine buckets. The grades that are harder, from 40 to 64 Rockwell C, are used for various tools discussed below.

For tool applications these alloys usually contain from 25 to 35% Cr. The tungsten and molybdenum contents vary from 4 to 25%, or preferably from 6 to 20%, depending on the hardness desired. Carbon, present in amounts from 1 to 3%, exerts a marked hardening effect. The carbon content generally increases as the tungsten content increases. Manganese and silicon are present as deoxidizers, and other elements, such as vanadium, boron, tantalum and columbium, may be added to impart other special properties. Small amounts of iron or nickel are always present, usually as impurities; however, nickel is sometimes added intentionally as a softening and toughening agent.

Although these alloys are highly resistant to corrosion, they are not generally used unless corrosion is accompanied by wear. Outstanding resistance to wear makes them suitable for such applications as machinery parts and metal-cutting tools. The success of their applications results from their ability to stay hard at high temperatures, that is, their "red hardness". High speed steel makes better cutting tools than plain carbon steel because it has a higher hardness at elevated temperatures. Similarly the Co-Cr-W alloys are superior to high speed steel. "Red hardness" also makes these alloys more capable of resisting wear under all conditions where high local surface temperatures are developed. In addition, these alloys have comparatively low coefficients of friction, which means that they develop lower temperatures; thus they remain hard. The Co-Cr-W alloys have certain disadvantages of being appreciably weaker and somewhat more brittle than high speed steels; for these reasons the tools should not be subjected to extreme conditions of stress that might cause breakage.

The metallographic structure of the alloy is complicated. The most noticeable constituent is a large hexagonal carbide crystal that usually appears in an elongated or needle-like form and can be identified as chromium carbide (Cr_7C_3) in which some of the chromium may be replaced by cobalt and tungsten. The matrix consists of various binary and ternary eutectics containing all the constituents of the alloy. The structure is stable at temperatures as high as about 1000 C.

Some of the pertinent properties of these cobalt-base alloys are given in Table I. These properties are influenced by method of manufacture as well as by composition.

Table I

Nominal Compositions and Properties of Co-Cr-W Alloys

	Soft	Medium	Hard
Basic Composition, percentage			
Chromium	30.00	30.00	32.00
Tungsten	4.00	9.00	18.00
Carbon	1.00	1.50	2.50
Manganese	0.50	0.25	0.60
Silicon	0.50	0.75	0.40
Cobalt	Remainder	Remainder	Remainder
Hardness, Rockwell C	40	48	62
Tensile Strength, psi	105,000	76,000	65,000
Elongation, percentage	1	0	0
Melting Point, deg Cent	1275	1250	1270
deg Fahr	2327	2282	2318
Brinell Hardness Number			
At room temperature	375	470	690
At 600 C (1110 F)	280	340	480
At 900 C (1650 F)	100	150	200

Metal-cutting tools are made of the "hard" type listed in Table I. The "medium" grade is used for parts subjected to wear, and the "soft" grade is used for valves, trimming dies and the like. The "soft" grade can be rolled and forged with difficulty.

Melting is usually done in electric furnaces and in small heats. Furnace practices vary with different manufacturers of these products; no descriptions of such procedures have been published.

Since these alloys retain their hardness at high temperatures, forging or rolling of the harder grades is impracticable; therefore they are generally cast to shape and size. These alloys can be ground easily at controlled operating speeds, with wheels especially recommended by the manufacturers; otherwise surface cracking may result.

As stated above, the alloys are usually cast to the desired shape and size. However, some of these alloys,

* Research Metallurgist, Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N. Y.

furnished as welding rod, can be applied as a hard surface coating over steel and cast-iron parts.*

This method of surface coating is usual for producing such equipment as valves, earth-working machinery and trimming dies. It can also be applied to the production of metal-cutting tools. Such a procedure is not recommended, however, because the cutting quality will be lower than that of a cast bit or blade, but surface coating can be applied in an emergency to produce a form tool that cannot otherwise be readily secured.

Cutting Field. The Co-Cr-W metal-cutting tools are widely used for machining steel, cast and malleable iron, cast steel, stainless steel, brass, bronze and most machinable materials. They are selected for operations requiring speeds faster than high speed steel tools will stand, but not so fast as those at which tungsten carbide tools are generally used. Cast alloy tools are also chosen on the basis of the toughness required for any specific operation. The cast alloy tools are not so tough as high speed steel, but will stand more impact, pressure and vibration than carbide tools. Here again the cast alloys have properties intermediate between high speed steel and tungsten carbide. Careful analysis of specific machining operations is necessary in selecting the proper tool. Important factors include condition of machine tool, hardness of stock to be machined, amount of stock to be removed, finish required and production required per hour or per day. Actual comparative tests are always the best means for putting the proper tool on each job.

Table II. Recommended Speeds and Depths of Cut at 1/32-in. Feed per Revolution

Material Being Machined	Depth of Cut, inch 1/32	1/4	5/8
	Surface Speeds, fpm		
Steel			
Plain Carbon (SAE 1010 to 1040)	250	160	105
Plain Carbon (SAE 1080 to 1095)	150	100	65
Free-Cutting (SAE 11xx and X13xx	300	200	130
Nickel-Chromium (SAE 3115 to 3450)	135	90	58
Molybdenum (SAE 4130 to 4820)	150	100	65
High-Chromium (SAE 52xxx)	125	85	70
Cast Steel			
115 to 140 Brinell	160	125	80
140 to 160 Brinell	150	110	65
Cast Iron			
160 to 180 Brinell	190	155	95
225 to 250 Brinell	150	115	70
Brass	500	333	200
Bronze			
Soft	190	126	75
Hard	150	100	60
Aluminum	1200	870	520
18-8 Stainless Steel	225	170	120

Lathe Tools. One of the most important cutting-tool applications is as single-point lathe bits or tools. One manufacturer recommends these tools for use at surface speeds as great as 100% more than those employed with high speed steel tools, using the same or heavier feeds and depths of cut. Specific recommendations for cutting conditions cannot be made for various operations in different shops; only general data to be used for cutting tests can be given. Typical examples are given in Table II.

Specific instructions, such as size of tool, type of grind and method of grinding, should be obtained from the manufacturer of the tools.

Milling. Another application of these alloys is in milling-cutter blades for large inserted-tooth cutters and in solid cast cutters of the smaller sizes. The general information in Table III indicates normal operating conditions for these cutters.

Table III

Recommended Loads and Speeds for Milling Cutters

Material	Roughing: Chip Load Per Tooth, in.	Roughing: Surface Speed, fpm	Finishing: Chip Load Per Tooth, in.	Finishing: Surface Speed, fpm
Cast or Malleable Iron	0.010 to 0.015	80 to 140	0.005 to 0.010	150 to 300
Cast Steel	0.010 to 0.015	60 to 80	0.005 to 0.010	80 to 100
Bronze	Up to 0.030	175	Up to 0.030	250
Aluminum	Up to 0.030	800	Up to 0.030	1200
Copper	Up to 0.030	400	Up to 0.030	600
Brass	Up to 0.030	400	Up to 0.030	600

Special Tools. Many designs of special tools are available, including spot facers, reamers, form tools and cutoff blades. These tools permit faster cutting speeds than can be obtained with steel tools.

Trimming Dies. Dies can be hard-faced along the cutting edges by the oxyactylene welding process. Such dies usually last many times longer than plain steel dies, and may also be rebuilt, after they have become worn, at only a fraction of their original cost.

Gages. A layer of a hard grade of these Co-Cr-W alloys on the contact surfaces of gages makes them last longer. The coefficient of thermal expansion is very close to that of iron and ordinary steels. Gage blocks of both solid and bimetal construction are now available in one of these alloys.

Burnishing Rollers. Burnishing rollers made of one of these Co-Cr-W alloys are standard in many of the railroad shops for burnishing locomotive driving-axle journals, piston rods, crank pins and other parts that require extremely high finishes and excellent resistance to wear. Such rollers can be run at higher speeds and feeds than steel rollers and also at extremely high pressures. Consequently, one pass with such a roller will give results equal to those obtained by several passes of steel burnishers.

Wear Strips. Pilot bars for boring tools and the like, must resist wear, because the accuracy of the job depends on the wear on such bars. A common procedure is to insert five or six alloy wear strips around the bar.

Agricultural and Earthworking Equipment. Such equipment as plowshares and cultivators for farm use, and dipper-bucket teeth and bucket lips for excavating or dredging are usually hard-faced, and cobalt-base alloys are among the most successful materials for such applications. In general, the life as compared with that of plain steel parts is increased three to six times or more. The wearing parts of crushing and grinding machinery for handling clay, rock, ores and the like are hard-faced with comparable results.

* For additional information, see "Surfacing by Welding", page 722.

Abrasive Wheels for Grinding Metals

By G. T. Rideout*

ALTHOUGH grinding is an essential part of the modern production line it is still an inexact science. A grinding wheel should be selected only after careful consideration of both constant and variable factors. Since many combinations are possible because of differences in these factors, grinding is considered an art. As yet, no mathematical formula can be applied which will result in the correct specification for the grinding wheel. The starting point in choosing a grinding wheel is a table for wheel selection, based on actual experience. Such a table must be used carefully after consideration of the factors involved.

Components of Grinding Wheels. Every grinding wheel has two components—the *abrasive* that does the actual cutting and the *bond* that holds the abrasive grains while they cut. The arrangement of these two components in the abrasive product gives a definite characteristic known as *structure*. These components can be varied by the manufacturer of the wheel to give thousands of combinations.

* Norton Company, Worcester, Mass.

Grinding Wheel Markings. In 1944 the Grinding Wheel Manufacturers' Association adopted a standard marking system. It is a standard of markings only and not of grinding action. The abrasives, the bonds and the manufacturing procedures used by different wheelmakers are not identical; therefore, wheels similarly marked but made by different manufacturers may not grind alike.

The markings can be used to explain the characteristics of a grinding wheel and to show the many possible combinations of the components.

The standard marking consists of six parts as shown by this typical marking.

32A 46 – K 5 V BE
1 2 3 4 5 6

1 Abrasive. The letter indicates the kind of abrasive (*A*, aluminum oxide; *C*, silicon carbide) and the figure indicates the particular type of that abrasive.

2 Grain Size. There are 26 standard grain sizes from 10 (coarse) to 600 (very fine). The number indicates the approximate number of meshes per linear inch of a screen through which the grains will pass.

3 Grade of Hardness. The letters designating grade indicate the relative strength (holding power) of the bond that holds the abrasive grains in place. The grade letters range from *A* to *Z* in the order of increasing "hardness".

4 Structure Number. The structure is given a special number determined by the proportion and arrangement of the abrasive and bond. When the abrasive grains are close together relative to their grain size, the wheels have low structure numbers, such as 0, 1, 2, 3, 4, 5. Wider spacing relative to grain size is designated by higher structure numbers, such as 8, 9, 10, 11, 12.

5 Bond. There are six general types of bond—vitrified, silicate, shellac, resinoid, rubber and magnesite.

6 Manufacturer's Record. Many variations are possible in the control of the processes, methods of mixing and molding, and the use of special bonds. The characteristics of the wheel can be varied to meet the requirements of special grinding operations and these differences are revealed by the sixth (final) symbol in the marking.

Work and Operating Conditions. The four constant factors to consider when making the selection of grinding wheel specifications are: (1) material to be ground, (2) amount of stock to be removed, accuracy, finish required and rate of production, (3) area of contact or size of wheel, and (4) type of grinding machine.

In addition, the selection of the grinding wheel is influenced by the five variable factors that are under the control of the user. The variable factors to consider are: (1) wheel speed, (2) work speed (pressure, if off-hand grinding), (3) condition of the grinding machine, (4) skill of the workman, and (5) use of coolant or lubricant.

Selection of the Grinding Wheel. Too often it is wrongly believed that a knowledge of the material to be ground is all that is needed to enable one to select the proper grinding wheel for a given job. An analysis of the steel, if that happens to be the material, will help in the choice of abrasive and, to a certain extent, in the choice of structure number. However, other essential factors must be considered before a dependable selection of wheel can be made.

Factors Affecting the Selection of the Abrasive. The mechanical properties of the material to be ground affect the selection of abrasive. Aluminum oxide is used for materials of high tensile stress, such as carbon, alloy and high speed steels, annealed malleable iron, wrought iron and strong bronzes. Silicon carbide is used for materials of low tensile strength, such as aluminum, copper, brass, soft bronzes, gray iron, chilled iron and cemented carbides.

One form of aluminum oxide may be better than another; for example, heavy cuts on carbon steel may require the regular, tough aluminum oxide abrasive while light cuts on high speed steel will require one of the modified forms of friable aluminum oxide for cooler cutting action.

Factors Affecting the Selection of Abrasive Grain Size.

1 *Amount of material to be removed.* Coarse grit size for fast cutting. (Exception—very hard materials where depth of grain penetration is small.)

2 *Finish desired.* Fine grain for fine finish.

3 *Mechanical properties of material to be ground.* Coarse grain for soft ductile materials and fine grain for hard and brittle materials.

Factors Affecting the Selection of the Grade.

1 *Mechanical properties of material to be ground.* Hard grades for soft materials; soft grades for hard materials.

2 *Area of contact.* The smaller the area of contact, the harder the grade should be.

3 *Wheel speed and work speed.* The higher the wheel speed with relation to work speed, the softer the wheel should be.

4 *Condition of grinding machine.* Presence of vibration or worn master parts usually calls for harder grades.

5 *Skill of workman.* Skillful operators can use softer wheels than unskilled; softer wheels mean faster rate of production and lower grinding costs per piece when total grinding costs are considered, including overhead. The cost of the wheel, one of the smallest items of the total, will give a false cost per piece when it is considered alone.

Factors Affecting the Selection of Structure Number.

1 *Mechanical properties of material to be ground.* Soft, tough, and ductile materials require a wide relative spacing of the abrasive grains designated by high structure numbers such as 8, 9, 10, 11 and 12. Conversely, hard brittle materials usually require a wheel with a low number.

2 *Finish required.* Fine finish requires wheels with close relative spacing of the abrasive grains and designated by low structure numbers, such as 3, 4 and 5.

3 *Kind of grinding.* Operations with flexible application of pressure, such as snagging, require high structure numbers. Surfacing operations call for high structure numbers. Cylindrical, centerless and tool grinding usually work best with medium structure numbers. Heavy pressures, which tend to destroy the form of shaped wheels, call for low structure numbers.

Factors Affecting the Selection of Bond.

1 *Dimensions of wheel.* Thin cutting-off wheels and others subjected to deflection strains require resinoid, shellac or rubber bonds. Wheels more than 42 in. in diam and made in one piece, are usually of silicate bond.

2 *Operating speed.* Vitrified bonds are usually best for speeds slower than 6500 sfpm. Resinoid, shellac or rubber bonds are necessary for speeds greater than 6500 sfpm.

3 *Finish required.* Resinoid, rubber or shellac bonds are generally best for high finish.

4 *Kind of operation.* Vitrified bonds for fast cutting with long service in production or precision grinding. Silicate bonds are suitable for grinding edge tools, cutlery and some machine knives, where heat generated in grinding must be kept at a minimum. Shellac bonds are satisfactory for grinding camshafts and rolls. Resinoid bonds are preferable for high-speed snagging wheels in foundries and billet shops and for cutting-off jobs. Rubber serves best as bonding material for centerless feed wheels and for race grinding, deburring, polishing, cutting-off operations with minimum burning and burr, and snagging operations where finish is important. Magnesite bonds are used for certain types of disk grinding.

Truing and Dressing the Grinding Wheel. *Truing.* A grinding wheel is trued in order to restore its cutting face to accuracy in running, so that it will produce perfectly round (or flat) and smooth work; or to alter the cutting face for grinding special contours.

Dressing. A grinding wheel is dressed in order to improve or to alter its cutting action. Dressing removes the outside layer of dulled abrasive grains or any loading, and may be considered a sharpening operation.

Crush Dressing. A formed crusher applied to the wheel face quickly forms the grinding wheel to the desired shape. Crush dressing permits a more rapid rate of production of formed parts. In addition, it permits grinding of intricate forms that could not be ground with a wheel trued by a diamond. Grinding is cooler and freer than with other methods of dressing. Finish is not quite so good, as determined by measurement.

Coolants, Lubricants and Treatments. The importance of the proper coolant, lubricant or wheel treatment is becoming more apparent each year. Some grinding operations cannot be performed without the correct preparation.

Coolants. The essential purpose is to cool the work and to prevent it from rusting. The use of oils or compounds that are soluble in water will permit faster removal of stock and more pieces per dressing than are possible with dry grinding.

Lubricants. Usually grinding oils have advantages over soluble oils. They allow the wheel to grind in a free-cutting manner with a minimum of wheel breakdown. There is less loading, so the wheel holds its original dressed or trued condition longer and, as a result, stays sharp longer. In fact, the grinding wheel serves four times longer when used with grinding oils instead of soluble oils. In the grinding of some materials even greater benefits are obtained. For these reasons it is advisable to use grinding oils for form grinding or with crush-dressed wheels. The temperature of the work material must be watched in order to permit grinding to the correct size.

Treatments. When dry grinding must be used, especially on nonferrous materials, the grinding wheel becomes loaded quickly. Various materials or treatments are used to impregnate the abrasive wheel for the purpose of improving the grinding action and reducing the tendency to load.

Wheels of Open Structure. In recent years a grinding wheel with especially large pores has been introduced. The special structure gives such wheels a distinctive porous appearance. They are made with vitrified or resinoid bonds and in soft grades are used for broad contact grinding, tool and cutter grinding, surface grinding, and internal grinding of holes that have a large diameter. They are especially useful when grinding tough, ductile, stringy materials.

Causes, Detection and Prevention of Cracking. *Causes.* When cracks appear in ground steel surfaces, grinding is not necessarily the sole cause. Cracks form in hardened steel at spots where stresses exceed the rupture strength of the metal.

Improper grinding procedure may cause cracking from excessive depth of cut, inadequate cooling of the work, improper dressing, or use of too hard a grinding wheel.

Detection. During grinding, if the surface of a piece of hardened steel is found to be cracked and proves to have been burned, then the grinding operation is probably responsible and should be improved. A burned structure may not be visible, since it may have been cleaned off in grinding, but it can be detected by etching the surface in 10% nital or dilute nitric acid, a treatment that makes the burned portion turn dark.

Prevention and Remedies. When retained austenite, untempered martensite or grain-boundary cementite is eliminated by heat treatment, the susceptibility to cracking is greatly decreased. Some of the more common remedies for unsatisfactory grinding are:

Dressing to keep the wheel sharp
A softer grade of grinding wheel
Slower speed of the wheel or increased speed of the work metal
A narrower wheel or area of contact
In wet grinding, a copious supply of coolant on the work
An increase in the rate of traverse
A cooler cutting wheel—"open structure" or porous
In some instances, a beneficial change from wet to dry grinding

Cutting Fluids for Machining

By O. W. Boston and the Subcommittee on Cutting Fluids*

CUTTING FLUIDS, frequently referred to as lubricants or coolants, consist of those liquids, solids and gases applied to the material being cut and to the tool used in order to facilitate the cutting operation. Lubricants for cutting operations are recommended in this article.

In metal cutting, it is desirable to have high cutting speed, long tool life, low cutting temperature, low consumption of power, the best surface finish, well-broken chips and freedom from corrosion. In different operations these factors vary in importance and usually some are obtained at the expense of others. For instance, in heavy roughing cuts, temperature is of little consequence because minimum distortion and high surface finish are not required. In screw-machine work, however, surface finish, dimensional accuracy as affecting interchangeability, and long tool life are of great importance. For either type of work, desired results are obtained by varying the tool material and shape, the cutting speed, feed, and depth of cut, the structure of material cut, and cutting fluid.

Purpose of Cutting Fluids. A cutting fluid is used for the following purposes: (1) to keep the tool cool, preventing it from becoming heated to a temperature at which the hardness and resistance to abrasion are reduced; (2) to keep the work material cool, thus preventing it from being machined in a warped shape and having consequently inaccurate final dimensions; (3) possibly through lubrication to reduce the power consumption, wear on the tool, and the generation of heat; (4) to provide a good finish on the work; (5) to aid in a satisfactory formation of chips; (6) to wash away the chips (a function particularly desirable in drilling deep holes, hacksawing, milling and grinding); (7) to prevent corrosion of the work piece and machine; (8) to lubricate moving machine parts near the cutting tool.

Classification of Cutting Fluids or Coolants. Cutting fluids and coolants may be divided into the following classes: (1) air used as suction or blast, (2) water, either plain or containing an alkali, (3) emulsions of a soluble oil or paste, (4) oils, such as mineral, fixed, compounded, sulfurized, chlorinated and sulfurchlorinated.

Types of Cutting Fluids and Their Applications. Air is often used as a suction for internal and surface grinding and polishing operations or for grinding and boring operations on gray iron. The main purpose is to remove the small chips or dust from the air, but the temperature is decreased somewhat also. This is referred to as dry cutting.

Water solutions, containing as much as 1 or 2% by weight of an alkali, such as borax, sodium carbonate or trisodium phosphate, have high cooling properties and sufficient corrosion-prevention properties for some jobs. They are inexpensive and are sometimes used for grinding, drilling, sawing, light milling, or turning operations.

Emulsions consist of a soluble emulsifying oil or paste emulsified with water in the ratio of 1 part oil to 10 to 100 parts of water, depending on the type of product and the operation. This inexpensive cutting fluid is used for nearly all types of cutting and grinding in the machining of all types of metals. The richer mixtures of oil and water, such as 1 to 10, are used for broaching, threading, and gear cutting, where an oil is not required in order to secure the desired surface finish or machine lubrication. For most operations a solution of 1 part soluble oil to 20 parts water will be satisfactory for turret lathe work, some screw-machine work, gear hobbing, milling and drilling. Leaner mixtures may be used in simple turning or drilling operations. Lean mixtures, such as 1 to 50 or even 1 to 100, may be used for some drilling and most grinding operations. Often the concentration of the emulsion is determined by the requirements for preventing rust on the metal being machined, or by the requirements for lubricating the machine, and not by the actual machining operation.

* The members of this subcommittee are O. W. Boston, *Chairman* (University of Michigan), E. J. Hergenroether (International Nickel Company, Inc.), H. L. Moir (Pure Oil Company), W. H. Oldacre (D. A. Stuart and Company) and E. M. Slaughter (Republic Steel Corporation).

The preparation of this article has been facilitated by the contributions of Joseph Geschelin, Technical Editor, "Automotive Industries".

A variety of oils are used for the cutting of metal where machine lubrication is essential, or where a high-grade finish is desirable at low speeds, although superior finishes are obtained sometimes with the emulsions. Oils should have a Saybolt viscosity of 80 to 160 at 100 F. Plain mineral oil, fixed oil, compounded oils are used, or oil with additives—sulfur, chlorine, graphite and such—to improve the properties of the oil or to impart new properties to the oil.

Sulfurized oils are used generally as cutting fluids for rapid production involving good surface finish and close tolerances on metals difficult to machine. These sulfurized oils may be classified in three groups, as follows:

1 Sulfurized mineral oils. These cutting fluids contain as much as 4% active sulfur in straight mineral oil.

2 Sulfurized compounded oils. These oils are combinations of fatty oils, such as lard, rapeseed, degras, sulfur and petroleum oils.

3 Sulfurized-base oils. These are concentrates of fatty oils containing relatively high percentages of sulfur compounds, which the user blends with mineral oil to meet individual requirements.

Sulfurized oils are used extensively in broaching, gear cutting, automatic screw-machine work involving threading and tapping on straight carbon or alloyed steels and hot rolled steels. Sulfurized oils are satisfactory also for machining stainless steel, high-nickel alloys and copper; however, because sulfur stains copper, mineral-lard oil (5 to 10% lard) is more often used.

In addition to the above, various chemicals such as phosphorus and chlorine compounds may be used in cutting fluids. Graphite, mica, white lead and similar solids are sometimes used. Further applications of cutting fluids for copper, aluminum, steel and zinc are discussed below.

Quantity of Cutting Fluid. Best results are obtained when any of the cutting fluids is applied to the work and tool in ample quantity, such as 3 to 5 gal per min for each single-point tool, and at a temperature of 70 to 85 F.

Practical Cutting-Fluid Recommendations

To simplify and to clarify the use of a table of recommendations for the application of cutting fluids to various processes, involving different metals, the metals themselves are first classified in accordance with their machinability ratings when high speed steel tools are used. A wide variety of ferrous and nonferrous metals are rated individually and then arranged in the six classes of Table I.

Table I. The Six Classes of Metals for Which Cutting Fluids Are Recommended

Ferrous metals as compared with AISI B 1112 cold drawn steel	
Class 1	70% or more
Class 2	50% to 65%
Class 3	40% to 50%
Class 4	less than 40%
Nonferrous metals as compared with AISI B 1112 cold drawn steel	
Class 5	100% or more
Class 6	less than 100%

The machinability rating of each metal of the several groups has been given values to the nearest 5%. The various metals have then been grouped into classes, as shown in Table II, to facilitate the drawing up of the cutting-fluid chart. The ratings are based on steels in a cold drawn condition unless otherwise stated. Metals that have been heat treated or processed in any way other than by cold drawing will have different machinability ratings.

It is important to note that because of the favorable difference in price, many users prefer hot rolled steels for numerous purposes. The relative effect of hot rolling may be expressed very briefly as follows:

(*a*) In steels containing 0.30% C or less, cold rolled bars have better machinability than hot rolled bars.

(*b*) In steels containing from 0.30 to 0.40% C, there is little difference in machinability between cold rolled and hot rolled bars.

(*c*) In steels containing more than 0.40% C, the hot rolled material has machinability superior to that of the cold rolled or cold drawn. It is recommended that the carbon steels having 0.40% C or more and alloy steels having 0.30% C or more be annealed for machining; otherwise, lower cutting speeds are necessary. This also applies to paragraph (*b*).

The range of Brinell hardness values for each of the ferrous materials is intended to provide the most desirable limits for normal machinability ratings and, in general, describes the commercial practice in filling steel purchase orders. It is generally accepted that the limiting value of hardness for normal machinability is of the order of 355 Brinell, although many steels are now being machined in mass production at hardnesses of 400 Brinell and higher.

Factors influencing machinability are many. The ratings by tests often show greater variation because of different heats than because of a wide range in composition. Similar steels from different manufacturers may vary greatly in machinability. The relative rating of several materials when cut according to one size and shape of cut with one type of cutting fluid may be quite different if another cut, tool shape, tool material, or cutting fluid is used. The different processes, such as drilling, turning and milling, will yield different orders of ratings for a group of metals. Surface conditions, such as scale and hardness from cold working, may also vary the results. Because there is a lack of specific conditions for almost every variable, it is felt that these ratings are close enough to permit the production man to set up each job, and then from observation, to modify the setup to get best results.

Machining Operations Classified. A similar classification has been given to machining operations, arranging them in the order of severity; for example, the most severe operation (No. I, Table III) is internal broaching, and the easiest (No. 10) is sawing.

Recommendations. Table III indicates the severity of the operation and lists the cutting fluid recommended for each class of metal. Those who use this table may profit by the following general notes on selecting cutting fluids.

The preferred recommendations in **bold face** in Table III are based on general practice and on the results of a survey. The recommendations are intended to serve only as a guide in selection of a cutting fluid. Selection of a suitable fluid should be based on the individual operation; the material being machined; the tool, its material, size and shape; the conditions of operation, such as speed, depth of cut and feed; and the results desired in tool life, chip formation and finish.

The function of this report is to correlate recommendations from general use and practice, together with suggestions for each specific cutting problem. These recommendations represent the average practice of the majority of users of cutting fluids when normal operating conditions are maintained.

It is possible to determine the proper cutting fluid for these normal operating conditions by referring to the table; for example, a normal milling operation, where the operating condition is within the limits specified by the manufacturer of the machine, and the steel of one class as given in the table. However, if a deeper cut, higher cutting speed, heavier feed or the like is desired, it will be necessary for the fabricator to use the table as a guide in placing the operation in the proper classification of severity, indicating the cutting oils recommended for the more severe operation.

In Table III the recommendations for cutting fluids are necessarily types of fluids rather than the specific products of individual companies. This should be remembered in the purchase of such fluids, since two fluids of the same type may be quite different in effectiveness on a given machining operation, because of different manufacturing techniques of the producers.

It is possible to classify these cutting fluids considerably farther and perhaps more specifically. However, such a breakdown of operations, together with the various cutting fluids, feeds, cutting speeds, depth of cut, and the like, makes the analysis bulky and unwieldy. Such a list of recommendations would be difficult to interpret.

Generally, mineral-lard oil and sulfurized oil mixtures that contain low percentages of sulfur are interchangeable.

Table II. Machinability Rating of Ferrous Metals of Four Class Groups and Nonferrous Metals of Two Class Groups*

Class 1. Ferrous (70% and higher)

AISI	Rating, per cent	Brinell
C 1109	85	137 to 166
C 1115	85	143 to 179
C 1117	85	143 to 179
C 1118	80	143 to 179
C 1120	80	143 to 179
C 1132	75	187 to 229
C 1137	70	187 to 229
C 1022	70	159 to 192
C 1016	70	137 to 174
B 1111	95	179 to 229
B 1112	100	179 to 229
B 1113	135	179 to 229
A 4023	70	156 to 207
A 4027*	70	166 to 212
Malleable iron, standard	120	110 to 145
Malleable iron, pearlitic	90	180 to 200
Malleable iron, pearlitic	80	200 to 240
Cast steel (0.35% C)	70	170 to 212
Stainless iron, 12% Cr (Free cutting)	70	163 to 207

* Denotes steel in mill-annealed condition

Class 2. Ferrous (50% to 65%)

AISI	Rating, per cent	Brinell
C 1141	65	183 to 241
C 1020	65	137 to 174
C 1030	65	170 to 212
C 1035	65	174 to 217
C 1040*	60	179 to 229
C 1045*	60	179 to 229
A 2317	55	174 to 217
A 3120	60	163 to 207
A 3130*	55	179 to 217
A 3140*	55	187 to 229
A 3145*	50	187 to 235
A 4032*	65	170 to 229
A 4037*	65	179 to 229
A 4042*	60	183 to 235
A 4047*	55	183 to 235
A 4130*	65	187 to 229
A 4137*	60	187 to 229
A 4145*	55	187 to 229
A 4150*	50	187 to 235
A 4320	55	197 to 228
A 4615	65	174 to 217
A 4640*	55	187 to 235
A 4815	50	187 to 229
A 5120	65	170 to 212
A 5140*	60	174 to 229
A 5150*	55	179 to 235
A 8620 or 8720	60	170 to 217
A 8630* or 8730*	65	179 to 229
A 8640* or 8740*	60	179 to 229
A 8645* or 8745*	55	183 to 235
A 8650* or 8750*	50	183 to 241
A 9420	60	170 to 217
A 9440*	60	187 to 235
Cast iron, soft	80	160 to 193
Cast iron, medium	65	193 to 220
Cast iron, hard	50	220 to 240

* Denotes steel in mill-annealed condition

Class 3, Ferrous (40% to 50%)

AISI	Rating, per cent	Brinell
C 1008	50	126 to 163
C 1010	50	131 to 170
C 1015	50	131 to 170
C 1050*	50	179 to 229
C 1070*	45	183 to 241
A 1320	50	170 to 229

Sulfurized oils have a tendency to stain certain nonferrous metals, such as copper and its alloys; therefore mineral-lard oil is more often used on these metals.

Certain materials, such as carbon tetrachloride, chloroform and other volatile solvents, should not be added to cutting fluids, since harmful physiological effects may follow.

In the machining of aluminum, cutting oils are often diluted with kerosene or mineral seal oil with satisfactory results. Kerosene, in amounts as large as 15%, is frequently added to emulsions to improve the surface quality of machined aluminum. For further information, see "Machining Aluminum Alloys".

Magnesium and its alloys are usually machined with mineral seal oil, except where it is desirable to machine dry. A supply of clean cast-iron chips in powdered form, or pitch or graphite should be kept handy to smother a sudden fire. Tools should be kept sharp and heavy feeds should be used. Chips should not be permitted to accumulate on the machine. For more data, see "Machining Magnesium Alloys".

* Each metal is rated to the nearest 5% based on the 100% rating of AISI steel specification B 1112, cold rolled or cold drawn, when machined with a suitable cutting fluid at 180 fpm under normal cutting conditions using high speed steel tools.

Symbols for Cutting Fluids

K	Kerosene
L	Lard oil
MO	Mineral oils
ML	Mineral-lard oils
Dry	No cutting fluid
Sulf	Sulfurized oils; see note (a)
Em	Soluble or emulsifiable oils and compounds

(a) Oils containing both sulfur and chlorine, when carefully manufactured and sponsored, may be used where sulfurized oils are indicated.
(b) Preferred recommendations are in **bold face** type.
(c) In threading copper, palm oil is frequently used.
(d) It has been reported by several observers that emulsions are usually unsatisfactory on some precision machine tools such as Fellows Gear Shapers and Gleason Gear Generators.

In machining brass, which shows no change in cutting pressures with various cutting fluids, it is advisable to apply a cutting fluid to function as a coolant. Since most free-cutting brass is machined in automatic screw machines, an oil is advisable for lubricating the moving parts of the machine. A paraffin or light mineral oil may suffice, or the mineral oil blended with 10% fatty oil may be used to advantage.

Zinc may be drilled, threaded and turned with common emulsions. The parts should then be worked in an alkaline cleaner, rinsed in hot and cold waters and dried.

In turning monel metal, it has been found that an emulsion permits slightly longer tool life than a sulfurized mineral oil. However, the latter produces broken chips, in many instances desirable. Also see the article entitled "Machining Nickel and Nickel Alloys".

In general, cutting fluids should be applied in large quantities at the highest velocity possible without splashing, directly on the point of the tool where the chip is being formed. From 3 to 5 gal for each single-point tool is most effective. Particularly when carbide tools are used, the cutting fluid should flood the tool before the start of the cut and be applied continuously during the cut. A rapid change in temperature is injurious to most tools.

Cutting fluids should be kept cool, either by sufficient volume or by cooling agents. For satisfactory tool life, the temperature of the cutting fluid should not be permitted to exceed 110 F.

Cutting fluids should be kept clean, and free from suspended chips, bacteria and high acidity.

Oils should be used on complicated machines, where parts such as tool slides must be lubricated. On some types of work, such as milling and drilling, lubrication of the chips in the flutes or chip space is an important factor in removal of the chips.

In high-speed operations, cooling is more important than lubrication, since the speed itself usually provides good surface quality. At low speeds, where the segmental or discontinuous type of chip is formed, the face of the tool may be lubricated periodically; consequently oils are desirable, particularly a sulfurized oil for threading and broaching.

Lubrication for Forming and Wire Drawing

By B. H. McGar*

THIS ARTICLE deals with the lubrication of aluminum, copper and brass, steel, and zinc during forming and wire-drawing processes.

Aluminum. When light-gage aluminum strip is being drawn, a petroleum oil that has a Saybolt viscosity of 100 to 200 at 100 F will give satisfactory lubrication; or a lubricant may be used that is composed of 75% petroleum oil with a Saybolt viscosity of 200 at 100 F, and 25% lard oil with a maximum content of free fatty acid of 3%. On light-gage difficult draws, a lubricant is satisfactory that is composed of 50% high-viscosity petroleum oil and 50% lard oil having a maximum free fatty acid content of 3%. For heavy-gage aluminum a straight oil that is low in content of free fatty acid should be used.

Aluminum wire can be drawn dry by using grease, powdered soap, or a mixture of calcium carbonate and fatty oil, such as lard oil. If a bright, clean finish is desired, it is customary to use either grease or the mixture of fatty oil and calcium carbonate. When wire is to be drawn wet, a light petroleum oil plus a fatty oil is used.

Copper and Brass. A suitable lubricant must be used as an aid in forming and drawing strip copper and brass. For most operations, an aqueous solution (3 to 5% by weight) made from a good grade of soap powder or chips will furnish an excellent lubricant. The solution should be kept slightly warm to prevent it from forming a gel. For

* Asst. Director of Research, Chase Brass & Copper Co., Waterbury, Conn.

more intricate operations it is sometimes necessary to use a 3% aqueous solution of a soap-fatty oil compound composed of approximately 50% free fats, 15% soap, and 35% moisture. Compounds of this general character are readily obtainable on the market. Before the drawing operation, the strip of copper or brass can be completely submerged in the lubricant and drained, or the solution can be applied with a swab or, better still, applied by felt rollers that pick up the lubricant and distribute it evenly over the surface of the strip as it is fed into the press. Partly formed or drawn articles are immersed in the solution and are then allowed to drain before being placed in the press again for redrawing. On large-scale production it is feasible to spray a hot (175 F) 6% soap solution on the partially formed articles and dry the soap on the pieces with a blast of hot air. The adherent soap film provides an excellent lubricant for the subsequent operation. Regardless of whether the brass articles are to be left in the as-drawn condition or later annealed, it is good practice to wash them shortly after drawing to prevent red stains. The lubricant can be removed from the articles in a suitable alkaline cleaner, which may be composed of the proper mixture of caustic soda, soda ash, trisodium phosphate and sodium orthosilicate, together with a wetting agent. Usually 3 to 4 oz of cleaner is added to 1 gal of water and used at approximately 185 F. The articles are then thoroughly rinsed in both cold water and hot water and dried.

Copper wire and brass wire are sometimes drawn dry with powdered soap, but ordinarily the wet drawing method is used. A suitable lubricant is obtained by making a water emulsion with a soap-fatty oil compound and controlling the free fat content from 2 to 3%. The solution should be circulated through the machines so that the proper amount of lubricant will fall on the dies and the wire while it is being drawn. It is also essential to control the temperature of the drawing solution, and for that reason a large amount of the solution should be used and cooled in tanks for this purpose, before being recirculated on the machines. It is also common practice in the brass industry to use fermented bran liquor as a lubricant for drawing brass wire. The objection to using such a solution is its offensive odor, but the solution provides adequate lubrication and is inexpensive. The solution is made by adding approximately 1 lb of wheat bran and middlings to 5 gal of water, and allowing them to ferment in a tank for at least one week. The resulting liquor is filtered and used directly in the wire-drawing machines. When a comparatively small reduction is required on brass wire, powdered soap may be used in the die block. Occasionally this soap should be paddled so as to prevent channeling, and the operator should see that the wire comes in contact with the soap before entering the die. Another lubricant used for making small reductions on brass wire is a solution made by adding ¼ lb of powdered soap or chips to 1 gal of water, and the temperature of the bath should be kept at approximately 185 F. The coils of brass wire are completely submerged in this solution, then drained for a short period, and the wire is ready to draw without any additional lubricant other than that which clings to the surface of the wire.

Steel. When forming, drawing, and stamping soft, light-gage steel strip or sheet, a suitable lubricant can be made by adding ¼ lb of deodorized fish-oil soap to 1 gal of water, or by using a light petroleum oil that has a Saybolt viscosity of 100 to 200 at 100 F. Satisfactory results may also be obtained by applying a heavy emulsion composed of 1 part naphthenic-base soap to 4 or 5 parts of water. When a deep or intricate draw is required, a satisfactory emulsion is one made of 1 part of soap-fatty oil compound, consisting of 50% free fats, 15% soap, and 35% moisture, with 3 parts of water. Some operators prefer to use a solution composed of 5 parts of water and 1 part of a filled drawing compound, the latter having a composition of approximately 15% soap, 20% filler (such as talc, fine clay, calcium carbonate, barium sulfate), 30% free fats, and 35% moisture. For light drawing of medium-gage sheet steel, 1 part of filled drawing compound and 2 parts of water is a suitable lubricant. Also, a solution may be used that is made by adding ½ lb of deodorized fish-oil soap to 1 gal of water. When deep drawing the heavier gages it is common practice to use filled compounds composed of 40 to 60% filler and 40 to 60% free fats without dilution. It is also possible to use straight sulfur-base oil for such operations. When selecting a lubricant for any of the above operations, some care and thought should be given to subsequent operations and what type of finish will be applied to the article ultimately, since the cleaning problem might present difficulties.

Steel wire is drawn dry with powdered soap, powdered soap plus lime, aluminum stearate, grease, or grease and lime mixtures. The wire is usually coated with lime before drawing, or covered with a proprietary coating compound. For wet-drawing intermediate gage steel wire, including copper-coated and zinc-coated wire, a water emulsion made from a soap-fatty oil compound makes a satisfactory lubricant, and the free fat content should be controlled at approximately 3%. Fine wire is usually drawn with a soap solution or with an emulsion made from a compound containing a large amount of soap and a small amount of free fat. The emulsion should be controlled so as to have a free fat content of about 1.5% and a pH of 9. The drawing lubricants should be circulated in the machines and cooled in tanks as in the drawing of copper and brass wire. Stainless steel is usually drawn with a petroleum oil plus an extreme pressure additive, or a sulfated base soluble oil containing an extreme pressure additive. The lubricants used for stainless steel will also give satisfactory results for drawing Inconel and Monel wire.

Zinc. Zinc may be drawn successfully in a 3 to 5% aqueous soap solution. Sometimes it has been found beneficial to add to this solution a small portion of lard oil. The lubricant may be applied to the sheet zinc in any of the ways mentioned under copper and brass.

Zinc wire may be drawn in an emulsion made from a compound low in soap content, high in free fat content; the free fat in the lubricant should be controlled between 2 and 3%. Care should be taken to keep the emulsion as nearly neutral as possible to prevent the formation of zinc salts that will render the lubricant useless.

Welding Processes

BY THE SUBCOMMITTEE ON WELDING AND CUTTING*

THIS article outlines and discusses the metallurgical aspects of fusion welding and certain allied processes. Recent remarkable advances have given welding a dominant place in the metal industries. It has become common practice to shape and prepare metal parts and then join them by welding to produce engineering structures.

The aim is not to describe at length the equipment and the technique used in applying the various welding processes. Instead, the metallurgical features that affect the satisfactory welding of metals will be analyzed; some methods of inspecting and testing to determine weld quality will be presented; and hazards and safety precautions will be discussed briefly. For more detailed information concerning the application of the various welding processes to particular ferrous and nonferrous metals, the reader may refer to the sections of this Handbook listed at the end of this article.

Since "fusion welding" is defined fundamentally as a group of processes in which metals are joined by bringing them to the molten state at the abutting surfaces, the importance of the effect of heat in all welding operations must be recognized. Welding is usually employed to unite like metals where the joining is required to develop strength and transmit stress.

General Considerations. The metallurgical, chemical, physical, and thermal characteristics of metals greatly influence their weldability. The weld has been defined as "a localized union or consolidation of metals". A number of processes can accomplish such a union, but all processes now in general use have two characteristics in common. First, the union or consolidation is localized; and second, the weld is accomplished in a comparatively short time and frequently in a progressive manner. Thus a small volume in a large mass of cold metal is heated from room temperature to a high temperature and cooled again immediately to a temperature lower than black heat. For ferrous metals, the high temperature is above the transformation range.

In fusion processes the temperature frequently rises considerably higher than the melting point and all temperatures within the indicated range are present at the same time in bordering zones. Throughout the temperature range required by the process, thermal changes such as expansion and contraction must be considered, as well as metallurgical effects such as crystallization and heat treatment; chemical reactions; and changes in physical characteristics, such as strength and ductility.

The simplest phenomenon that occurs in metals during heating is expansion. In the initial stages, expansion is purely a change of volume and in most metals is a completely reversible change regardless of the rate of heating or cooling. At the same time that they are expanding, most metals become increasingly soft, ductile and weak, a fact that is both an advantage and a disadvantage. Consequently stresses become dissipated and advantageously spread over the heated area because the metal can stretch and yield with ease. On the other hand, the low strength at these elevated temperatures makes it necessary to be certain that the piece being welded is free to move so that too great a load will not be placed on the hot metal. Some metals become so weak that it is necessary to support them to prevent buckling or other change of shape.

Particular attention must be paid to the final weld of a closed structure or to the joining of a light section to a heavy section, in order to reduce the residual stress in the structure to a minimum.* Metals that have a high rate of thermal conductivity present a particular problem because the heat is generally spread over a wider area and thus the expansion is greater; also such metals usually undergo a much greater reduction in strength during heating and frequently require support to prevent buckling.

Most common metals react with oxygen of the atmosphere. At higher temperatures the rate of oxidation increases rapidly. Nitrogen from the air also reacts with some metals, forming nitrides, which tend to increase the strength and reduce the ductility. These conditions can be prevented by protecting the molten metal from contact with the atmosphere.

Because weld metal cools rather rapidly, consideration must be given to the effect of gases, either dissolved or entrapped, in the molten weld metal. To ensure sound welds, free from porosity, the molten metal must be free from these gases before it solidifies.

In fusion welding processes metals under the effect of heat are subject to the same thermal, chemical, physical, and metallurgical changes involved in the manufacture of metals. In the welding of steel, for example, the weld is in some respects a steel casting made in a steel mold and the metal of this casting comes either from the steel mold itself or from a combination of the steel mold and the welding rod or electrode. In gas welding, the heat applied to both the mold and the rod is from external sources. In arc welding, the heat results from electrical energy that passes through both the electrode and the mold.

* The members of this subcommittee are C. W. Obert, *Chairman* (The Linde Air Products Company), C. L. Altenburger (Great Lakes Steel Corporation), Roger W. Clark (General Electric Company), C. H. Jennings (Westinghouse Electric Corporation), H. L. Maxwell (E. I. du Pont de Nemours & Company), H. R. Morrison (The Linde Air Products Company) and E. H. Roper (Air Reduction Sales Co.).

* The relief of residual stresses in weldments and other structures is discussed in the article on page 237. The reader may refer to that article for a statement of the principles of stress relieving and a summary of certain code requirements for the relief of stresses in welded products. The codes summarized include especially those relating to fusion-welded pressure vessels and pressure piping.

Pressure Welding Processes

Forge Welding. This is the oldest welding process and the only one in which the general practice antedates the twentieth century. It is essentially a process of joining metal pieces that have been heated, within the area of joining, to a condition that approaches plasticity on the surface. As soon as the plastic condition is reached, the parts are quickly superimposed and worked into complete union, either by hammering or by pressure. The hammering is performed either manually or by machine and the force of the hammering or pressure depends largely on the size and mass of the pieces or parts that are being joined.

Oxyacetylene Pressure Welding. There are two methods by which gas welding utilizes pressure to make the weld. In the first, carefully machined and cleaned ends of pieces are butted tightly together under pressure; then the heat is applied. This application of pressure welding is characterized by the fact that the bond is formed by diffusion and recrystallization at a temperature lower than the melting point of the materials being joined. Closed-face pressure welding is the only process effecting the bond completely in the solid phase. The second method involves heating with flames impinging directly on the welding faces, which have been spaced a short distance apart. These faces have previously been made substantially square. When the ends of the pieces have been brought to the fusion point the parts are brought rapidly together under pressure to effect the weld. In both processes an upset is created by the shortening of the parts. No filler metal is added in either process.

In oxyacetylene pressure welding, the strength of the joint can be made equal to that of the base metal. The finished weld is homogeneous and there is no evidence of the juncture except where steels of different alloy content have been joined. Dissimilar metals react differently to an etching reagent and the area of the joint can be detected although no fine line of demarcation exists under microscopic inspection.

Oxyacetylene pressure welding has been applied successfully to the complete range of carbon steels, to both high-alloy and low-alloy steels and to many nonferrous metals. Pressure welding is used for safe-ending boiler tubes, laying cross-country transmission lines for both oil and gas, railroad rails, aircraft landing struts, propeller hubs and 8-in. diam steam forging-hammer rods, to name only a few of the important applications of the process.

The equipment required for oxyacetylene pressure welding is relatively simple compared with other mechanical welding processes. Heating arrangements and a source of pressure are the major equipment. Furthermore, the operating conditions are readily adaptable to complete mechanization and automatic control.

Resistance Welding. In this process, the surfaces to be joined are heated to the plastic condition by the passage of a heavy localized electric current accompanied by mechanical pressure to bring the parts into complete union. To produce the required heavy current at low voltage, alternating current has been found most convenient since, by the use of suitable transformers, almost any desired combination of current and voltage can be obtained. Only in special instances is direct current used for this purpose.

An important factor in all resistance processes is the composition of the electrode, which must possess good thermal and electrical conductivity combined with maximum hardness and sufficient strength. An excellent combination of these requirements has been achieved by the use of a hard copper electrode faced with one of several alloys that have hardness, under welding conditions, much greater than that of copper.

Resistance Butt Welding. In the butt-welding form of the resistance process, pieces are gripped mechanically and pressed together while heat is generated by passing a high electric current through the area of contact. The original upset method is a form of butt welding in which high mechanical pressure is applied and maintained throughout the operation, while the temperature is kept below melting. The extruded metal is upset into a roughly convex form which, if desired, may be molded to a predetermined shape in a die, thus securing a kind of drop forging; or it may be ground off. Today the upset method is generally combined with flashing. The flash method as first developed is a form of butt welding in which, after initial contact and heating, the parts are slightly separated during a brief period, thereby causing intense arcing. The weld is then completed under pressure and at a temperature sufficient to bring to a plastic state a portion of the metal that is partly extruded in the form of a thin burr, which may be ground off. This method is still employed for large pieces, but on smaller pieces the flashing effect that was secured in the original process by separation of the parts, is obtained automatically by successive adjustments of pressure. Because there is no hesitation in the cycle, this form of flash welding is quite rapid.

Resistance Spot Welding. In the spot-welding form of the resistance process, two or more sheets of base metal are held between metal electrodes that pass a large current of fairly low voltage through the sheets. Immediately following this, and with current maintained, the electrodes are forced together with sufficient mechanical pressure to unite the surface of the sheets in a spot approximately the same size as the end of the electrodes. This pressure is maintained until after the current has been cut off.

Resistance Projection Welding. In resistance projection welding, small projections are formed on one or both pieces of base metal to localize the current.

Resistance Seam Welding. The seam-welding form of the resistance process is a series of overlapping welds. Two or more sheets of base metal are usually passed between electrode rollers, which transmit the current and also the mechanical pressure required for producing a welded seam. A current interrupter is used for this type of weld.

Resistance Percussion Welding. The percussive methods differ from the usual forms of resistance welding in that (1) a direct-current supply is essential; (2) there is a sudden discharge of electrical energy at the junction, with an arc, which is extinguished by a percussive blow; and (3) the surfaces united are partially fluid. The energy may be supplied by the discharge of a condenser (electrostatic) or transformed by the collapse of a magnetic field (electromagnetic).

Thermit Pressure Welding. This plastic welding process —used only for joining ferrous metals—differs from the forge and resistance welding processes principally in that the heating to plasticity is obtained from the thermit chemical reaction rather than from fire or electric current.

The chemical reaction that generates the heat required for welding is described later in this article under the heading Thermit Welding. The molten steel and the alumina slag are conducted around the abutting ends to be welded, in such a manner as to localize the heating as near the joint as possible. This requires a suitable mold, ordinarily made of light cast-iron segments, which can be clamped in position and then removed easily after the thermit reaction. This thermit reaction is controlled so that the alumina slag enters the mold first and leaves a coating on it and on the ends being joined, thus protecting these parts from the superheated iron. The passage of the iron through the mold brings the work to welding temperature in a short time, which varies from a few seconds to several minutes, depending on the size. Then a quick application of pressure completes the weld.

Fusion Welding Processes (Nonpressure)

These processes differ from those previously enumerated in that they depart from the union of plastic metals and utilize fusion of metal to effect the desired union. The joining is accomplished by the fusion of metal on or between the surfaces of the parts that are being united. The fused metal is generally obtained by deposit from an external source, although in some instances the abutting edges are merely fused together to form the joint.

Gas Welding. In this process, heat is supplied by the combustion of a suitable fuel gas with atmospheric or pure oxygen. The fuel gas and oxygen are mixed in a suitable torch, regulated to produce an impinging flame that has the desired characteristics. The gases most commonly

used are oxygen and acetylene, although hydrogen and other combustible gases are used to some extent.

Oxyacetylene Welding. In this form of fusion welding the heat required is supplied by the oxyacetylene flame. Usually in fusion welding, a filler metal is added in the form of welding rod to make the welded joint (Fig. 1), although occasionally in oxyacetylene welding, the parts to be joined are merely fused together without the addition of welding rod. To float out impurities or aid in obtaining a satisfactory bond, flux is employed in the welding of some metals, such as cast iron, certain alloy steels, and the nonferrous metals.

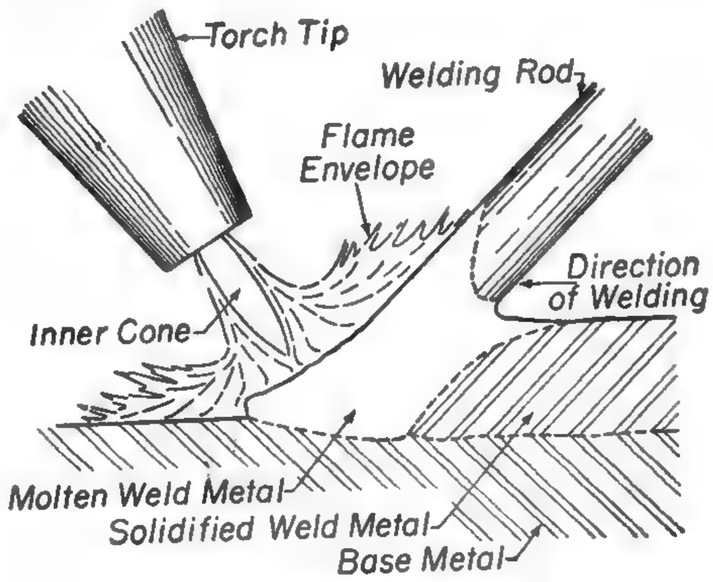

Fig. 1 Oxyacetylene welding

In the combustion of acetylene and oxygen the resulting flame has characteristics that indicate whether it is reducing, oxidizing, or carburizing in character (Fig. 2). If the acetylene and oxygen are in proportion, a neutral flame results. In most gas welding, the neutral flame is recommended; in some welding applications, however, a slightly carburizing or slightly oxidizing flame is considered desirable. Certain of the alloy steels are welded to advantage with a slightly reducing or carburizing flame, and under certain conditions a reducing flame is considered desirable.

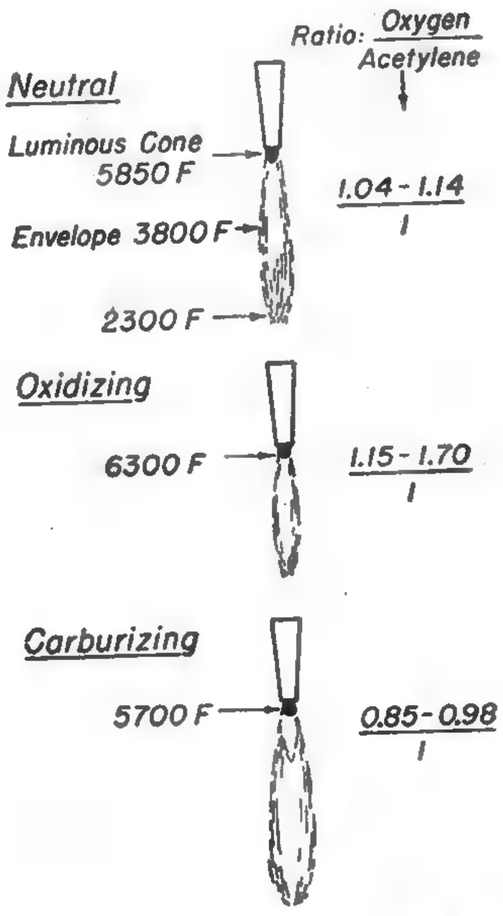

Fig. 2 Characteristics of oxyacetylene welding flame. For complete combustion of acetylene, 1 molecular volume (380 cu ft at 60 F) of acetylene, plus 2½ molecular volumes of oxygen burns to form 2 molecular volumes of carbon dioxide plus 1 molecular volume of water vapor, liberating 542,700 Btu of heat

An important characteristic of the oxyacetylene flame is that the outer envelope of the flame protects the molten metal from atmospheric attack. The oxygen surrounding this envelope of the flame is consumed in the final combustion stage.

Arc Welding. In arc welding, the surfaces to be joined are fused by the heat of an electric arc. Each of the three forms of arc welding derives its name from an identifying feature, such as the electrode material used or the means of transferring heat. These forms are carbon-arc welding, metal-arc welding, and atomic hydrogen arc welding.

Welding current for carbon-arc welding is always direct current. Metal-arc welding utilizes either direct or alternating current. Atomic hydrogen arc welding is ordinarily done with alternating current. Direct current for arc welding is obtained usually from a motor-generator set. The generator may be of either the variable-voltage single-operator type or the specially designed constant-voltage multiple-operator type with suitable controls. Rectifier units are also used for this purpose. For alternating current two methods are used: (1) the static transformer, which is a single-phase unit specially designed for arc welding and which uses various methods of control that are all of the variable-voltage single-operator type; and (2) the alternating-current method of rotating frequency-changer sets, which convert the usual frequency to several times that of the power supply line.

Carbon-Arc Welding. In this process the arc is usually drawn between a carbon or graphite pencil or electrode and the work material to be welded. The heat of the arc causes fusion of the base metal and, if additional metal is required, also fuses a filler rod that is fed into the joint at the desired rate. This process of welding may be accomplished either manually or mechanically. When performed by mechanical methods, this type of welding is commonly called "automatic" carbon-arc welding. The hand process is used only for special applications, largely on account of the erratic nature of such an arc. In the automatic process, the arc is controlled by superimposed magnetic fields.

Unshielded Carbon-Arc Welding. This term is applied when either type of carbon-arc welding is performed without the aid of appreciable amounts of flux. When applied to ferrous materials, unshielded carbon-arc welding is used on relatively unimportant joints only, but with proper procedure it is used to a considerable extent in the welding of deoxidized copper.

Shielded Carbon-Arc Welding. This process utilizes fluxes, in the form of treated paper, powder, paste or gas, or a combination of these. These fluxes have various functions—for example, to envelop the molten metal in a noncontaminating atmosphere to the exclusion of the oxygen and nitrogen of the air; to scavenge impurities from the molten metal; to retard the cooling rate of the weld metal; and to produce weld metal of the desired mechanical properties. This process is applied to most of the important joints to which the carbon arc is suited, generally in automatic form.

Metal-Arc Welding. In this process the arc is struck between a metal electrode and the work piece. The heat of the arc fuses not only the work material but also the electrode, which is in the form of a wire of suitable material. This fused electrode material passes through the arc and unites with the fused base metal to form the welded joint. The process is adaptable to either hand or automatic methods. There are two major classifications of metal-arc welding, *unshielded* and *shielded*. The term "unshielded" is applied when the electrode is either a bare wire (Fig. 3) or is lightly coated with small amounts of flux, sometimes called a "wash-coated" or "dust-coated" electrode.

In shielded metal-arc welding the metallic electrode is covered with a thick layer of fluxing ingredients with or without a fibrous binder (Fig. 4). These flux coverings function in several ways to produce weld metal of high mechanical properties and comparable with the base metal:

1 The flux coverings are usually consumed more slowly than the metal of the electrode, thus forming a cupped end that shields the arc partially from the air.

2 Combustion of the fluxes produces an envelope of gases around the arc, which excludes oxygen and nitrogen of the air from contact with the molten metal of the weld.

3 The fluxing ingredients scavenge impurities from the molten metal of the weld.

4 A protective slag covering is formed that covers the top of the weld and protects the molten metal from contamination by oxygen and nitrogen from the air; it also retards the cooling rate and thus partially heat treats the weld.

5 Alloying elements desired in the weld are sometimes supplied in the heavy flux coverings.

6 Materials are sometimes placed in the coatings to increase the arc stability by virtue of their ease of ionization or greater emission of electrons. Materials may also be added to make the flow of metal across the arc more uniform, by reducing the adhesive force between the molten metal and the end of the electrode, or by changing the surface tension of the molten metal so that globular formation is smaller and more uniform.

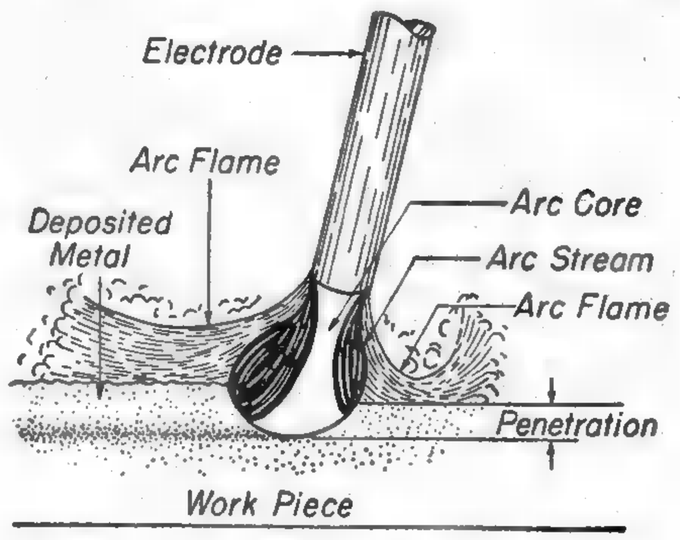

Fig. 3 Arc welding with bare electrode

Shielded-arc welding controls to such an extent the metallurgical processes involved in forming a weld that greater amounts of heat are generally used than without shielding. This results in greater welding speeds and at the same time physical properties in the weld metal equal to those of the base metal, and often superior.

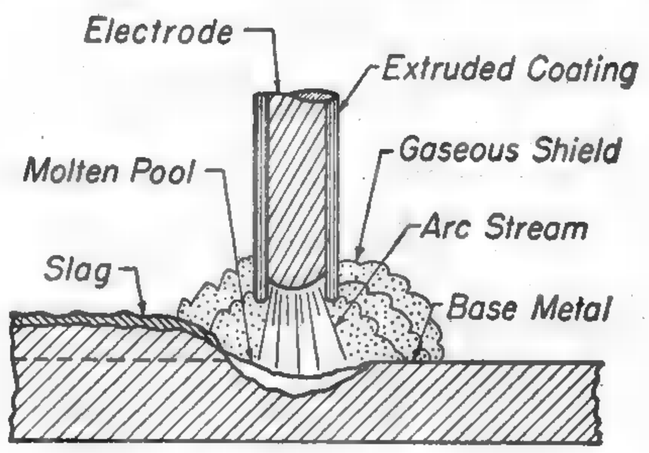

Fig. 4 Arc welding with shielded electrode

The average bare electrode deposit has from 0.11 to 0.15% nitrogen and about 0.3% oxygen (as oxides), while a shielded-arc electrode deposit contains from 0.010 to 0.023% nitrogen and about 0.068% oxygen. A comparison of the physical properties of typical all-weld-metal specimens is as follows:

	Bare Electrode	Shielded-Arc Electrode
Tensile strength, psi	40,000 to 60,000	65,000 to 85,000
Elongation in 2 in., %	5 to 10	20 to 30
Izod impact, ft-lb	5 to 15	50 to 80
Endurance limit, psi	12,000 to 15,000	28,000 to 32,000
Specific gravity	7.5 to 7.7	7.82 to 7.86
Corrosion resistance	poor	better than mild steel
Porosity detected by X-rays	considerable	almost no defects

Atomic Hydrogen Arc Welding. In the atomic hydrogen arc-welding process an alternating-current arc between two tungsten electrodes in a stream of hydrogen gas furnishes the source of heat. The arc column is defined by a thin brilliant line that forms a loop under the influence of its own magnetic field and the streaming gas. In this arc column, which has a temperature between 5500 and 6000 F, the hydrogen molecules are completely broken down into atoms, and during this process a great deal of energy is absorbed. When this atomic hydrogen flame, which is coincidental with the arc column, is placed in contact with the metal parts being welded, the dissociated hydrogen atoms recombine into molecules, giving to the surface the heat that was absorbed during dissociation. The weld metal may be supplied as surplus metal from the parts being welded, or may be added from a filler rod. The atomic hydrogen arc is surrounded by an envelope of hydrogen gas that protects the work material and electrodes from oxidation and reduces existing oxides in the metal. The operator can adjust the size of the atomic hydrogen arc by changing the electrode separation during operation; in this way an arc is obtainable that varies in size from ⅛ in. to more than 1 in. The freedom from oxidation, the intense concentration of heat, the flexibility and ease of operation, combined with freedom from magnetic blowing effects, are features that characterize atomic hydrogen arc welding.

Inert-Gas-Shielded Arc Welding. This is an electric-arc welding process that employs a blanket of monatomic inert gas to shield the weld area. Highly concentrated heat is produced by an arc drawn between a single, virtually nonconsumable tungsten electrode and the work piece. The inert gas (argon or helium) is fed through a nozzle surrounding the electrode in the head of the torch, and flows out to blanket the electrode completely, as well as the arc and weld puddle, for the total exclusion of the oxidizing atmosphere.

The process is used successfully for welding magnesium, aluminum, stainless steel, high-alloy steel, nickel and nickel alloys, brass, silicon bronze, pure silver and other metals. The outstanding characteristic is that all these metals can be welded without the use of flux. Because no flux is needed, corrosion from entrapment of flux in the weld is eliminated.

Among the conspicuous advantages of inert-gas-shielded arc welding are welds free from flux inclusions, slag and spatter. High speeds of welding are practical.

The equipment necessary consists of a torch, used to hold the electrode and to provide a means of getting the helium or argon around the weld; a tungsten electrode; a supply of inert gas, governed by a regulator and measured by a low-pressure flowmeter; and a source of electric current.

Either straight-polarity direct current or alternating current is used. The choice depends somewhat on the alloy and the thickness. Reverse-polarity direct current (electrode positive) has been used for welding magnesium, but many fabricators prefer alternating current because of its greater penetration, speed and range of thickness capacity. Likewise alternating current is almost always used for welding aluminum since straight-polarity direct current will not produce a satisfactory weld. For stainless steel, alloy steels and some copper alloys, either alternating current or direct current may be used. Alternating current is generally preferred for light material because of better arc stability. Direct current is favored for heavier material because of the deeper and narrower weld beads. Standard direct-current and alternating-current welding machines are employed; however, the latter must have a superimposed (low-power) high-frequency current for stabilizing the arc. Successful use has been made of high open-circuit voltage (200 to 300 v) transformers without high frequency for welding aluminum. These applications have been limited mostly to special mechanized operations.

Submerged-Melt Welding Process. This is a method of welding electrically beneath a protective layer of granular and molten mineral material. The process is used for welding virtually all steels, as well as other ferrous and nonferrous metals and alloys. The granular material is usually laid down directly ahead of the welding zone. In the welding zone, the granular material fuses and serves as a medium for conducting the welding current, concentrating the heat produced and protecting the weld from the effects of the atmosphere. Since the atmosphere is excluded from the weld, bare welding wire can be fed directly into the welding zone. There is no flash, glare, or spatter. The molten material also removes impurities from the weld, and as it cools it solidifies, forming a protective cover over the weld. When cool, the fused material cracks off, or can be removed easily. Because of the deep penetration, relatively small amounts of welding rod are required. The welds produced are dense, uniform, and are as strong as the parent metal, or stronger.

The use of the process is limited only by the capacity

of the equipment. With present equipment, material ranging from 22-gage sheet to 3-in. plate can be welded in a single pass. Material of any thickness can be welded by a suitable number of passes.

Speeds of about 200 in. per min can be used on thin material. The currents required vary with the material and are usually about 6 to 10 times those used with the manual electric-arc welding methods. A maximum of about 4000 amp can be applied with the present equipment. This would be approximately the current required to weld plates 3 in. thick in a single pass.

Because of the nature of the process, welds must be made in a horizontal, or nearly horizontal, position. Such welds can be made without special plate-edge preparation in material less than ½ in. thick. Thicker material is usually prepared with a single or double V. Single-pass butt welds are usually backed up by a copper strip or a layer of granular material pressed against the back of the weld. With this process, butt, fillet (positioned and non-positioned), and plug welds can be made.

The process has been widely used in the fabrication of pressure vessels, in shipbuilding, and in all types of steel fabrication where the material can be assembled and positioned suitably for welding. It has also been used in rebuilding worn surfaces or increasing wear resistance.

Thermit Welding. The thermit fusion process, commonly known as thermit welding, originated with a discovery made in Germany, in about 1900, by Dr. Hans Goldschmidt. He found that if a mixture of a metallic oxide and finely divided aluminum were ignited at one spot, the two materials would react exothermically and the reaction would progress throughout the mixture, thereby converting it into two new materials, a superheated mass of the metal itself and a slag composed of molten aluminum oxide (alumina). He found further that the reaction would progress so rapidly that, in the melting of most metals by the thermit process, as much as a ton of material could be converted from a cold mixture in half a minute. Later the most suitable kind of iron oxide (Fe_3O_4), the best size of oxide flakes, and the optimum fineness for use in welding steel were determined, as well as the possibilities resulting from the addition of such elements as chromium, nickel, vanadium, and manganese to a thermit steel mixture.

In the thermit process, the parts to be united are separated by a space, the extent of which depends on their size. The surfaces are thoroughly cleaned by sand blast or otherwise. Usually the space is given the form of a parallel-sided gap cut by means of a gas torch. The slight layer of oxide resulting from the cutting process is apparently beneficial. Around the parts a wax pattern is formed in the shape of the reinforcement desired. A sheet-iron box is placed around this pattern with a space between it and the pattern, and when the wax has hardened, sand is rammed into the space, after provision has been made for the proper number of risers and pouring and heating gates. The wax is then melted by directing a flame into each heating gate, and as the wax flows away, it leaves clear the space to be occupied later by the thermit steel. Heat is continued so as to dry out the sand mold and to bring to a red temperature the parts to be united. If multiple sections are to be welded, a two-part mold and a special wooden pattern may be substituted for the box and the wax.

A proper thermit mixture is then placed in a crucible supported over a pouring gate or gates, and when the work is ready, it is ignited. In about half a minute the reaction is complete, and the thermit steel is then tapped from the bottom of the crucible into the pouring gate. The superheated metal flows around and between the parts to be united, thoroughly combining with their surfaces and welding them into one homogeneous mass, while the molten alumina slag overflows into a basin on top of the mold.

Bronze Welding

The term "bronze welding" is understood by the welding operator to refer to the joining of metals with high melting points, such as cast iron, nickel, and copper, by the use of copper alloy weld metal. Actually, the word "bronze" is not correct, since the alloys are brasses in some instances. For many welding applications, bronze welding offers advantages of speed, economy, and ability to do jobs that might otherwise be difficult or impossible.

Bronze welding is essentially an application of the oxyacetylene process in which the joints produced are not true fusion welds, since the base metal is not melted, although a metallic bond is evidently formed between the deposited metal and the base metal as explained below. Bronze forms a strong bond with metal surfaces that have been heated to the proper temperature and treated with a suitable flux.

The oxyacetylene flame supplies the heat required for the preparation of the edges to be joined and for the melting of the welding rod. Because of the lower melting point of the rods used for bronze welding as compared with that of the material to be joined and the fact that the parts to be joined are required to be heated only to a temperature where tinning and amalgamation with the bronze take place, a much lower welding temperature is required in the bronze welding of steel, for instance, than in the making of a steel fusion weld.

Bronze welding with the electric arc may be accomplished by using a carbon arc and bronze or monel metal filler rod; the arc is directed on the filler metal. Ferrous metals may be welded with bronze or monel metal electrodes by the metal-arc process, although in this process, fusion of the base metal results. It should be noted, however, that the depth of fusion is not great.

Physical Nature of the Bond Between Filler Metal and Base Metal. Investigators have studied the character of the bond between copper alloy and base metal, which produces an adherence of copper alloy to base metal, stronger than the base metal itself when that metal is cast iron. It has been found that three distinct forces act to maintain adherence of the copper alloy to the base metal.

1 Tinning. A clean metal surface will receive a thin film of a molten metal of low surface tension. The bond thus produced depends on the action of atomic forces at the interface between copper alloy and base metal.

2 Alloying. A diffusion of the constituents of the filler metal—copper, zinc, tin, and others—into the base metal, and a corresponding diffusion of base-metal constituents into the filler metal takes place in a narrow zone at the interface between copper alloy and base metal. The base-metal crystals at the interface, when examined under the microscope, show a diffusion of the copper alloy constituents into the crystal grains, and an alloying of the filler metal with the base metal.

3 Intergranular Penetration. The action of the molten copper alloy on the base-metal surface opens the crystal grain structure of the base-metal surface and allows the filler metal to penetrate the base metal along the grain boundaries. This effect of alloying and intergranular penetration accounts for the strength of the bond between copper alloy and base metal, which can be produced without surface fusion of the base metal.

Copper Alloy Welding Rods. The copper alloy welding rod should tin readily when used with a suitable flux. It should be capable of building up a deposited metal that is virtually free from defects that result from slag inclusions, or blowholes. The fumes from zinc or other ingredients of the rod should be kept at a minimum since they may hinder the operator.

In general, the rods have a copper-zinc ratio of 60 to 40 and contain additions of tin, iron, manganese, or silicon, which improve the flowing qualities, deoxidize the weld metal, decrease the tendency to fume, and increase the hardness of the deposited metal for greater wear resistance.

With the arc process, a phosphor bronze or monel electrode may be used. When heavily coated electrodes are used, the coating aids in promoting an easy flow of metal.

Advantages. Bronze welding affords several advantages. Because of the lower temperature at which the filler metal can be added to the base metal, there is an increase in speed of making the joint, and less heat is required than in making a true fusion weld. The copper alloys yield readily while they cool until the temperature is lower than 500 F and there is an appreciable yielding under reasonably low stresses even at atmospheric temperature. This yielding as a single operation does not weaken the deposited metal. Therefore, residual stresses are reduced greatly in bronze welded castings.

Bronze welding should not be used where the finished work is to be subjected to temperatures higher than 500 F. It has also been learned that bronze should not be used where stresses as high as about 15,000 psi may be applied to the finished work with such rapidity as to cause fatigue of the metal. Since iron castings are seldom subject to stresses greater than 5000 psi, this effect can never be an important one in the bronze welding of cast iron. This same comment can be made with regard to bronze welding of malleable iron.

Inspection and Testing

Many products and structures, such as pressure vessels, ships, tanks, buildings and machinery, fabricated by fusion welding, are made under some form of specification that requires inspection by the purchaser. In some welding applications the inspection must conform to some code of construction requirements, and tests are specified to govern the qualification of the welding operator or the quality of the welding performed.

The tests that have been devised include destructive tests and nondestructive tests. Only the destructive tests are definitely quantitative; the nondestructive tests are indicative of quality only, and some of these are indicative only to a limited extent. The destructive tests include tensile, bend, specific gravity, nick-break tests, impact, and hardness tests. The nondestructive tests that have been used on welded joints include the visual, the stethoscopic, X-ray, and gamma ray tests. Electric resistance, magnetic and supersonic inspection methods have also been developed and are being used successfully in many instances. The hydrostatic proof test is a form of nondestructive test that is used for pressure vessels and closed containers.

Visual inspection of fusion welding during the process is also possible, although not generally specified directly. For this inspection the fusion-welded joint offers the peculiar advantage that the inside of the joint may be observed while it is being made. Visual inspection is valuable in studying procedure, but it requires a careful observer, properly trained. The inspector watches the rod or electrode and observes how it melts down, notes the fusion and penetration, and listens to the sound of the arc, or observes the flame adjustment of the torch. All these items properly studied and understood will give a skilled inspector considerable information regarding the quality of the weld under observation.

Mechanical Tests. The application of mechanical tests to weld metal and welded joints is discussed in the article on page 137 of this Handbook. The tests described are: tension, shear, bend (ductility), nick-break, and notched-bar impact.

Nondestructive Tests. *Stethoscope.* The object of the stethoscopic test is to determine by means of the tone that a weld gives off when tapped with a hammer, whether the metal is sound or contains defects, such as lack of fusion or cracks. Just as a sound bell gives a clear ringing note and a cracked bell gives a reedy note, so good weld metal gives a good ringing sound and a poor weld gives a flat sound or note.

In order to identify the sound readily, an ordinary medical stethoscope is used. As a special precaution the end is protected with rubber to avoid any extraneous sounds that would result from scraping the stethoscope on the metal.

The stethoscopic test (Fig. 5) has been applied successfully to pressure vessels, locomotive staybolts and other welded structures, but it is not extensively used today.

X-Ray. Metals can be X-rayed and their internal defects made visible on photographic films. In this way all types of defects can be detected, such as cracks, slag, blowholes, and lack of fusion. Generally the method consists of placing the test piece between the X-ray tube and a film. After an exposure ranging from a fraction of a minute to hours, depending on the power of the tube and the thickness of the metal, the film is developed and examined for defects in the weld. (*See* the article on "Radiography" in this Handbook, page 141.)

This method is used widely in industry and is recognized as the foremost nondestructive test. It is one of the requirements of the ASME Code for paragraph U68 quality welded pressure vessels.

Gamma Ray Tests. Gamma ray tests are similar in method to X-ray tests. The gamma rays emanating from radium penetrate metals rapidly and are more applicable to heavy sections that would require unusually long exposure by X-rays. This type of test has been successfully applied to pipe and to heavy castings such as are used in ship construction. On heavy work pieces overnight exposures are employed.

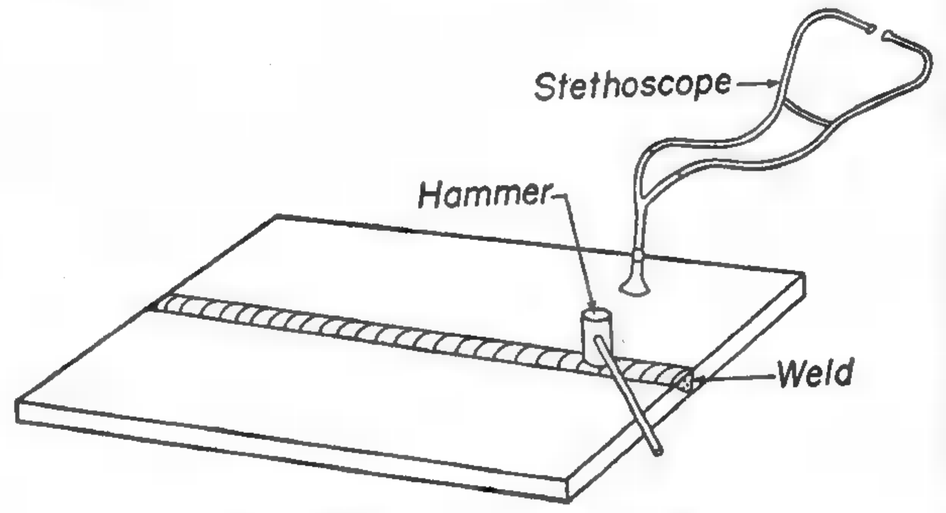

Fig. 5 Stethoscopic testing of welds

Several large castings may be arranged radially around a capsule that contains radium. The films for recording the results are placed on the farthest side of the castings in relation to the radium. Before attempting the use of radium for gamma ray testing, it is essential that the operator be familiar with the properties of radium, and that the necessary precautions be taken to protect persons who are to work with it.

Special Tests. Electric and magnetic tests that depend on variations produced in the flux density by weld flaws, have proved very successful in certain instances. Tests of this type are best adapted for routine inspection work and are frequently used to inspect welds in pipe and tubing.

The supersonic vibration method of testing welds is relatively new but it holds definite promise of becoming an important test method. This and other nondestructive tests are discussed in the section beginning page 141.

Safe Practices in Fusion Welding

The question of safe practices in fusion welding is an important one, since there are inherent hazards in certain applications, no matter what the welding process may be. Special attention will be devoted to the hazards, because it is not the purpose here to enumerate the safety precautions that must be observed in connection with the different welding processes. These precautions have been ably covered by the National Safety Council in Safe Practices Pamphlets No. 23 on Gas Welding and Flame Cutting and No. 105 on Electric Welding. Reference may be made also to American Standards Association War Standard Z49.1, which is now being revised into a peacetime standard, and to the publication of the International Acetylene Association on Safe Practices for Installation and Operation of Oxyacetylene Welding and Cutting Equipment. These pamphlets contain much valuable information concerning the fundamentals of gas welding and cutting, thermit welding, and electric welding, and they should be consulted by everyone who has charge of fusion welding operations.

All operators of welding equipment should be conversant with the safe operating instructions that are furnished with all fusion welding equipment. As a rule, welding equipment is constituted in a way that makes it quite convenient to observe the usual precautions for safety, but in the application of the process involved, there are certain conditions and operations that may endanger the operator if the possibility is not anticipated and avoided. Some of these hazards will be enumerated.

Eye Protection. A serious hazard in welding applications is that of injury to the eyes, from the heat and glare of the flame or arc, and from particles of hot metal that may fly up from the work. Properly colored lenses fitted in goggles

will protect the eyes from the gas flame, but in electric-arc welding, the intensity of the ultraviolet and infrared rays is such that all persons exposed must use shields or helmets that will protect not only the eyes but the skin as well. The lenses of goggles should be selected with considerable care in order to obtain the desired visibility together with adequate protection for the eye; the exterior surfaces of these lenses may be protected from flying sparks by superimposing a clear glass lens over each. The selection of lenses for use with the electric arc must be based on laboratory tests, because the transmission of ultraviolet and infrared radiation cannot be determined by visual inspection; proper protection for the eyes requires more than mere reduction of the glare. Goggle frames should be made of noncombustible material, preferably a nonconductor of heat; if made of metal they should be padded. The frames should have vent holes in the cups to provide ventilation behind the lenses.

Special precautions must be taken to protect other workers or passers-by from the harmful rays given off from arc-welding operations. It is preferable to locate these jobs in special rooms. If this is impracticable, the operations should be screened or enclosed, not only to prevent workers or passers-by from looking directly at the arc, but also to protect them from reflected rays as much as possible. Further protection against reflected rays is frequently provided by applying paint to the screen or enclosure and to other nearby surfaces. Zinc oxide is satisfactory when combined with lamp black to produce a bluish gray color.

Clothing. The welding operator should have some protection from the heat of welding, particularly when working on heavy pieces and for long periods of time. Fire-resisting gauntlets and aprons will serve as a protection against the radiated heat. Woolen clothing is to be preferred to cotton, because it is less readily ignited and it protects the operator from changes in temperature. Operators engaged in arc welding are advised to wear only fireproofed outer clothing.

There have been instances when the operator's clothing has been set on fire by sparks of molten metal that lodge in rolled-up sleeves, and in pockets of clothing. Operators should be warned to keep sleeves buttoned around the wrist and collars buttoned to prevent lodgment of sparks. Some suggest that it is advisable to eliminate pockets from the front of overalls and aprons. A sheet-iron screen in front of the worker's legs will provide further protection against sparks and molten metal in gas cutting.

Electric Installation. When installing and operating electric equipment, the provisions of the National Electrical Safety Code should be followed. The voltage is ordinarily so low that there is little danger of shock from the welding circuit; still the usual precautions should be taken. However, some types of equipment have a high voltage under open-circuit conditions and these should be properly guarded.

Fire Protection. Where welding or cutting must be done in the vicinity of combustible material, special precautions should be taken to make certain that sparks or hot slag from the welding or cutting operations do not reach the combustible material and start a fire.

Cutting or welding work that can be transported should be removed to a safe location in a building that is noncombustible or equipped with sprinklers. If the work cannot be moved, exposed combustible material should be moved a safe distance away, if possible 30 or 40 ft. Also wherever there are floor openings or cracks in the flooring, it is advisable to make certain that no highly combustible materials are stored on the floor below, where they would be exposed to sparks that might drop through the floor.

The sparks and hot slag should be watched to see that they do not come in contact with combustible material, do not lodge in floor cracks, and do not drop through holes to the floor below. Sheet metal guards or asbestos curtains should be used where needed; it is important to make sure that the guards and curtains are adequate. Because hot slag may roll along the floor for a considerable distance, it is important, when using asbestos blankets as a curtain, that no openings exist between the curtain and the floor. The use of tarpaulins should be avoided because experience has shown that they do not provide adequate protection.

Extra men should be stationed nearby with small hose, chemical extinguishers, or fire pails, when the nature of the work requires that blowpipes be used near wooden constructions or in locations where combustible material cannot be removed. In buildings equipped with sprinklers, this protection should be maintained without interruption while cutting blowpipes are being used. A man should be kept at the scene for half an hour after the work is completed, in order to make certain that sparks have not started smoldering fires.

In certain mines, mills, industrial plants, and plants where lacquers and the like are sprayed, dusty and gassy atmospheres require extra precautions to avoid explosions or fires from electric sparks, matches and open fires. Welding or cutting in such treacherous places should be done only when proper precautions have been taken and only after the responsible official in charge has inspected the situation and has given instructions personally to proceed.

Special Precautions. No welding or cutting should be done on used drums, barrels, tanks or other containers until they have been cleaned thoroughly enough to make absolutely certain that no flammable materials are present. Where steam is available, it may be used to remove materials that are easily volatile. Washing with strong caustic soda solution will remove heavier oils. Even after thorough cleansing, the container should be filled with water, if possible, before any welding, cutting, or other hot work is done. Almost always it will be found possible to place the container in such a position that it can be kept filled with water within a few inches of the point where welding or cutting is to be done. It is important to make sure that there is a vent or opening to provide for the release of heated air from inside the container. This can usually be done by opening the bung, hand hole, or other fitting which is above the water level.

Where alterations or repairs are being carried out on large containers that have held flammable substances, periodic examination of the air contents of the vessels should be made from time to time, wherever possible, by means of a gas detector where such an instrument is available. Although the vessel may have been steamed and flushed with soda, there may still be traces of oil or grease under seams, and the heat of the welding or cutting operations may cause such oil or grease to give off flammable vapor, forming an explosive mixture inside the tank. If possible, a supply of carbon dioxide should be kept in the vessels while they are under the process of repair. The use of carbon tetrachloride for this purpose is not recommended because carbon tetrachloride gives off a poisonous vapor when heated.

A jacketed vessel, tank or container should never be welded until after every possible precaution has been taken to vent the confined air sufficiently. A metal part that is suspiciously light is hollow inside, and should be drilled before heating; otherwise it will act like a bomb.

When gas cutting is done, judgment and care should be used in regard to the effect on the structure. No important structural member should be cut while it is under load, except where the removal of the part will not reduce the strength of the whole. Also great caution should be used in cutting holes in structural members or removing portions, unless the design provides for such cutting, without weakening. If gas cutting is used to remove rivets, great care should be taken in removing the head, to avoid reducing the thickness of the base metal at the rivet hole. In cutting away any important or heavy part of a machine or structure, caution should be used to make sure that the severed part will not fall and cause damage to adjacent equipment. If the work part is likely to fall and injure the operator or other workmen, care should be taken to support it properly while it is being cut.

Health Protection. When painted or lead-coated materials are cut or welded, the lead volatilizes and may be breathed into the operator's lungs, causing lead poisoning. In a similar way "zinc chills" may result from breathing the fumes when zinc, brass, bronze, or galvanized metal is being welded.

Under such conditions, protection of the operators depends on ventilation—or better, the operators should be required to wear special gas masks or fresh-air masks.

Special care is required when welding or cutting operations are carried on in confined and poorly ventilated spaces, as in tanks, compartments and holds of vessels.

Artificial ventilation may be necessary to replace the oxygen consumed from the air and the operators should be under close observation by an outside attendant so that help can be rendered immediately in an emergency.

Brazing, Silver Brazing, Copper-Hydrogen Brazing and Related Joining Methods

By the Subcommittee on Brazing*

BRAZING is a term commonly applied to a metal-joining process distinguished by two prominent characteristics:

1 Appropriate cementing metals or alloys are used that can be divided into the two general types given here with appropriate ranges of temperature for brazing: (*a*) Silver brazing alloys, containing silver with or without copper, zinc, cadmium, tin, manganese, nickel, and phosphorus, are used between 1175 F (635 C) and 1550 F (843 C) or higher. (*b*) Copper is used with or without zinc, tin, nickel, phosphorus or silver, separately or together, between 1300 F (704 C) and 2150 F (1177 C).

2 In the brazing process there is no melting of the metals or alloys that are being joined. The molten brazing metal or alloy flows between the heated, unfused, adjacent or overlapping surfaces of the joint members by capillary force, or is melted in place between such surfaces.

Brazing, therefore, presupposes the use of a brazing metal that melts and flows at a temperature lower than the temperature of the metals and alloys that are being joined. The "bronze welding" joining process (see page 75) is the same as brazing to the extent that the base metal is not fused, but bronze welding differs from the usual brazing process in that most of the strength of the joint is developed in tension through the bronze deposited in an open V or fillet, rather than in a thin filler that may be in shear between overlapping surfaces or may be in tension or shear or both, between adjacent surfaces.

Metallurgy of Brazing. The metallurgical requirements for successful brazing involve the consideration of the properties of the brazing metal and the metals to be joined.

*Requirements for the Brazing Metal.** Since the brazing metal or alloy must melt and flow freely at a temperature lower than that required for melting the parts being joined, it is necessary to provide a reasonable working differential. Where the temperatures can be controlled accurately, as in dip brazing or in the use of a closely regulated furnace, this temperature differential may be as low as 50 F. Skilled workmen may be successful with this low differential when using a blowpipe or torch, but for commercial work, it is preferable to use a brazing material that flows freely at a temperature at least 200 F below the melting point of the metals or alloys to be joined.

The brazing metal when molten must wet the base metal. The type of film formed on the liquid brazing metal and the character of the surface on the base metal have much to do with the interaction of the brazing metal and the base metal at the brazing temperature. Ordinarily the molten brazing metal should not oxidize too freely, and the oxide that is formed should be readily fluxed; that is, readily dissolved in a flux that is liquid at the brazing temperature. The oxides of copper, silver, zinc, tin and cadmium are readily fluxed. Nickel, silicon, aluminum, chromium and beryllium oxides, in the order named, are increasingly difficult to dissolve in flux. Phosphorus vapor, rising to the surface as a colorless gas at brazing temperatures, reduces copper oxide, thus improving the free-flowing qualities of the brazing metal that contains phosphorus.

The brazing metal must not diffuse too freely into the base metal at the brazing temperature, and it must not dissolve too much of the base metal. These properties affect the penetration of the molten brazing metal when it is introduced into the space between overlapping surfaces. The greater the mutual solubility of the two metals at the brazing temperature, the wider must be the spacing of the overlapping surfaces in order to avoid a situation where the brazing metal becomes spent; that is, alloyed with base metal before it penetrates the desired depth. If, however, the spacing is made too wide between the surfaces to be brazed, the capillary attraction becomes too weak to cause the molten brazing metal to penetrate the desired depth, and gravity comes into play. A compromise must usually be made in spacing the base-metal surfaces.

The brazing metal should not dissolve appreciable amounts of gaseous hydrogen, nitrogen, carbon oxide gases, phosphorous oxide gas or water vapor at the brazing temperature. Silver, copper and their alloys with zinc, tin, nickel or cadmium, singly or in combination, are satisfactory in this respect.

Requirements for the Base Metal. The base metal must have a melting point higher than that of the brazing metal.

The surface must be chemically clean, except for flux, at the start of the brazing operation. Oxides, sulfides, graphite or carbon (from grease broken down by the brazing heat or from the heating gases) are all objectionable.

The surface must be free from oxides at the brazing temperature. Aluminum, chromium and beryllium oxides are difficult to flux. However, the formation of these oxides can be prevented to some extent by fluxing before heating. Also, certain fluoride fluxes can usually dissolve enough of the oxides to permit a braze to be made.

Character of the Brazed Bond. The bond between the brazing metal and the clean base metal is obtained by a slight diffusion of the brazing metal into the hot, solid base metal or by surface alloying of the base metal and the brazing metal.

Effect of Brazing Heat on the Base Metal. If the base metal is in the annealed condition at the time it is brazed, an appropriate brazing temperature will cause no harmful change in physical properties. When the base metal is in the work hardened condition (as for example, cold rolled steel, cold drawn copper line or trolley wire) a certain amount of softening occurs in the metal that reaches the brazing temperature.

However, annealing is a function of both time and temperature and, not infrequently, a part of the work hardness and strength can be retained. This is particularly true when a brazing alloy is used that has a low melting point and the time at temperature is brief, as when the oxyacetylene torch is used or when the dip-brazing method is employed.

When precipitation hardening alloys, such as beryllium copper, chromium copper, and duralumin, or quench hardening steels are to be brazed, all the heating processes—solution, precipitation, and tempering—should be considered. A comparison of the heat treating temperatures with the brazing temperature will indicate whether the braze should be made before or after the solution treatment, or after the complete heat treatment, or between the solution and the

* The members of this subcommittee are R. H. Leach, *Chairman* (Handy & Harman), J. R. Freeman, Jr. (The American Brass Company) and I. T. Hook (The American Brass Company).

* The cementing metal, not the base metal. "Brazing brass" is a name often applied to the alpha brass made of 75% Cu plus 25% Zn and so-called because it can be brazed with the 50-50 zinc-copper spelter solder, without being melted itself. It is seldom used as a brazing metal.

precipitation or tempering. For example, (1) steel brazed with copper at 2100 F can be reheated to 1400 F for solution of carbide and quenching. If the same steel were brazed with a silver solder at 1450 F, it is doubtful that the reheating could be accomplished without weakening the joint. (2) Chromium copper or beryllium copper cannot be brazed before the solution heat treatment because if they were, the braze would fall apart at the high temperatures employed.

Applications. The brazing process is used where a ductile joint is desired that will have high strength and resistance to fatigue and corrosion, at a reasonable cost. Such joints may be made singly or in mass production in a continuous furnace or heating setup. They are able to withstand higher service temperatures and higher service stresses than are joints sweated with a soft solder. Steel, copper, brass, bronze, cast iron, cast brass and cast bronze are the metals commonly joined by a brazing process. Aluminum alloys are brazed by a special process at temperatures from 1060 to 1185 F. Frequently, two or more base parts are assembled by pressing, spot welding, staking, pinning, jigging, weighting or clamping and are then fluxed, heated and brazed. Often the various parts of the assembly are made of different metals.

Preparation and Design of the Joint. Clean and properly fitted joints are a prerequisite for satisfactory bonding. All surface scale or oxides should be removed by either chemical or mechanical means. Oil, grease and dirt of any description interfere with good work. If the joints are brazed in an atmosphere rich in hydrogen, the hydrogen at brazing temperature will reduce iron, copper, tin and lead oxides but not oxides of zinc, chromium, aluminum and beryllium. Nor will the hydrogen clean off carbon or dirt.

The allowable clearance between the surfaces to be joined will vary according to the alloy used, the type of joint, the method of heating and the metals joined. With free-flowing brazing alloys, such as copper, silver solder, the spelter solders on steel, or the silver solders on base metals of copper alloy, closely fitted joints will give the best results. The maximum clearance should not exceed a few thousandths of an inch. When bronze welding rods are used, it is common practice to make an open V joint and to fill the joint with successive layers of the brazing alloy. However, the closely overlapping or scarfed joint is often made by means of bronze welding rods.

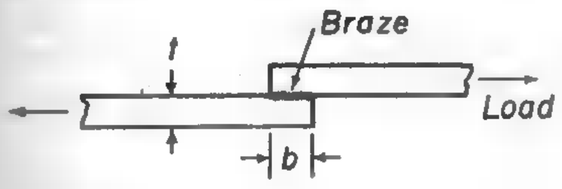

Fig. 1

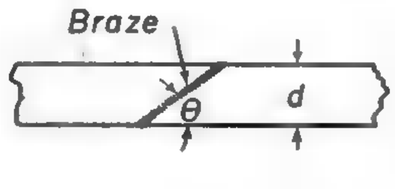

Fig. 2

Fig. 1 A lap braze in sheet metal or flat bars. The dimension *b* is 2 to 3 times *t*

Fig. 2 A scarfed joint in round or flat rods, wire or sheet

When the full strength of sheet metal, or of round or rectangular bars or wires is to be developed by means of a braze in shear, or partly in shear and partly in tension, a common rule is to make the brazed area 2 to 3 times the area of the right section of the base metal (Fig. 1 and 2). In Fig. 2, the brazed area equals right section area/sine θ or for various values of θ the size of the brazed area should be as follows:

θ, degrees	Brazed Area
45	1.4 × Right section area
30	2.0 × Right section area
22½	2.6 × Right section area
19½	3.0 × Right section area

Thus, the angle of the scarfed joint, θ, measured from the axis of the rod, wire or sheet, would be 30 to 19½ deg, if the brazed area is to be made 2 to 3 times the right section area, according to the common rule.

Fluxes. The temperatures required for brazing cause rapid oxidation of the surfaces of the joint and of the brazing metal if these surfaces are exposed to air during the heating. A thin film of oxide will prevent proper bonding of brazing metal to base metal. Hence, the surfaces should be protected with a salt or combination of salts that will help to prevent oxidation and will dissolve or flux any oxides that may form. (A neutral or reducing gas may also be used to forestall oxidation.)

Common borax is a thin fluid at 1400 F and at this temperature it dissolves the oxides of iron, copper, tin, zinc, cadmium, silicon, silver and nickel, but not those of aluminum, chromium and beryllium. It contains approximately 47% water of crystallization, which is driven off when heated, thus causing the flux to "bubble"; therefore, fused borax is generally preferred. If borax is used as a paste, it should be mixed with alcohol, because the fused borax quickly takes up water and becomes common crystalline borax again.

Boric acid is sometimes used alone as a flux, but generally in combination with borax or other salts. Although less active than borax for dissolving oxides of metals, boric acid will spread over the surface at a relatively low temperature and will thus protect the surface from oxidizing during the heating period. Combinations of borax and boric acid are extensively used, particularly with brazing alloys at temperatures higher than 1500 F.

The alkali bifluorides in combination with borax and boric acid are used as fluxes in the joining of metals that have refractory oxides, such as the oxide of chromium on stainless steels, the oxide of silicon on the silicon bronzes, the oxide of aluminum on the aluminum bronzes, or on aluminum or aluminum alloys, and the oxide of beryllium on beryllium copper. The potassium salts are more effective than the sodium salts and, by variation in the proportions of the salts enumerated in this and preceding paragraphs, a wide range of fluxes can be produced to meet the different conditions encountered in brazing.

Many satisfactory prepared fluxes are available, some of which may contain phosphates or halogen salts. Regardless of the particular composition selected, it is most important that the flux be applied in such a manner as to ensure that all oxide films will be removed. Moreover, the flux should be a thin liquid at the brazing temperature, in order to prevent inclusions, which will subsequently give trouble. The surfaces both of the joint and of the brazing alloy should be protected with flux to produce the best results.

The flux may be used dry, in paste form, or in a saturated solution. When used as a paste or as a hot solution, the flux should be brushed over the surfaces before they are heated. Thus a more uniform coating can be obtained and there is less chance for bare spots that will oxidize during the heating. When the brazing alloys are in granular form, it is common practice to mix the flux with the alloy before spreading along the joint. Strip, wire and rods may be coated with flux before they are used, or the end may be dipped into a small can of flux paste just before applying flux to the joint, or the rods may be heated and the dry flux sprinkled on them.

In the process known as "copper-hydrogen brazing", a furnace or blowpipe atmosphere, rich in hydrogen, is used in the absence of a flux. The hot hydrogen has the effect of reducing the less refractory oxides, such as those of iron, copper, tin, nickel and manganese, or of preventing their formation. The refractory oxides of aluminum, beryllium and chromium are more difficult to reduce with hydrogen or to dissolve with flux. Special fluxes, usually with additions of one or more fluorides, are frequently required. Fluxes are also used with brass.

Methods of Heating. There are several different methods of supplying the heat necessary for brazing.

Dip Brazing. In dip brazing, the alloy is melted in a refractory container and covered with flux to prevent oxidation. The parts to be brazed are assembled in a suitable jig to hold them in position and are dipped into the molten alloy. Sometimes a preheat is employed. The size of the bath of metal must be in proper proportion to the work. The bath may be heated by any of the methods used with pot furnaces.

Salt Bath Brazing. Another kind of dip brazing can be done in the salt bath type of furnace. First the parts are assembled and the solder is applied to the joints; then the articles to be brazed are immersed in the bath of molten salt. (*See* page 283.)

Torch (Blowpipe) Brazing. Different types of blowpipes or torches are used, including air-gas, oxygen-gas, oxyacetylene and oxyhydrogen. The high temperature of the oxyacetylene flame allows rapid heating, which is an advantage. A neutral or slightly reducing flame should be used in general, although for some types of bronze welding a slightly oxidizing flame is recommended.

Furnace Brazing. The furnace should be large enough to allow rapid heating, and whenever possible the temperature of the furnace should be considerably higher than the melting point of the brazing alloy. If the assembly consists of many parts, care must be taken to regulate the temperature so that all the joints reach the brazing temperature at approximately the same time.

Electrical Resistance Brazing. The electrical resistance method is used for small parts or for other parts where a thin sheet of the brazing alloy can be inserted into the joint. This method has the advantages of localizing the heat and working quickly. Frequently the principal part of the heat comes from the carbon electrodes, which are in contact with the work material.

Brazing by Induction Heating. In another form of electrical heating, the assembled parts are surrounded with a coil through which a high-frequency current is passed. The currents induced in the parts provide a quick, clean method of heating.

Multiple Gas-Burner Brazing. Rows of gas burners between which the assembled parts may be passed afford another quick and uniform method of heating.

Types of Brazing Alloys. The selection of the best brazing alloy for a given joint depends on many different factors. Since the brazing metal must melt at a temperature lower than the melting point of the base metal or metals to be joined, the melting points of the brazing alloys give a basis for two broad classifications, as mentioned in the early part of this article:

Class I Silver brazing alloys or silver solders
Class II Brass and nickel silver brazing alloys
Copper and copper alloys and brazing rods

A general description of these two groups follows:

*Silver Brazing Alloys.** Ternary alloys of silver, copper and zinc in varying proportions have been used for many years as brazing alloys and are commonly called "silver solders". The addition of silver to binary copper-zinc alloys lowers the melting point; thus a series of alloys can be made that will flow freely at temperatures from 1250 to 1600 F. (*See* CONSTITUTION OF ALLOYS.) Other metals used in making silver brazing alloys are cadmium, tin, nickel, manganese and phosphorus.

Because of their strength, low melting points, free flowing properties and resistance to corrosion, these silver brazing alloys are used extensively on nearly all nonferrous metals and alloys and on steels and iron. The strongest joints are made with small clearances, not more than three or four thousandths of an inch for best results. Such joints withstand severe shock and vibration.

The silver-copper-phosphorus eutectic melts at 1190 F and a self-fluxing alloy containing about 2.5% less phosphorus than the eutectic is used for brazing copper. This alloy, which flows freely at 1300 F, is available as thin-gage sheet, small rods and wire. With brass and other alloys, only a small amount of flux is required. Borax can be used as a flux but special fluxes, more fluid than borax at 1300 F, are preferable.

In general, the use of silver brazing alloys should be considered where the higher temperatures required for other brazing alloys might cause excessive grain growth or damage to the metals to be joined, and where strong ductile joints are necessary. Silver brazing alloys can be obtained in all sizes of wire and gages of sheet, as well as in filings and powders of different sizes, making it possible to apply the most convenient and economical form for the particular use.

Table I gives a list of 15 of the common alloys that are used.

Table I. Silver Brazing Alloys

	Composition, percentage						Melting Point, deg Fahr	Flow Point, deg Fahr
	Ag	Cu	Zn	Cd	P	Sn

(a) Proprietary alloy, "Easy Flo"
(b) Proprietary alloy, "Sil Fos"
(c) Proprietary alloy, "Ready Flo"

The first eight alloys in Table I are taken from the ASTM Standard Specification for Silver Solders or Silver Brazing Alloys. They represent the range of composition of the old standard silver solders, which were considered to cover ordinary requirements and to eliminate a large number of compositions that really served no useful purpose. The following addenda are given with these specifications, which are still in common use:

The addition, not to exceed 0.50%, of Cd to assist in fabricating the first and second items shall not be considered as harmful impurity.

Items 1, 2 and 3 are suitable for brazing purposes which require a solder that flows more readily than the ordinary copper-zinc brazing solders.

Items 4 and 5 flow freely at a still lower temperature and are recommended for use where strong joints are required and in cases where heating to a sufficiently high temperature to flow items 1, 2 or 3 would be injurious to the article being soldered. Items 6, 7 and 8 are higher grade silver solders and are recommended for special cases where a high degree of malleability and ductility is required.

It is evident that a large number of variations are possible, but except for some special purpose, a selection from

* For additional information concerning the properties of silver brazing alloys, see page 1113, in the PRECIOUS METALS SECTION.

Table II. Brass, Nickel Silver and Copper Brazing Alloys

Brazing Alloy	Melting Range, deg Fahr		Composition, percentage			Remarks
			Copper	Zinc	Others	
ASTM 50–50	1595	1620	50 to 53	Remainder	0.50 Lead, max	Common spelter solders, brass yellow color, in granulated and lump form for general brazing
ASTM 52–48	1600	1620	52 to 53	Remainder	0.50 Lead, max	
Spelter bronze	1575	....	Remainder	45	3 to 5 Tin	Pale yellow in granulated or lump form for special work. Harder than ASTM grades
Black button	1385	1440	Remainder	57 to 65	5 to 9 Tin	Gray to black, granulated, moderate strength. Contains 1% Fe
White spelter solder	....	1600	Remainder	55 to 59	7 to 9 Nickel	White, granulated form, match for nickel silver, cupro-nickel and the like
Phos-copper	1304	1526	93	Remainder	Phosphorus	Rod or strip for self-fluxing brazes on copper. Gray color.
White brazing rod	....	1700	47	42	11 Nickel	High-strength brazing rod
Yellow bronze	1595	1625	Remainder	42	0.5 Tin	General-purpose brazing or bronze-welding rod
Copper	1981	2050	99.9	....	....	Tough-pitch or deoxidized copper in wire, granulated, or electrodeposited on steel for brazing in a hydrogen atmosphere

the above list should be satisfactory. In recent years, the alloys with lower melting points have been widely used; however, the alloys containing lower percentages of silver and having higher melting points are still in common use. In selecting a suitable brazing alloy, it is necessary to consider all factors and then to determine which alloy will give the most economical and satisfactory results. The alloys with lower melting points have the advantage of providing a greater factor of safety, making it less likely that the parts to be joined will be overheated and thus damaged. The use of alloys with lower melting points also shortens the time required for making the joints.

The 72-28 Ag-Cu alloy in the above table is commonly used where the presence of a volatile metal such as zinc or cadmium might be harmful.

Brass and Nickel Silver Brazing Alloys. Brass brazing alloys, generally known as "spelter solders" or "brazing solders", are alloys of copper and zinc in about equal proportions and occasionally contain smaller amounts of tin and nickel. These brazing solders are ordinarily applied in powder or granulated form often mixed with flux, and they are melted by heating the several parts to be brazed, just higher than the melting point of the brazing solder. At this temperature the solder becomes fluid and runs readily between the contacting surfaces, alloying and bonding them together in a manner similar to soft and silver soldering. Dip brazing is also widely used. In this method, the parts to be brazed are first clamped together suitably in the desired positions, are fluxed and sometimes preheated, and are then dipped into a molten bath of the brazing alloy.

From the compositions given in Table II many variations are possible. However, the nine alloys listed are representative. Additional information is given in the article on "Welding Processes" under the heading Bronze Welding.

Brazing solders are supplied in various forms from fine to coarse powders; lump and rod forms are also occasionally used. The lumps are generally melted in a pot for dip brazing, while the rods are more conveniently applied with the oxyacetylene torch.

The ASTM 50-50 copper-zinc spelter solder is the most common of these brazing solders. The white spelter solder is used principally because the color matches that of nickel silver, cupro-nickel or steel.

The black button solder is used where an inexpensive solder of moderate strength and melting range is desired.

The phosphorus-copper alloy is seldom used on any base metal other than copper.

The white and yellow brazing (or bronze-welding) rods are generally used to make a fillet or to fill an open V.

A cupro-nickel alloy is occasionally used instead of pure copper for copper-hydrogen brazing and for the brazing of steel articles that must withstand elevated temperatures.

Fluxes for these alloys are, in general, the same as for silver solders. Fused borax or a mixture of fused borax with boric acid is satisfactory for most purposes. The finer powdered spelter solder is often mixed into a paste with the flux before application to the joint. The paste should be mixed with water-free alcohol or, if it is to be used immediately, with boiling water.

Joints are often brazed in a furnace. If the furnace has an air or burned-gas atmosphere, a flux is necessary on the joint with the brazing alloy. However, electrically heated furnaces with atmospheres rich in hydrogen are in common use. In such furnaces no flux is required, since hydrogen will exclude oxygen and reduce any scale that may be on the metal. Pure copper, in powder, sheet, wire or electroplated form, is most often used. The copper will penetrate long distances between closely overlapping steel surfaces and make a strong, ductile joint.

As with the silver solders, electrical heating by carbon resistor electrodes or induction heating is often preferred.

Soldering With Soft Solders

By George O. Hiers* and E. E. Schumacher*

THE USE and application of solder alloys, such as lead-tin, lead-tin-cadmium and others, are discussed in this article. Attention is given to varieties of metals that can be soldered, type of fluxes and soldering techniques.

Definition. The alloys mentioned are generally referred to as "soft solders", distinguished from "hard solders" (brazing solders and silver solders), which are described on page 78. The term "soft solders" in this discussion is restricted to alloys that are fusible at temperatures below 700 F, whereas the hard solders are fusible above approximately 1200 F. One of the distinctions between a soldered joint and a welded joint is that in the former, the metals to be joined are not heated to their melting points. Consequently one of the requisites for a solder is that the melting point must be lower than that of the metals being joined.

Materials Soldered. Solders are employed for joining cast or fabricated metals of various compositions. These are principally iron, copper, nickel, lead, tin, zinc, and many of their alloys. Even such materials as glass and porcelain may be joined by soldering, after their surfaces have been coated by metal spraying or other suitable processes.

Solder Compositions. In general, solders are lead-tin alloys with or without the addition of other elements. Table I lists the more common alloys. For many joining operations tin is the major alloying or wetting ingredient. As shown in the phase diagram, melting points are obtainable that are lower than those of either tin or lead. In many cases, the greater the tin content, the more rapid the wetting of the metal to be joined by solder and the more rapid the melting. Within certain limits the useful physical properties are also improved by increased tin content. Where a plastic range under solidifying conditions is required, as in a wiping solder, the selection of alloys is necessarily limited.

Under postwar conditions the use of tin is restricted by various government tin conservation orders. In general, the wartime emergency solders have been satisfactory, although more time and care are required for their application. It has been found difficult to make hermetic seals by using the low-tin solders.

Fundamentals. For good soldering work these rules should be followed:

1 It is essential for a solder to wet or alloy with the metal surfaces on which it is applied.

2 The metal surfaces to be soldered must be clean, free from foreign matter and objectionable grease.

3 The flux should be molten, preferably at temperatures below the solidus point of the solder, in order to insure activity, maintain a continuous film and minimize entrapment in the solder. Gaseous fluxes, such as chlorine or hydrochloric acid gas, have been used to a limited extent to reduce flux inclusions.

4 During soldering, the metal surfaces must attain a

* Metallurgist, Research Laboratories, National Lead Company, Brooklyn
* Metallurgist, Bell Telephone Laboratories, Inc., Murray Hill, N. J.

temperature above the solidus point and preferably above the liquidus point of the solder.

5 All traces of corrosive fluxes should be removed with particular care after the joints have been made.

Selection of a Solder. Most of the solders in Table I will wet all common metals with the exception of aluminum and magnesium. The selection of the particular alloy will depend on permissible temperatures, method of application, physical properties required, economic considerations and governmental restrictions. Table I is a guide.

Preparation for Soldering. Parts should be free from foreign matter and excessive grease. In electrical assemblies copper conductors are often sufficiently clean to permit soldering with rosin flux, without previous treatment. Where tarnish is present, removal by abrasion or chemical means is necessary. Other metallic materials, particularly ferrous parts, require either mechanical abrasion to remove oxides, or cleaning by chemical means. The effectiveness of any soldered joint depends on cleanliness of the surfaces.

Fluxing. For practical purposes, it is generally necessary to use a flux when soft soldering. The chief functions of a flux[1] are to remove mild oxide, to prevent oxidation of the surfaces, to dissolve oxides that may form on these surfaces while they are being heated to the soldering temperature, and to promote the mutual contact between atoms of the solder elements and atoms of the metallic elements to be joined. The flux should be fluid at the temperature of molten solder and should be applied in such a way that by gravity, capillarity or other forces, the solder can displace the flux at the joint.

Mild fluxes, such as rosin, tallow, and stearin particularly, prevent oxidation but are not very effective in removing oxides already present. Zinc chloride, with or without the addition of ammonium chloride, acts both as an oxidation preventive and as a scavenger. Zinc chloride has a melting point of 504 F and the eutectic mixture of zinc chloride with ammonium chloride (71% $ZnCl_2$, 29% NH_4Cl) has a melting point of 354 F, which is slightly below that of many lead-tin solders. Hydrous zinc chloride acts as a flux, thereby permitting soldering below the melting point of the anhydrous chloride. It is generally agreed that the addition of ammonium chloride improves the effectiveness of this flux. A popular paste flux contains about 75% petroleum jelly, 20% $ZnCl_2$, and 5% NH_4Cl with a small amount of water as an emulsifying agent.

In the consideration of new fluxes, attention should be directed to the kind of metals to be joined and to their massiveness. Ordinarily more heat is required for soldering iron or steel than for soldering lead. Whenever a soldering iron is used for large parts, the heating is localized and the heat may be conducted away rapidly; consequently the tool must be exceptionally hot when the article is not preheated. In such situations, the use of rosin as a flux would be unsatisfactory, since this material carbonizes at these higher temperatures, thereby preventing rather than aiding soldering. It is nearly always desirable to tin large metal parts individually before assembling them for soldering together. This preparation facilitates the soldering and makes stronger joints. Preheating is sometimes desirable. Before soldering cast iron, the use of a cold

Table I. Alloys for Soldering and Some of Their Uses[a]

(a) The above solders represent typical compositions and uses. The classifications are informative and not complete or restrictive. In the trade, solder designations usually give the tin content first and the lead second; for example, 40:60 means 40% Sn, 60% Pb.

ASTM Tentative Specifications B 32–46T employ a system of designations illustrated by the following example:

"Alloy Grade 40A" refers to nominal 40 Sn, 60 Pb, 0.12 Sb max
"Alloy Grade 40B" refers to nominal 40 Sn, 60 Pb, 0.50 Sb max
"Alloy Grade 40C" refers to nominal 40 Sn, 60 Pb, 2.0 Sb max

(b) This solder is known to be sensitive to corrosion in outdoor environments.

pickling bath of 5% HF is recommended.[2] A more effective method is to use some process wherein the cast-iron surface is first decarburized, then fluxed and soldered.[3]

The selection of fluxes is controlled by the design of the joint, the materials to be joined, and the efficiency with which corrosive fluxes can be removed. In general, ferrous parts cannot be soldered effectively by using mild fluxes, such as rosin, tallow and the like. An active flux is required, such as zinc chloride, zinc chloride–ammonium chloride, or phosphoric acid. Where parts cannot be subjected economically to neutralization of flux or removal of flux after soldering, they should be tinned with the use of corrosive flux, which is neutralized or removed before assembly, thus making the use of a noncorrosive flux possible on final assembly soldering. In the electrical industry, rosin is used ordinarily for fluxing in joining conductors. Some of the other fluxes (for example, tallow) decompose during the soldering operation, giving weak organic acids that ultimately corrode conductors. Stearin, containing 10% oleic acid, is widely used as a flux for lead and many lead alloys. Iron, steel, zinc or galvanized iron general require an active flux for soldering.

Methods of Application. Most common metals and their alloys may be joined readily by means of solder. The method of applying solder to the metals to be joined varies according to the character of the metals, their position, the size of the parts, the speed with which the operation must be completed, and the shape, tensile strength, and appearance required in the finished product. In every instance, the surfaces to be soldered must be brought to the melting temperature of the solder. The necessary heat may be obtained in one of the following ways: by molten solder being poured repeatedly over the surfaces to be joined, as in the wiping method; by the use of a soldering iron; by the use of a torch; by a solder bath; by electric induction heating; by electric resistance heating; or by a stream of hot neutral gas.

Wiping Methods. Wiping is used for joining sections of lead pipe, or lead pipe with brass, bronze or copper fittings; and for joining lead-covered electrical cables, using a lead sleeve. After the cleaning and fluxing procedures, the parts to be joined are heated to the soldering temperature by the careful pouring of molten solder over the joint area. The operator catches the extra solder, which runs off the joint onto a cloth pad, and holds it against the underside of the joint. To effect uniform heating, the solder that is caught is frequently wiped up and around the joint and fresh hot solder is poured over the joint, until it is heated above the solidus temperature of the solder and completely tinned. The plastic, semimolten mass is then manipulated by using wiping cloths to give the joint the desired shape. Old practice required the building of a large mound of solder at the joint. More recent experience in joining lead cable sheath has shown that only a fillet[4] of solder is required for joint tightness.

Stearin in stick form, containing 10% oleic acid, is generally used for fluxing in wiping joints. Plumbers' wiping cloths are sometimes impregnated with tallow or lard oil, which acts as a flux.

Most of the wiping solders used in this country for making joints on pipes or cable sheathing contain 58 to 70% Pb with the remainder tin, although some users prefer the addition of 2% Sb or less. These alloys have a solidification range of about 140 F and contain a considerable quantity of eutectic. The combination of these two factors makes possible the wiping of joints.[5] Other wiping solders are shown in Table I.

Use of a Soldering Tool. A soldering tool is ordinarily referred to as a "soldering iron" and sometimes as a "soldering copper". It is ordinarily made of copper, even when called an "iron". Before the tool can be used efficiently, it must be "tinned" or coated with solder and kept clean.

For making electrical connections, an electrically heated soldering iron is used almost exclusively. Such irons are available in various sizes, with tips made of copper or iron-clad copper. The tool is heated to a temperature high enough to melt the solder quickly, and is drawn at such a rate along the edges to be joined that the momentary high temperature of the edges, together with the rapid melting of the solder, promotes good wetting and aids in the formation of a tight seal. Proper fluxing facilitates transfer of heat in the melting of the solder. Flux-cored solder wires are widely used for efficiency.

The soldering iron serves also in other work where the use of a flame or the pouring of molten solder over the surfaces is prohibitive, because of the fire hazard.

Use of a Torch. Where parts to be joined are too large to be heated by a soldering iron, or are shaped in a way that would make rapid soldering difficult, heating is accomplished by playing the flame of a torch on adjacent surfaces and then applying the solder cold, in bar or wire form of appropriate cross section. Flames should not impinge directly on the fluxed surfaces. The heated surfaces melt the solder and excess solder is removed by wiping before complete solidification. This method is commonly employed by electrical workers for soldering wire joints and sweating on lugs. Plumbers use this procedure with copper water-pipe sleeve couplings.

Solder Bath. Where parts are numerous and can be assembled in a jig, soldering can be accomplished by immersion in a bath of molten solder.

The soldering of automobile radiators is a good illustration of this procedure. The radiator cores, assembled in frames and tightly clamped there, have their tube ends dipped into a solder bath just deep enough to form the required joint. For making up the bath, the solder may be purchased in the form of slabs weighing from 15 to 35 lb. Popular compositions for the bath are 50% Sn, 50% Pb and 40% Sn, 60% Pb, although compositions outside these limits are used.

The soldering of side seams in tin cans is another good example of commercial technique. The cans are carried by a chain belt. The side seams contact a solder-coated roll, picking up some adherent solder that is being carried out of a solder bath in which the roll is partly immersed. In a modern machine 300 cans per minute can be soldered in a single stream or procession.

The leads from the glass envelope of vacuum tubes are joined to the base prongs by immersion in a solder bath.

Induction Heating. Many soldered joints are made by heat supplied by high-frequency inductive means. This method is most effective on ferrous materials but is economical only where equipment is available or production large. Parts should be cleaned, set in a jig and fluxed, and the solder should be placed and adequately shaped for the areas to be joined. Solder wire with flux on the outside may be used. The heating unit consists of copper tubing that is located near the areas to be heated, and situated in such a way as to permit easy arrangement around the work surfaces. In heating sections that require anything more than a minimum power for a short period, water cooling is required in the heating coil. A frequency of 500 kc is often used for these applications.

Resistance Heating. Where small lapped areas are to be soldered, it is sometimes economical to use electric currents to supply the heat. The conditions are similar to those necessary for spot welding, with the current at a considerably lower value. The solder must be placed and some flux used. Shaped carbon blocks serve as electrical contact materials.

Stream of Hot Neutral Gas. In certain delicate soldering operations, a stream of heated nitrogen is used to heat the parts to the soldering temperature. Preplaced solder has been found satisfactory with or without flux, depending on conditions.

Other Methods. In soldering many specialties, the usual soldering methods are often modified or combined, and special tools are devised to fit special conditions. However, no new principles are involved in these special practices.

Neutralization. Where corrosive fluxes are used it is essential, in order to avoid corrosion hazards, to remove the excess flux and flux residues from the parts by any one of a number of methods. Since most corrosive flux and flux residues are soluble in water, thorough rinsing of fluxed parts, preferably in hot running water, is effective. A solution of 5 oz of sodium citrate per gallon of water is effective on nonferrous parts, or only 1 oz of trisodium phosphate per gallon of water on either ferrous or nonferrous parts. These treatments should be followed by a

dip in clean water. The immersion time required will vary with the nature of the joint. Exposed joints will be cleaned in a shorter time than complicated assemblies. The immersion time should be approximately 5 to 20 min. On electrical connections soldered with chloride-bearing flux, extreme care should be used in the elimination of excess flux and residues. Where aqueous solutions are objectionable, as on some electrical parts, alcohol washes may be employed.

Maintenance of Molten Solder Bath. A pot of solder should never be heated beyond the necessary working temperature. On large work, where much heat is required to bring the work to proper temperature for efficient soldering, it is better practice to supply this heat by means of a large volume of solder at about the usual soldering temperature than to raise the temperature of a small pot of the solder unusually high.

As the temperature of the molten solder rises, the surface exposed to the action of the air is oxidized to an increasing degree, unless protected by a reducing material, such as charcoal.

Overheating solder in pots causes considerable dross and should be avoided. Dross may be skimmed off at a moderate temperature. A small amount of ammonium chloride stirred into the dross minimizes solder losses during cleaning.

During solidification of 35:65 or similar solder, the primary crystals of lead sink to the bottom of the melting pot, because of their greater density, and permit the lead-tin eutectic to segregate toward the surface. To insure uniformity of composition, the solder must be kept at a temperature higher than the liquidus temperature of the alloy, and must be thoroughly stirred after melting.

Mechanical Properties. Nightingale's tests[6] show 0.003 in. as a desirable thickness for a solder film on copper, and 0.005 in. on steel. Crow[7] previously indicated that the thinner the solder film, the stronger the joint.

The National Bureau of Standards[8] has investigated seams for copper sheeting. It was decided there that lap seams should be at least ¾ in. wide. For such a seam the maximum safe load was placed at approximately 350 lb per sq in. of seam area. The corresponding load for ½ in. previously tinned, flat lock seams was 375 lb per sq in. of seam area. A 50:50 solder was used for the tests.

For automobile radiator cores of the honeycomb type 40% Sn, 60% Pb solders are favored because of their supposedly greater resistance to vibration fatigue. Data for endurance limits are not available.

A 5% Sn, 95% Pb alloy has become fairly popular for use in joints maintained at 250 F under stress, as shown in Table II. The alloy containing 1.5% Ag, 1% Sn, 97.5% Pb is excellent for this application.

Table II. Shear Strength of Soldered Copper Sleeve Joints

Nominal Composition of Solder						Strength at 85 F (Quick Test)	Maximum Allowable Prolonged Stress		
Pb	Sn	Ag	Cd	Zn	Sb	psi	85 F psi	250 F psi	325 F psi

■	..	..	17.5	0.5	..	6000	740	...	90
50	50	..	..	..	..	5500	235	80	...
..	95	..	..	..	5	6200	1200	380	275

The National Bureau of Standards has also studied the strength of soft-soldered copper-tube sleeve joints.[9,18] The data in Table II are illustrative of the strength of soldered joints in general. By enlarging the dimensions, soldered joints may be designed to have greater strength than the parts that are united. The studies conducted by investigators at the Bureau indicate that solders containing quantities of tin should not be used on copper joints maintained at temperatures higher than 250 F.

Since solder is frequently used to join metals stronger than itself, seams must be reinforced by crimping, interlocking, riveting, or bolting before soldering,[10] in order to insure high strength. Thus a joint can be made stronger by relieving the solder of the load and making the major function of the solder the hermetic sealing of the seam. Soldering frequently helps in making efficient, electrically conductive joints.

Miscellaneous Notes. Aluminum may be soldered with alloys rich in tin that contain also considerable zinc. One method is to rub the aluminum surface beneath molten solder, thereby piercing the oxide film and permitting the solder to alloy with the aluminum.[11,12,17] Brazing or welding aluminum is usually preferred to soldering.

When soldering stainless steel, ample time should be allowed for the flux to act properly before the solder is applied. For this purpose either zinc chloride–ammonium chloride flux containing hydrochloric acid, or orthophosphoric acid flux is satisfactory.

For soldering zinc or galvanized iron, the presence of antimony in the solder is undesirable, because with zinc, antimony forms a compound difficult to fuse, thereby interfering with the flow of the solder unless the soldering is done rapidly. A similar reaction occurs when high-antimony solders are used on copper.

Some pastes and powders on the market are composed of pulverized tin or solder mixed with flux. Tubular solder wire is quite popular, with one or more cores containing rosin or other flux. A new variety is soft solder wire containing flux in grooves in the outer surface.[13] Adequate amounts of solder should be used in joints, but economy suggests using no more than enough. To aid the consumer in the economical use of soldering materials, manufacturers offer suitable forms and dimensions of solder. Some of the forms obtainable are tinner's bar, triangular bar, meter bar, ingot, wire in spools or in segments, drops, capping bar, slabs, powder, tape, ribbon and miscellaneous forms.

The time required to make a good soldered joint may preferably and actually be extremely short. Prolonging the period of time in which the solder in a joint is molten may increase the amount of alloying, but the effect is not generally considered beneficial. For soldering copper, it is advisable to use a temperature lower than 752 F, in order to reduce the formation of brittle copper-tin compounds that tend to decrease the strength of a joint.

Mechanical Property Tests of Metal Products

BY R. L. TEMPLIN*

THE mechanical property tests most commonly used in evaluating the quality of metal products include the tension, hardness, torsion, notched-bar impact, and some type of bend test. Other types of tests may be used, depending on the particular product or its intended application. Generally, the values obtained from such tests pertain specifically to the samples selected. It is essential, therefore, to select samples properly if the test data are to be closely representative of a metal product.

Uses of Data From Mechanical Property Tests. One of the primary purposes, in making mechanical property tests of metal products, is to determine conformance or nonconformance with specifications. The data may thus serve as an index to the quality of a product in comparison with similar products obtained previously or from other sources. Such data may also be used for comparison of a given material with other materials and, in conjunction with other factors, may assist in satisfactory replacement or improvement of a material. Manufacturers of metal products frequently use such data for control of manufacturing methods as well as for guidance in the development of new materials. Finally, one of the major uses of mechanical property values is to furnish a basis for the selection of values for engineering design.

Sampling. Metal products often exhibit variations in their mechanical properties, caused by unavoidable variations in the details of the commercial processes used in the manufacturing of the products. Although knowledge of the scope of these variations may be of considerable interest to both the producer and the user of the products, yet in most specifications for metal products, the primary purpose of the mechanical property tests specified is to furnish evidence that the piece of product sampled and tested has as good quality as similar pieces previously furnished. It is assumed that the piece selected for testing represents adequately the other pieces in a given lot. On this basis, specifications for products frequently indicate quite definitely from exactly what location in the product, as well as from how many pieces, specimens are to be taken for mechanical property tests.

Not all tests of mechanical properties require that pieces or coupons be taken from the sample selected. For example, most of the hardness tests can be performed on the sample selected, without destroying the sample or preventing its subsequent use in service. With such nondestructive types of mechanical property tests, it is possible to test every piece in a lot of material. However, mechanical property tests such as the tension, compression, bending and notched-bar types, require taking of samples, and it is important to select the method of sampling that will furnish the desired information.

For metal castings three sampling procedures are avail-

* Assistant Director of Research and Chief Engineer of Tests, Aluminum Research Laboratories, Aluminum Company of America, New Kensington, Pa.

Prepared for the Subcommittee on Mechanical Testing.

able: test coupons may be cut from sample castings, separately cast or attached test coupons may be used, or sample castings may be tested as a whole. Data concerning the mechanical properties of test coupons that have been cut from a given location in a casting may give a reliable indication of the mechanical properties of the casting in that particular location but, in general, these data will not represent the properties at other locations in the casting. Likewise, separately cast or attached test coupons cannot be expected to represent closely the properties throughout a casting, particularly if there is a marked difference between the dimensions of the casting and those of the coupon. The separately cast and attached test coupons, however, do serve in many instances as a satisfactory index of the quality of the casting they represent. Proof tests or maximum load tests of selected sample castings, wherein the method of testing as well as the amount of load can be agreed upon, often furnish satisfactory data for use as a basis of acceptance or rejection of the product. For further information about the method of sampling to be used for metal castings, the reader is referred to the article "Mechanical Testing of Castings", page 136.

In general, the sampling of wrought metal products involves fewer difficulties than the sampling of castings. This is particularly so for sheet, plate, bar, wire and tubular products. However, variations in the mechanical properties of sheet and plate may be expected, depending on whether the specimens are taken parallel or normal to the direction of rolling, as well as whether coupons are taken from the center, near the edge, or near one end or the other of large pieces. Large forgings often present problems in sampling similar to those found in the testing of castings. Product specifications intended to insure the quality of such products should, therefore, indicate the type and location of test specimen in sufficient detail to be used in determining the acceptability of the product.

If the purpose of the mechanical property tests to be made is to assist in the selection of a new material, or in the development of new manufacturing processes or changes in present processes, the sampling should be extensive enough to explore adequately the variations occurring in the material or product. In such instances, it is usually not necessary to save the sample item being tested, and the tests called for in standard specifications pertinent to the product are supplemented by those additional tests necessary to explore the sample thoroughly.

Test Specimens. Specimens for mechanical property tests are prepared from test coupons or samples and ordinarily have empirical dimensions for size and shape which, by general consent, have come to be recognized as standard. Because changes in size and shape affect some of the mechanical property values appreciably, it has been found necessary to put mandatory requirements for specimen dimensions into specifications for metal products. Compliance with these requirements is essential if the test data are to be mutually satisfactory to producer and user, and if a comparison is to be made with data from similar items.

Since variations in the methods used in preparing test specimens may have considerable effect on the test data, it is essential that careful and uniform procedures be followed in machining and finishing test specimens. Procedures should be used that will not cause temperature changes or distortions which, in turn, would affect appreciably the mechanical property values.

Mechanical Testing Apparatus. Most apparatus for testing mechanical properties consists essentially of a machine for applying a force or load to a specimen in a prescribed manner, a means whereby the force or load applied can be measured within acceptable limits, and a means for measuring deformation of the specimen. In all such equipment the errors involved in the indicated values for force, load or deformation should be within specified limits, generally given in specifications for standard testing methods. To insure the continued maintenance of such equipment, standard methods of calibration of apparatus have been developed and accepted, such as those found in specifications of the American Society for Testing Materials.

The Preparation of Test Specimens

By R. L. Templin*

THE proper preparation of test specimens from samples of metal products requires careful attention to the details of the procedures involved, if satisfactory test data are expected. Given a sample of a metal product, the problem presented is to prepare from the sample the desired size and shape of test specimen in the most economical manner and without appreciably affecting the mechanical properties of the material of the sample. If the sample or specimen coupon has been cut from the product by means of the cutting torch or by shearing, the metal adjacent to the cut edges, which has been affected by the cutting heat or cold working, must not be included in the portion of the test specimen that directly governs the test data to be determined. The amount of metal to be removed adjacent to heated or cold worked edges will depend on a number of factors, but primarily on the size of the article from which the coupon is taken and the kind of metal. The kind and size of cutting torch that is used may also be important. In the preparation of coupons sheared from sheet or plate, an approximate safe rule to follow is to remove an amount of metal equal to the thickness of the sheared material; that is, if the coupon was sheared from plate ¼ in. thick, ¼ in. of metal adjacent to the sheared edge should be removed between the sheared edge and the edge of the reduced section of a tensile specimen.

Care must be used in trepanning specimen coupons so as not to induce objectionable stresses in them. When this is unavoidable, provision is sometimes made for stress-relieving procedures that depend on the material and on agreement between supplier and purchaser.

Tensile Specimens. The most widely used types of tension test specimens for sheet, plate, strip, and thin-wall tubular metal products with large diameter are those shown in Fig. 1 and 2. The smaller type of specimen has more detail dimensions specified than the larger type, because experience has shown that the additional details indicated are necessary for satisfactory results in testing thin metal products. Symmetry about the principal axes of tensile specimens is one of the essential requisites towards obtaining axial and uniform stressing during testing.

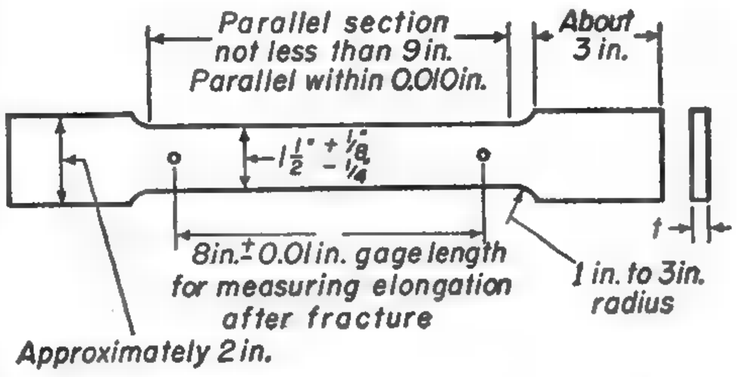
Tensile specimens of these two types should not be prepared by blanking or shearing to the finished dimensions specified, because of the cold working effects, the distortion of the specimen edges, and the roughness of the sheared surfaces. All these factors affect the test results to a varying degree, depending on the composition, the temper and the thickness of the metal, as well as on the details of the blanking or shearing tools and their lubrication. It is satisfactory, however, in testing some thin metal products, to blank or shear tensile specimen blanks, which are then finished to final size in the reduced section by filing, shaping, milling or grinding. This practice is particularly satisfactory in the preparation of specimens wherein half the difference in width between the ends and the reduced section of the specimen is equal to or greater than the thickness of the specimen.

Theoretically, it is desirable to use a tension test specimen with uniform cross section throughout the length of its reduced section. Practically, this is difficult to obtain in the two types of specimens being discussed, because of the variations in thickness of the metal products from

* Assistant Director of Research and Chief Engineer of Tests, Aluminum Research Laboratories, Aluminum Company of America, New Kensington, Pa.

Prepared for the Subcommittee on Mechanical Testing.

which they are taken, and because of the difficulties frequently experienced in machining the specimens. To overcome these troubles and to compensate for the effects of the gage marks usually put on the specimens, it has been found desirable to relieve the width of the reduced section of the specimens at the center. This relief is accomplished preferably by gradually tapering the width (or the diameter of round specimens) of the reduced section from the fillets to the center, as shown by the dimensions specified for the specimen in Fig. 2.



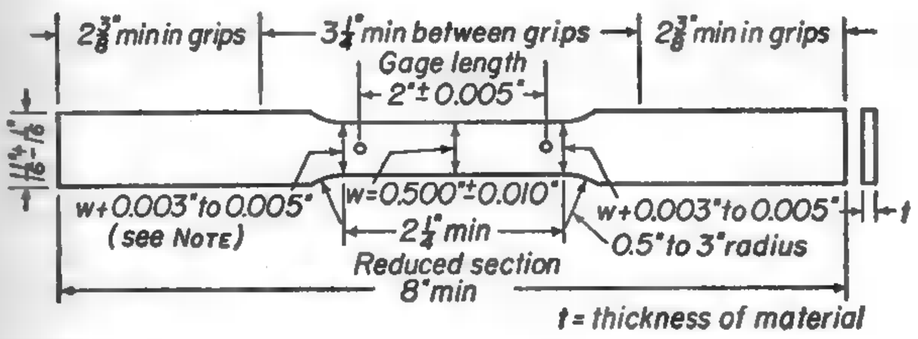
Note 1. When necessary, it is permissible to use a narrower specimen, but in such a case the reduced portion shall be not less than 1 in. in width.

Note 2. Punch marks for measuring elongation after fracture shall be made on the flat or on the edge of the specimen and within the parallel section; either a set of nine punch marks 1 in. apart, or one or more sets of 8-in. punch marks may be used.

Note 3. The dimension "t" is the thickness of the test specimen as provided for in the applicable material specifications.

Fig. 1 Standard rectangular tension test specimen for plate material ranging from ⅛ to 1½ in. thick. For plate more than 1½ in. thick the specimen may be machined to not less than ¾ in. in thickness, or a standard round tension test specimen may be used. (ASTM)

When they are to be prepared in considerable numbers, the smaller, rectangular-shaped tensile specimens can be machined easily to the desired dimensions and quite economically by transverse milling, using a suitable vise for holding a pack of specimen blanks, and a set of suitable milling cutters.[1] When only a few specimens are to be prepared, the machining can be done by filing, shaping, longitudinal milling or grinding, or combinations of these. Irrespective of the procedure used, the final dimensions specified should be met and undercutting of specimen width, at the ends of the reduced section particularly, should be avoided. The final machine finish for tensile specimens is particularly important and should be of high quality. The surfaces should be smooth and all corners sharp but free from burrs or other undesirable irregularities.



Note: Gradual taper from ends of reduced section to middle. All machining dimensions are shown below and testing dimensions above specimen. The ends shall be symmetrical within 0.01 in.

Fig. 2 Standard rectangular tension test specimen for sheet metals ranging in thickness from 0.005 in. to, but not including, ½ in. (ASTM)

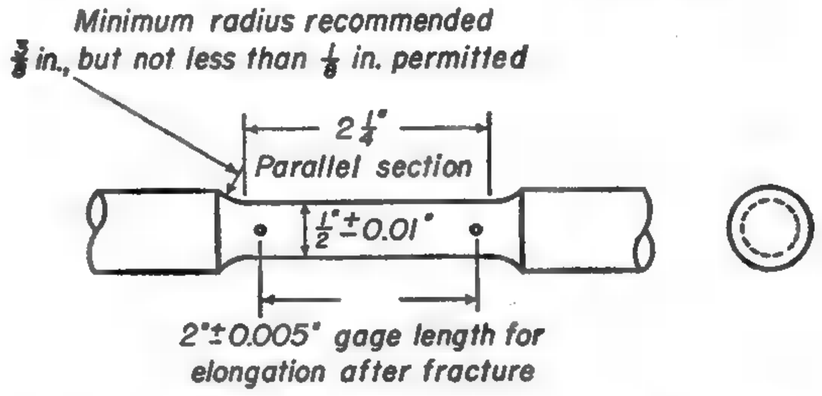
Commercial milling machines of specialized design are available for finishing the larger type of rectangular tensile specimen. These machines mill both edges of the reduced section simultaneously in a longitudinal direction. They were developed primarily for use in preparing specimens of mild steel plate.

Milling or other cutters used in machining test specimens should be sharp, maintained in good condition, and used in accordance with best practice for the material being machined. The rate of removing metal during the machining operation should be consistent with conditions insuring a good finish, desired dimensions and minimum effects on the metal by cold working or overheating.

Throughout the preparation and handling of the specimens, care should be taken to avoid damage, such as nicks, scratches, dents, kinks, bends and improper marking previous to testing. The proper marking for identification of thin sheet-metal tensile specimens often presents a serious problem. The use of steel stencils generally distorts the ends of the specimens enough that subsequently they cannot be held properly by any testing-machine grips. The thinner the specimens, the more serious the marking troubles. The use of sharp scribers, suitable inks, crayons or electric pencils is generally more satisfactory than steel dies or stencils.

The lengths of ends of the sheet and plate type of tensile specimens as specified are minimum lengths. In many instances, appreciably more reliable test results will be obtained by the use of longer specimen ends.

Where round tensile specimens can be used, they offer a number of advantages in comparison with the rectangular type. In general, they are easier to prepare, require less material and give more consistent data. Specimens of this type can be used satisfactorily throughout a considerable size range and give directly comparable test data if proper similitude in their dimensions is maintained.



Note: The gage length, parallel section, and fillets shall be as shown, but the ends may be of any shape to fit the holders of the testing machine in such a way that the load may be axial.

Fig. 3 Standard round tension test specimen for general use in testing metals (ASTM)

The basic size of round tensile specimen long used in this country is shown in Fig. 3. Some proportional sizes of similar smaller specimens are shown in Fig. 4. Irrespective of the size of these specimens, three types of ends are recognized and used, depending on the desire of the user or the testing equipment available. The details of the various types of specimen ends are not usually specified, but those shown in Fig. 4, 5, and 10 have proved satisfactory for many metal products. These specimens have plain round ends for use in wedge grips of the V type, shouldered round ends for use in special fixtures, and threaded ends to fit threaded adapters. In all instances, best results will be obtained if the grips, fixtures or adapters are loaded through suitable tension members that are spherically seated.

Round tensile specimens, when prepared from readily machinable metals, are generally turned on the engine lathe. If a relatively large number of specimens is to be made, special tooling can be used to decrease substantially both preparation time and cost. Forming tools, turret tool posts, combination center-drill and end-facing tools, automatic limit stops, special chucks, special lathe dogs, and automatic die heads for threaded-end specimens are some of the items that can be used in decreasing the time and cost of machining. In some instances, the turret lathe or automatic screw machine can be used to advantage. Round specimens of the light metals can be finished rapidly and economically by the use of a special forming tool on the cross slide of the engine lathe. Such a device uses a skiving cutter that has the same profile as the reduced section of the tensile specimen, including both the fillets and the taper in the specimen.

For round tensile specimens of metals that are not readily machined with the usual cutting tools or the tungsten-carbide tools, grinding probably offers the best method of finishing. To avoid grinding cracks in specimens of such materials, care should be taken to use suitable shape, grade

and bond in the wheel selected, together with proper speeds, feeds and coolants. If it is permissible, turning to size or slightly oversize, before hardening, is quite desirable, but if the hardening process causes warpage, provision should be made for correction to the desired dimensions by final grinding. The provision of suitable centers before hardening of the specimens usually facilitates the final grinding. Sometimes it is necessary to grind the centers before finish grinding the rest of the specimen, in order to obtain the desired final dimensions of the specimens. For some hardened metal specimens, suitable centers can be provided by soldering or brazing pieces of soft metal onto the ends of the specimens.

For best test results it is essential that the threads on the ends of threaded specimens be concentric with the axis of the specimen; that the inner or loading surfaces of shouldered-end specimens be plane and normal to the axis of the specimen; and that the ends of plain round specimens be symmetrical to and concentric with the axis of the specimen. Furthermore, for each of these types, the grips or fixtures into which the ends of the specimen fit should be so made and in such condition that the specimen will be stressed uniformly and axially, if satisfactory results are desired.

Tension specimens from tubular metal products that have outside diameters of 1½ in. or less are usually prepared from samples having full cross section and are provided with closely fitting bullet-shaped metal plugs, as shown in Fig. 6. If the capacity of the available testing machine is adequate, such specimens may be used for products as large as 2 in. OD. The thinner the wall thickness of such specimens, the closer the tolerances that should be used in fitting the end plugs. In general the plugs should be machined so that they require a light push or drive fit, preferably with no lubricant. The usual commercial tolerances for inside diameter of tubular products are greater than those giving satisfactory results in fitting plugs into tensile specimens. When numerous tension tests of tubular specimens are involved, it is economical to provide many pairs of plugs of various sizes which can be stored in suitable racks and machined to the desired sizes as needed, by light cuts or filing in a lathe. New plugs of the larger sizes are added as needed.

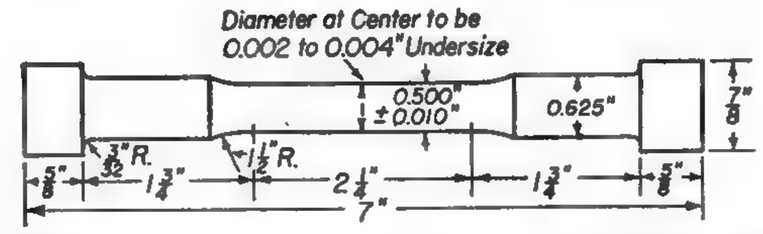


Fig. 5 Shouldered-end tension test specimen particularly adapted to hard steels and brittle materials

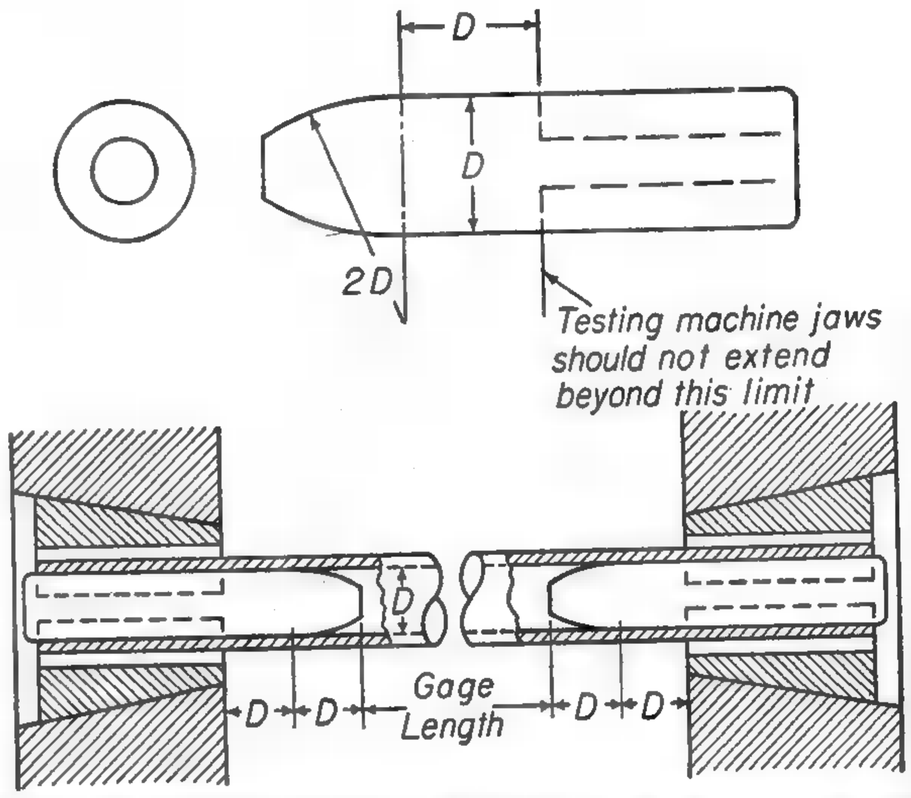

Fig. 6 Standard tension specimen for metal tubing ranging to as much as 2 in. OD but particularly for sizes 1½ in. OD and less (ASTM)

In the preparation of the plugs, leaving a narrow shoulder at their butt ends is very helpful in locating the plugs properly in the ends of the specimens. Obviously the height of these shoulders should always be less than the thickness of the specimen wall. The length of the parallel portion of the plugs is not specified, but a minimum value in terms of the specimen diameter is about two diameters for the larger specimens. For the smaller sizes of specimens, the lengths of the plugs are usually governed by the length of the V-wedge grips used, together with the length of plug required to extend beyond the ends of the grips. For discussion of tests for tubular products, see page 132.

After the plugged specimens have been tested, the plugs can be removed readily without damage to them, by expanding the specimen until they fall or are readily pulled out. This is done by hammering the plugged ends of the specimens on a suitable metal anvil or, still more easily, in a special hardened V block which has longitudinal stepped teeth ($\frac{1}{16}$-in. to ⅛-in. pitch) machined in the sides of the 90-deg V groove. When a wide range of specimen diameters is involved, the block is generally provided with two to four sizes of V grooves. Various sizes of hammers should be used, depending on the size of specimens.

In some instances the smaller sizes of tubular metal products, ½-in. OD and less, can be plugged with a low-melting alloy such as Wood's metal, and satisfactorily tested. Removal of plugs of this kind is accomplished by

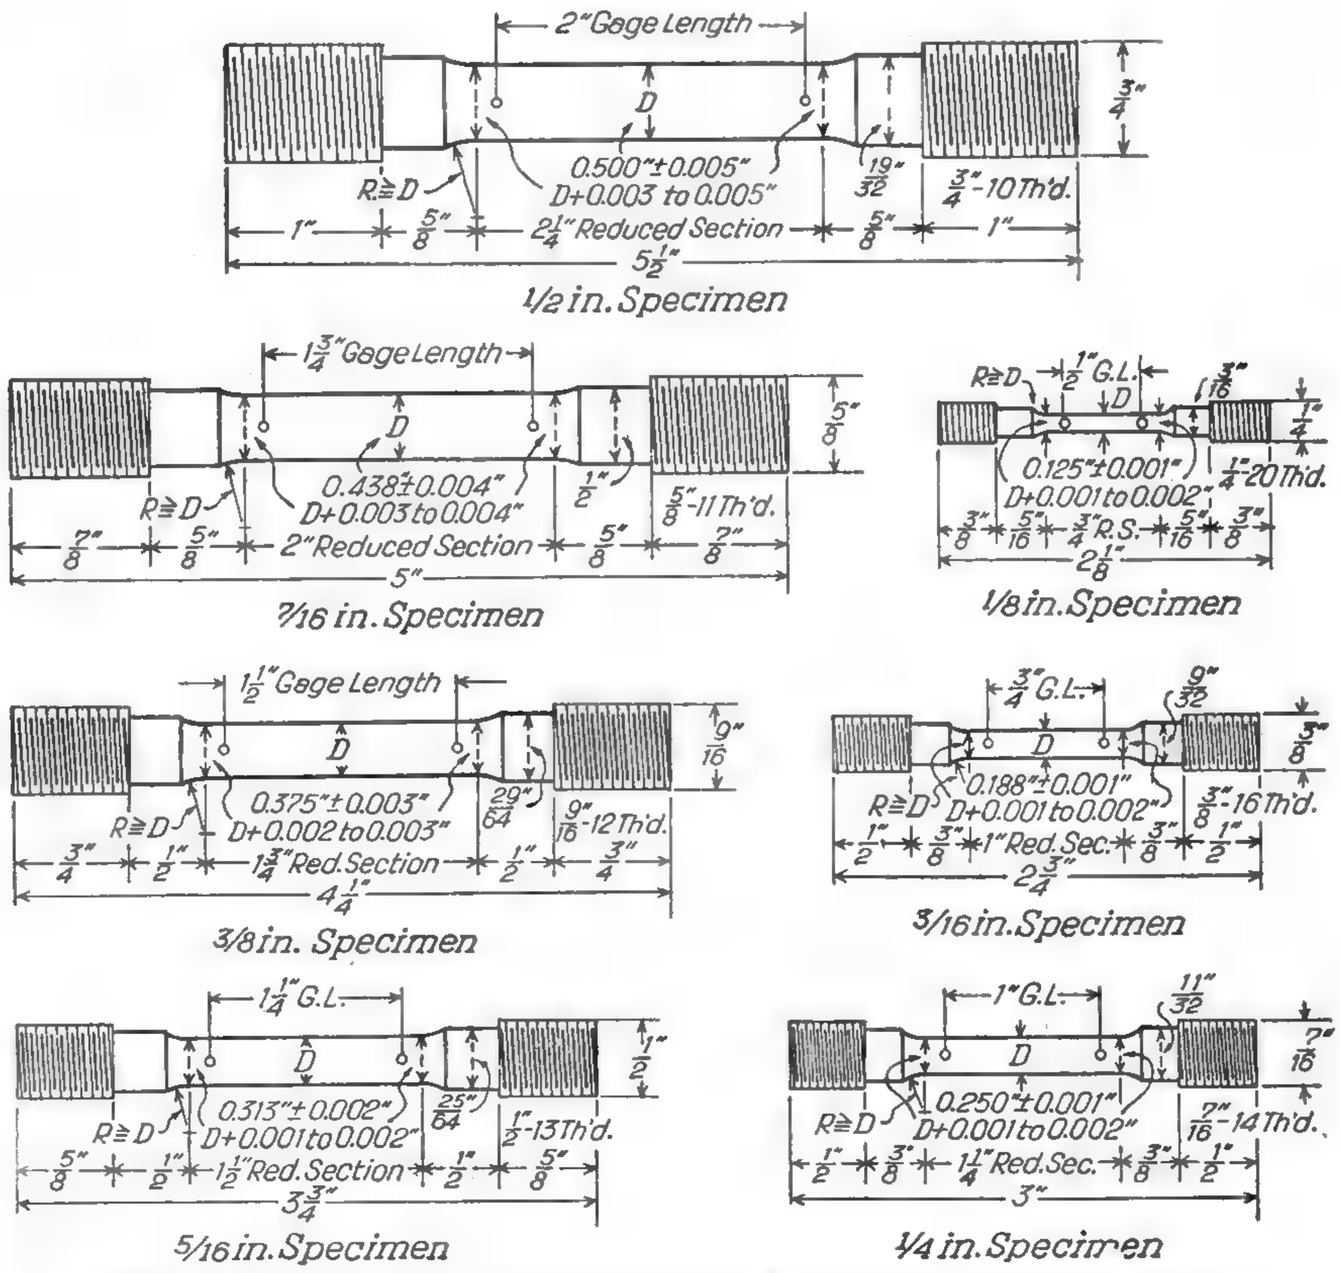

Fig. 4 Proportionate sizes of threaded-end round tension test specimens for metals

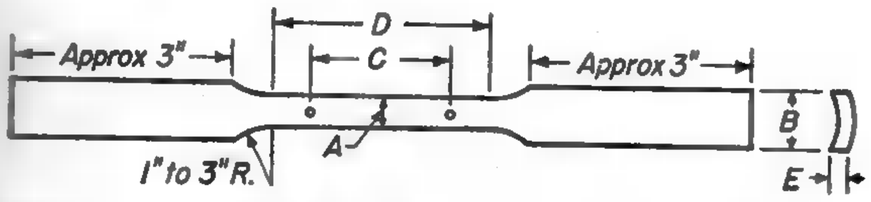
dipping in hot water so that the alloy is saved for subsequent use. Other low-melting alloys can be used for plugs in tubular specimens, but somewhat higher temperatures are required in removing these plugs after use. Some tubular products are tested by flattening the ends and testing with flat wedge grips.



Specimen	Dimensions, in. A	B	C	D min	E
No. 1	½ ± 0.010	1/16 ± 1/16	2	2¼	thickness
No. 2	¾ ± 0.010	1 ± 1/16	2 4	2¼ 4½	thickness
No. 3	1 ± 0.01	1½ ± 1/16	2 4	2¼ 4½	thickness
No. 4	1½ ± 0.01	2 ± 1/16	8	9	thickness

Cross-sectional area may be taken as the product of A and E

Fig. 7 Longitudinal tension test specimen for ferrous tubular products of large diameter (ASTM)

Tubular metal products larger than 1½ in. or 2 in. OD, with wall thicknesses less than ½ in., are generally tested for tensile properties by using the smaller rectangular specimen previously described (Fig. 2), or the one shown in Fig. 7. For the products having wall thicknesses ½ in. or greater, subsize round tensile specimens usually give best results. The testing-machine grips used with the rectangular type of specimens may have curved faces to fit the curved ends of the specimens, or the ends of the specimens

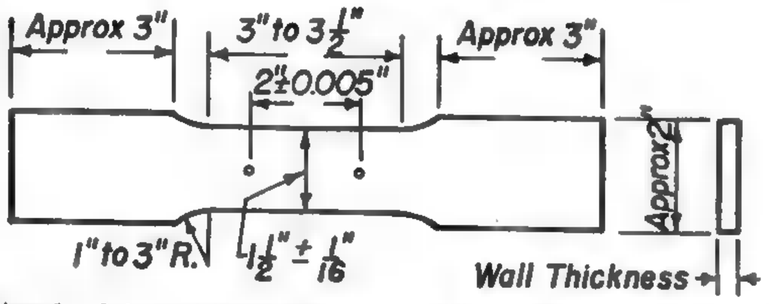


Fig. 8 Standard transverse tension test specimen machined from ring cut from tubular ferrous products (ASTM)

may be flattened so that they can be tested with flat-faced wedge grips. Difficulties with suitable end flattening procedures sometimes outweigh the slight additional cost of preparing the round type of tensile specimens. Transverse tensile specimens of the size shown in Fig. 8 are used for some ferrous tubular products. The location of such specimens is shown in Fig. 9. It may be pointed out that the elongation values obtained from tension tests of metal products vary inversely as the gage length and as some function of the cross-sectional area of the specimen.

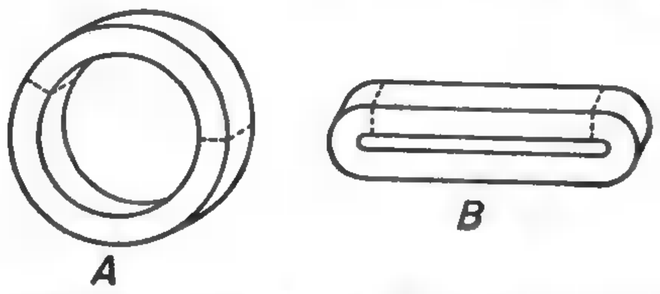

Fig. 9 Location of transverse tension test specimen in ring cut from tubular ferrous products (ASTM)

This makes direct comparison of elongation values difficult when using different sizes of specimens and a constant gage length. The tensile and yield strength values, on the contrary, show little if any variations within the range of specimen sizes generally used, if the specimens are uniformly and axially stressed.

Tension specimens for malleable iron and for cast iron are shown in Fig. 10 and 11.

Compression Specimens. Compression specimens for metals are not at the present time as standardized as the tensile specimens. Tentatively, however, three types are recognized as being suitable for metals. The short specimen is used for compression tests of bearing metals, the specimen of medium length for determining the general compressive strength properties, and the long specimen for determining the modulus of elasticity of metals. The dimensions suggested for general use are as follows:

Specimen	Diameter, in.	Length, in.
Short	1⅛[a] ± 0.01	1 ± 0.05
Medium length	0.798 ± 0.01	2⅜ ± ⅛
	1 ± 0.01	3 ± ⅛
	1⅛ ± 0.01	3⅜ ± ⅛
Long	0.798 ± 0.01	6⅜ ± ⅛
	1¼ ± 0.01	12½ min

(a) Area of cross section approximately 1 sq in.

Compression tests are appreciably more difficult to make, with satisfactory results, using the ordinary type of universal testing machine, than are the tension tests.

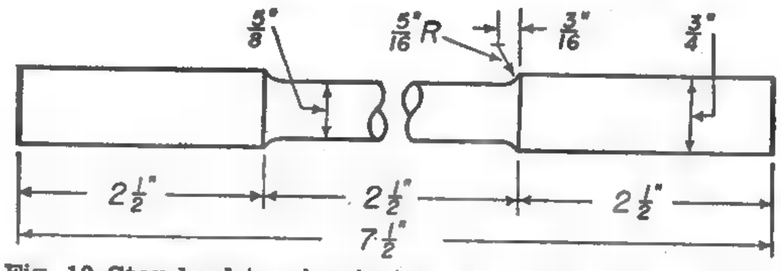

Fig. 10 Standard tension test specimen for malleable iron (not machined) (ASTM)

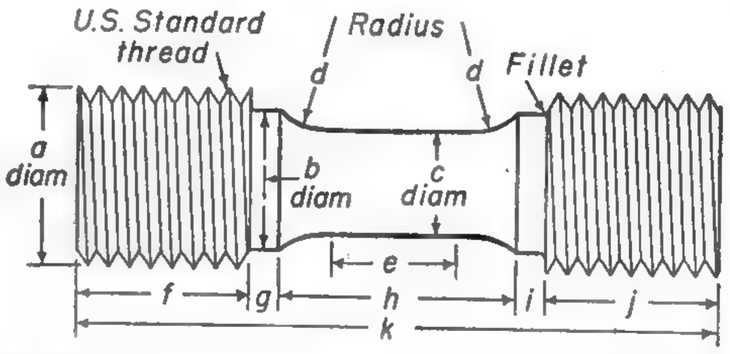
The reason for this greater difficulty is that in the compression tests eccentricities in loading tend to increase as the load on the specimen is increased, whereas in the tension tests, the eccentricities tend to decrease under increasing load. This is true especially for loads in the plastic range. In spite of these difficulties, compression tests can be carried out successfully if proper attention is given to details of apparatus and procedure.



Dimension (in inches)	Specimen A	Specimen B	Specimen C
a	¾	1⅛	1⅞
b	⅝	15/16	1 7/16
c	0.505	0.750	1.25
d	1.00	1.00	2.00
e[a]	Shall be equal to or greater than c (diameter)		
f	1.00	1.00	1¾
g	0.25	0.25	5/16
h, min	1.25	1.50	2¼
i	0.25	0.25	5/16
j	1.00	1.00	1¾
k, min	3.75	4.00	6⅜

(a) Length of parallel

Fig. 11 Standard tension test specimen for cast iron (ASTM)

It is very necessary that the ends of compression specimens be flat and mutually parallel. In addition, the end surfaces should be normal to the axis of the specimen within very close limits. As in the case of tensile specimens, compression specimens should be machined so as to have a surface finish of high quality. The corners of the specimens should be sharp and free from burrs, nicks, scratches and any other irregularities that would produce stress concentrations during testing. A final requisite, frequently neglected, is that both the ends of the specimen and the bearing surfaces with which they come in contact during testing should be clean and dry before assembly for testing. Cleaning can be accomplished by the use of suitable solvents, such as acetone, and is essential for the purpose of obtaining a symmetrical distribution of stress intensity on the ends of the specimen.

Suitable devices that assist in obtaining uniform stress

distribution on the ends of compression specimens during testing include spherical compression bearing blocks, properly designed and made; suitable adjustable bearing blocks for correcting out-of-parallelism of testing machine platens; and suitable compression tools or subpresses for insuring axial application of load during testing. Additional devices are necessary when making compression tests of thin specimens of sheet metal or long cylindrical specimens having low lateral stability.

Shear Specimens. Although a variety of shear tests are made on metal products, no generally recognized standard methods or specimens have been adopted. One type of shear test is the torsional, in which either a solid or tubular specimen is used. Solid specimens are often tested full size, but for more accurate results they may be reduced in lateral dimensions, as in the tensile specimens. The tubular or hollow specimens that have a thin wall are more suitable for obtaining shearing strength values for metals, largely because the cross section of the specimen has more nearly uniform stress than is found in the solid specimen. For ultimate shear strength determinations, the hollow specimens should have short reduced sections of about ½ diam, and a diameter-to-thickness ratio of from 10 to 12. For determination of shear modulus and yield strength values, a hollow specimen is to be preferred that has a length of at least 10 diam and a ratio of diameter to wall thickness of not over 10, for its reduced section. The actual dimensions of the specimen used may well be chosen to suit both the size and type of testing machine available, as well as the product to be tested.

Shear tests of sheet or plate are made by suitable punches and dies either fitted directly into a testing machine or into a subpress which can be used in a testing machine, so that the load required to shear a specimen of a given size can be measured. The punches and dies are usually circular and the specimen is of suitable size and shape to allow a complete disk to be punched from it and yet have a minimum margin beyond the shearing surface equal to or greater than about twice the thickness of the specimen. Another form of shear test (Amsler) is made by using three ringlike dies with either round or square holes through their axes, so that a specimen of the same shape can be inserted through the three dies; the outer dies are supported and the middle die is displaced laterally so as to shear a short section from the specimen by using a suitable fixture in a testing machine. From such a double shear test, the shearing strength is readily obtained. In such tests the shearing tools should be kept sharp and free from burred or nicked edges, and should be used under constant conditions of lubrication and speed.

Notched-Bar Impact Specimens. Tentative standard methods are now in use for making single-blow notched-bar tests of metals. The types and sizes of specimens recommended by the ASTM are shown in the article on page 112. Unnotched specimens ¼-in. sq have been extensively used for checking nonferrous die-cast metals.

Experiments have been made using many types of notched-bar tests, and numerous sizes and shapes of specimens have been studied in attempting to develop a satisfactory, so-called "shock resistance" test. This investigational work is still in progress, but so far no one type of test or specimen appears to suffice for all metals; consequently there are many differences in commercial testing practices. In some applications the notched-bar test has shown considerable merit, but in others even the best results obtained have been of dubious value.

Other forms of the "impact" test include repeated impact and torsion-impact tests, each requiring different sizes of specimens, depending on the testing machine used.

Preparation of specimens for the notched-bar test requires the same kind of care as that used in preparing tension or compression specimens. Particular attention must be given to the machining of the notches. When the specimens are of the type in which the notch can be made by drilling or by drilling and reaming, the direction of the machining scratches will be such as to have a minimum effect on the test results. Notches which must be milled transversely can usually be improved by polishing with a wire held in an electric drill using a suitable abrasive compound, or by other methods that will remove the tool marks that would be parallel to the axis of the notch. Furthermore, to insure consistent results the specimens should be square within close limits. The care necessary in finishing specimens will depend on the material tested.

Hardness Specimens. Hardness tests require no special size or shape of specimen but there are other limitations covered in the article "Hardness Tests", page 93.

Bend Specimens. A standard method of bend testing for determining the ductility of metals is now in use (ASTM E 16 – 39). The method was developed primarily for the testing of welds and was not intended to be substituted for the simpler and wholly adequate bend test requirements commonly specified for many wrought metal products. The test specimens required in the method just referred to, include both a rectangular and a round specimen. The rectangular type is usually the preferred form, with a width at least three times the thickness. The edges of the specimen should be smooth and the corners should have a radius not greater than ⅛ the thickness of the specimen. The length of the specimens is generally varied with the thickness, but this is considered unimportant provided sufficient length is allowed for performing the bending operation. When the round type of specimen is used, the results obtained should be considered as comparative only, since for most metals the elongation of the outer fiber has been found to vary with the diameter of the test specimen.

The gage length over which the elongation is to be measured is specified as 0.3 for plate from ¼ to ½ in. in thickness and 1 in. for all plates over ½ in. in thickness. The gage length should be located at the section of maximum bending, and in the center third of the width of the specimen. The detailed procedure for carrying out the bend tests using these types of specimens is given in the standard methods of the ASTM.

Other types of cold bend tests are used for different types of metal products. In general, such tests are made by bending a strip or piece of the metal around a mandrel or die of specified dimensions, by steady application of load, or by hammering until rupture occurs or until an angle of either 90 deg or 180 deg is attained. Many forms of cold bend attachments are available for commercial testing machines; also machines are available that are intended solely for the purpose of making bend tests. Although the cold bend test is one of the oldest tests and apparently one of the simplest, yet the results obtained are frequently affected by the procedure and apparatus used.

The well-known transverse flexure test as applied to brittle materials, such as cast iron, is sometimes considered a form of bend test. Three sizes of specimens have been standardized for use in making the transverse test on gray iron castings. These have the following as-cast or skin-machined dimensions:

Transverse Test Bar	Dimensions		Distance between Supports in Transverse Test, in.
	Diameter, in.	Length, in.	
A	0.875	15	12
B	1.20	21	18
C	2.00	27	24

Such tests give both breaking load and deflection data.

Fatigue Specimens. See "Fatigue Tests", page 118.

Cupping Specimens. Cupping tests of sheet metals are used as an index of the ductility and, in some instances, of the drawability of the material. Although these tests have been used for many years, at the present time no standard conditions of test have been generally accepted; the result is that the values from different types of machines are not concordant. The specimens used in these tests are usually in the form of disks, squares or strips of suitable dimensions (about 3 in. in diam or width) to fit into the testing machine, and of the same thickness as the sheet metal which they represent.

The Calibration of Testing Equipment

By Bruce L. Wilson*

ERRORS of the testing equipment used to determine the mechanical properties of materials result in errors in the test values obtained. Such errors may lead to disagreement between different laboratories or, if the errors are large, to failure of parts of machines or structures in service. If such errors are to be avoided, adequate calibration of all mechanical testing equipment is necessary.

The mechanical properties commonly used in specifications are defined in other sections of this book. Some of these properties can be determined with one piece of testing equipment; others require the use of several different instruments and machines. For instance, the breaking strength of a wire can be determined with one machine, a tension-testing machine, but the modulus of elasticity requires the use of equipment for determining the cross-sectional area of the specimen, a testing machine for applying loads, and a strainometer for measuring the strains under load. Since the error in any value determined by a mechanical property test is influenced by the errors of each instrument or machine used in its determination, the calibration of each piece of equipment is necessary to insure that the error in the result is no more than allowed.

Adequate calibration of mechanical testing equipment involves the determination of both the accuracy and the sensitivity of the equipment, and it is important that these two properties should not be confused. A sensitive instrument or machine is not necessarily accurate, but the accuracy is, in general, limited by the sensitivity.

The instruments used in calibrating mechanical testing equipment must be calibrated. Errors of instruments used for calibrating other equipment should be small compared with the errors to be determined. In general, the errors of instruments used for calibrating mechanical testing equipment should not exceed one fifth, or preferably one tenth, of the allowable errors of the equipment being calibrated.

Calibration of Testing Machines. The calibration of a testing machine which indicates the magnitude of the forces applied to specimens, usually consists of the calibration of the load-weighing mechanism of the testing machine. In such a calibration, the loads indicated by the testing machine and the loads indicated by the calibrating device are determined for several different loads. For each indicated load, the error is computed by subtracting the correct value of the load (determined with the calibrating device) from the load indicated by the testing machine. The loading range of a testing machine is then determined as the range of indicated loads for which the testing machine gives results within the permissible variation, which is usually expressed in per cent. The most generally recognized permissible error for testing machines is plus or minus 1%, the value given in the ASTM Standard Methods of Verification of Testing Machines.[1]

Four methods of calibration are given in the ASTM specification. These include calibration by standard weights, calibration by proving levers, calibration by elastic calibration device, and calibration by comparison.

In the calibration of testing machines the loads are usually applied in ascending order, since machines are most commonly used in this way. For some types of machines, particularly those in which the load is measured by measuring the pressure in a hydraulic jack, the errors for increasing and decreasing loads will not agree; therefore, it is important to calibrate a testing machine in the way in which it is used.

It is customary to calibrate a testing machine for ten or more test loads in each loading range. It is advisable to repeat some of the test loads several times to determine whether the testing machine gives reproducible results.

Specimens are usually loaded in testing machines in such a way as to make the resultant force coincident with the axis of the machine. For this reason the loading range of a testing machine is usually determined by applying the calibration loads so that the resultant load will be as nearly along the axis of the testing machine as possible. If a machine is to be used for measuring eccentric loads, the errors of the machine should be determined by applying calibration loads in such a way that the resultant load is applied at definite distances from the machine axis.

The errors of testing machines for rapid rates of loading may differ from the errors for slow rates of loading, and frequently may be considerably greater. These additional errors should not be neglected when determining the rates of loading to be used in testing.[2]

It is usually recommended that testing machines, when in constant use, be verified at intervals of 6 months, and when used intermittently, at intervals of 2 or 3 yr. However, it is important that a testing machine be calibrated immediately after repairs or adjustments have been made to the weighing mechanism, or after the machine has been moved, unless it is a self-contained portable machine. The character of the calibration graph, showing the errors of the machine as a function of the machine reading, is often valuable in locating sources of trouble in a testing machine.

Calibration by Standard Weights. Small vertical testing machines, with weighing mechanisms attached to their lower compression platens, can be calibrated to capacity by loading the machines with standardized weights. Standard metal weights are placed directly on the weighing platen of the testing machine, or upon trays or other supports suspended from the weighing platen. For axial loading, the weights are distributed symmetrically in relation to the weighing platen. The applied load and the indicated load are recorded for each test load, and the error is calculated from these values. This method of calibration can be used only on certain types of vertical testing machines and is seldom used for test loads greater than 2000 lb.

Calibration by Proving Levers. Vertical testing machines can be calibrated by means of standardized proving levers and standard weights. Proving levers are simple levers that have a ratio of about 10 to 1. Proving levers have been used for loads up to 200,000 lb but the capacity load of proving levers usually does not exceed 20,000 lb. Methods of standardizing and using proving levers are given in the ASTM Method.[1] Horizontal testing machines may be calibrated by means of bell crank levers. Methods of standardizing bell crank levers have been described.[3]

The chief disadvantages of proving levers are that the equipment is not portable and that the method is limited to relatively small loads, making it impossible to calibrate most testing machines to capacity by this method.

Calibration by Elastic Calibration Device. Usually testing machines are calibrated by means of elastic calibration devices. By far the most common of these devices is the proving ring developed at the Bureau of Standards about twenty years ago. Amsler boxes, and loops fitted with dial micrometers are also used. Because of the errors of the dial micrometers, it is usually recommended that devices fitted with dial micrometers be used only at the loads for which they have been calibrated, unless the calibration of the dial micrometers shows that the errors in this portion of the device would not, upon the interpolation of the values, result in load errors outside the tolerances for the calibrating device. Proving rings and Amsler boxes, which are equipped with micrometer screws, are used within their loading ranges to measure loads other than those for which they have been calibrated.

A proving ring is an elastic ring in which the deflection, when the ring is loaded along the diameter, is measured by means of a micrometer screw and a vibrating reed mounted diametrically in the ring. Compression proving rings that have capacities from 300 to 300,000 lb are commercially available. Tension proving rings are available in capacities as great as 100,000 lb. All proving rings submitted to the National Bureau of Standards are calibrated for compliance with the National Bureau of Standards Specification for Proving Rings.[4] This specification contains the requirements which have been found necessary

* Physicist, National Bureau of Standards, Washington, D. C.
Prepared for the Subcommittee on Mechanical Testing.

to insure that proving rings will be satisfactory, reliable instruments for calibrating testing machines.

Amsler boxes are essentially hollow cylinders equipped with a micrometer screw for measuring changes in volume with load. A plunger attached to the micrometer screw projects into the interior of the hollow cylinder, which is filled with mercury. By means of the micrometer screw, the mercury column in the glass capillary tube connected to the reservoir, is adjusted to an index mark.

It is essential that any type of elastic calibration device be calibrated by determining its readings under accurately known loads. For this purpose two dead weight testing machines have been installed at the National Bureau of Standards.[5] In one, loads from 200 to 10,100 lb may be applied by 100-lb increments in either tension or compression. In the other, loads from 2000 to 111,000 lb may be applied by 1000-lb increments. The weights of these machines were adjusted to within less than 0.02% of their nominal values.

For calibrating elastic devices in compression, with loads exceeding 111,000 lb, the loads applied to the device being calibrated are measured by means of three calibrated proving rings.

The ASTM Methods require that, for loads not exceeding 100,000 lb, an elastic device be calibrated by applying dead weights known to be accurate within 0.02%. For loads exceeding 100,000 lb, an elastic device may be calibrated by another elastic calibration device, by a combination of several elastic calibration devices, or by proving levers and dead weights, provided that the applied load is known to be accurate to within 0.1%. The use of the lever system of a compound-lever testing machine or of a platform scale is not allowed.

To minimize errors caused by temperature it is important that the elastic device and the testing machine be at nearly the same temperature during a calibration.

When a testing machine is being calibrated with an elastic device, the device should be preloaded, since this practice is followed in calibrating such devices. In preloading an elastic device, care should be taken not to exceed the capacity load of device or testing machine.

For some types of elastic calibration devices it is necessary to follow a fixed time schedule of loading in order to avoid errors resulting from small temperature effects caused by stress. These effects are less pronounced for devices subjected to bending than for devices subjected to direct tension or compression, as has been pointed out by Tuckerman.[6]

For ordinary purposes the ASTM Methods permit the use of elastic devices with errors not exceeding plus or minus 0.2%. The National Bureau of Standards Specification for Proving Rings requires an accuracy of plus or minus 0.5% at 10% of capacity load and plus or minus 0.1% at capacity load. The errors of most rings certified at the National Bureau of Standards comply with the ASTM tolerance of plus or minus 0.2% for loads from 10% of capacity load to capacity load.

Calibration by Comparison Method. In calibrating a testing machine by the comparison method, the tensile strengths of two groups of specimens taken from the same bar are determined with the machine being calibrated and with a testing machine which has been calibrated by one of the three methods described above. This method, which is described in detail in the ASTM Standards, is less accurate than the other methods.

Calibration of Torsion-Testing Machines. Known torques may be applied to the weighing mechanism of a torsion-testing machine, by applying known forces to a lever arm of known length. Forces may be applied either by means of dead weights or by means of an elastic calibration device and a jack.

Calibration of Hardness-Testing Machines. Two general methods, one direct and one indirect, are used in calibrating hardness-testing machines.

For indentation hardness-testing machines, such as the Brinell, the direct calibration involves a determination of the shape of the indenter, the errors of the applied loads, the rate and time of application of load, and the errors of the equipment used to measure the indentations. This method is applicable to Vickers and Tukon machines.

For some machines it is not practicable to carry out a direct calibration, because of a lack of the necessary equipment or because the shapes of the indenters and the constants of the machines have not been defined in terms of the fundamental units of length, mass and time. For such machines an indirect calibration is made by determining the hardness readings of standard test blocks, standardized and supplied by manufacturers of hardness-testing machines. Rockwell and Scleroscope machines are usually calibrated by means of test blocks.

Calibration of Impact-Testing Machines. Direct calibration of an impact-testing machine would involve a measurement of the decrease in the rotational velocity of the pendulum, the calculation of the corresponding difference in kinetic energy, and a comparison of the result with the value indicated by the machine. Because this direct method of calibration is very difficult to carry out, a simpler method is ordinarily used.

If frictional, vibrational and other losses are neglected, the kinetic energy of the pendulum at the instant of impact with the specimen is equal to the potential energy possessed by the pendulum before release; and the kinetic energy of the pendulum immediately after breaking the specimen is equal to the potential energy of the pendulum at the maximum elevation to which it swings after breaking the specimen. The energy absorbed by the specimen, neglecting losses, is the difference in the energy of the pendulum in its initial position and in the highest position that it attains after breaking the specimen. This energy may be calculated by multiplying the total weight of the pendulum by the change in elevation of the center of gravity.

The center of gravity of the pendulum is a point on the interior of the pendulum. Therefore it is more convenient to determine experimentally the product of the total weight of the pendulum and the elevation of the center of gravity, by a method described in detail in an ASTM Method.[7] This method involves the determination of the calibration weight of the pendulum by measuring the vertical force necessary at the center of the striking edge in order to support the pendulum in a horizontal position. The energy of the blow with which the specimen is struck is the product of the calibration weight and the change in elevation of the center of the striking edge, when the pendulum is raised from the point of impact with the specimen to the position from which it is released. The errors of the scale may be determined by a comparison of the indicated readings and the values may be calculated by multiplying the calibration weight by corresponding elevations of the striking edge above the impact position. Calibration should also include determination of corrections for friction and windage, determination of the location of the center of percussion and of the striking velocity, as outlined in the ASTM Method.

Calibration of Strainometers. The calibration of a strainometer, such as an extensometer, a compressometer or a strain gage, usually involves the determination of the calibration factor of the instrument and determination of the strainometer error for different instrument readings.

The calibration factor of an instrument is the factor by which the change in the instrument reading must be multiplied to obtain the equivalent strain. That is, the calibration factor equals the ratio of the change in length to the product of the gage length and the corresponding change in strainometer reading. For direct-reading strainometers, the calibration factor is unity. It is customary to determine the error of a strainometer for several different instrument readings by means of a suitable calibrating device.

A device for calibrating strainometers usually consists of a rigid frame, suitable coaxial spindles or other fixtures to which the strainometers may be attached, a mechanism for moving one spindle or fixture axially in relation to the other, and a means of measuring accurately the change in length so produced. It is important that the mechanism for moving one spindle with respect to the other should permit sensitive adjustments. The changes in length may be measured by means of an interferometer, a micrometer screw, or standard gage blocks and an indicator. If standard gage blocks and an indicator, or a micrometer screw

are used, they should be calibrated. The errors of the calibration device should not exceed one fifth of the permissible error of the strainometer.

A calibrating device with which the changes in length may be measured, either by means of standard gage blocks and an indicator, or by means of the interferometer method, has been described by A. H. Stang and L. R. Sweetman.[8] A calibrating device that makes use of a calibrated differential screw has been described by R. L. Templin.[9]

For some strainometers, the position during calibration, the mounting pressure, the material and hardness of the spindles of the calibrating device, and the temperature—all have been found to influence the readings. The effects of some of these variables on Huggenberger tensometers and Tuckerman strain gages have been described by Vose[10] and Wilson.[11] Care should be taken to eliminate errors caused by these variables, both during calibration and during the use of the instruments.

The calibration factor of the instrument may be obtained either graphically or algebraically from the strainometer readings and the ratios of the changes in length of the calibration device to the strainometer gage length.

The allowable error for a strainometer depends on the mechanical property being determined. Strainometers having errors which do not exceed 0.00005 or 0.00001 in. per in. are often used for determining values of the modulus of elasticity or elastic limits. The allowable error is usually greater for strainometers used for determining yield strengths.

Wire strain gages cannot be calibrated by means of the usual type of calibrating device. Selected gages are calibrated by attaching them to beams, or to tension or compression specimens, and loading the specimens to produce the desired strains as indicated by sensitive calibrated mechanical or optical strain gages. If careful control is maintained over the manufacture of gages, the calibration factors of the gages selected for calibration can be kept sufficiently constant to insure that the factors of the gages not calibrated will not differ by more than about 1 or 2% from the factors furnished for the gages. W. R. Campbell has given information concerning the performance of wire strain gages in tension and compression, and the errors from prestraining, temperature changes and weathering.[12–16]

Hardness Tests

BY THE SUBCOMMITTEE ON HARDNESS TESTING*

HARDNESS, as the term is commonly used in metallurgy, is a measure of the resistance of a material to indentation by an indenter of fixed geometry, under a static load. A hardness test of this type is known as an "indentation hardness test".

Considerable information can be derived from a hardness test, but intelligent appraisal of a hardness number requires knowledge of the composition and condition of the metal at the time of the test, as well as understanding of the factors that influence the accuracy of the test.

Applications of Hardness Testing

Inspection and Control. For optimum performance in a particular use, a metal is conditioned by heat treatment or cold work, or sometimes both. Such treatments are usually accompanied by a change in hardness of the material; thus, when the hardness resulting from treating a given material by a given process is established, it affords a nondestructive, rapid and simple means of inspection and control for the particular material and process.

Estimation of Other Properties of a Metal. For many practical purposes, the tensile strength of heat treated carbon steel and low-alloy steel may be estimated from the hardness of the steel, when the hardness is in the range from 200 to 500 Bhn. According to reported data,[1,2] multiplying the Brinell hardness number by 500 gives the approximate tensile strength. There seems to be no generally useful relationship between hardness and tensile strength for nonferrous materials. A hardness test is no substitute for the tensile test and provides no information concerning ductility, unless all factors determining mechanical properties are known to be controlled.

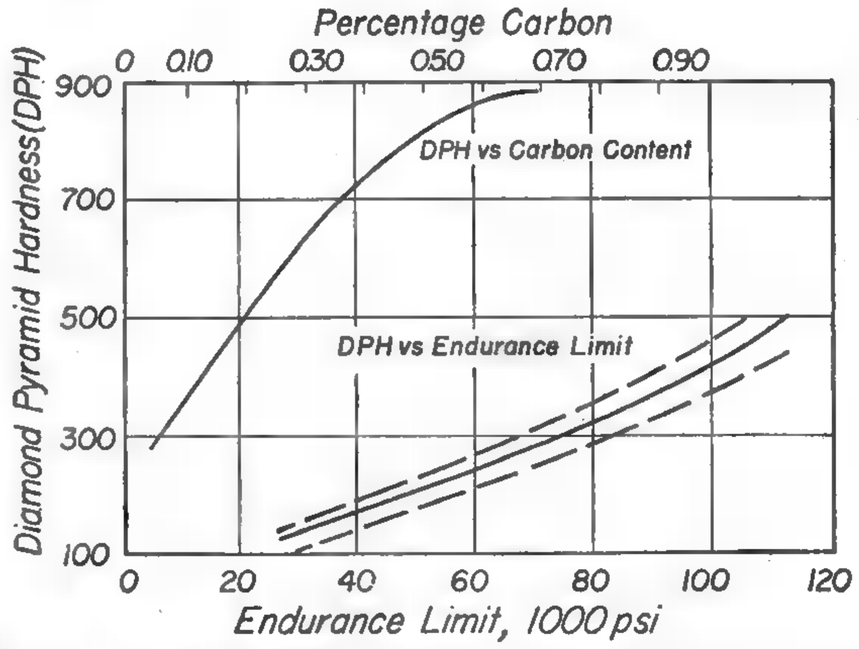

Fig. 1 Relationship between hardness and carbon content of ferrous materials, and between hardness and endurance limit. Hardness versus carbon content is based on hardness tests of material in the martensitic condition.

Figure 1[2] shows that with ferrous alloys there is an approximate correlation between hardness and endurance limit; nevertheless, care should be used in interpreting curves of hardness versus fatigue strength, since the relationship may be altered by heterogeneity of the metal, by surface finish and by residual stresses. This relationship applies to high-quality hot worked steels when prop-

* The members of this subcommittee are Howard Scott, *Chairman* (Westinghouse Electric Corporation), R. F. Campbell (United States Steel Corporation) and R. H. Heyer (The American Rolling Mill Company).

erties are varied by tempering temperature or carbon content chiefly, and when the steels are fully hardened to the martensitic condition before tempering.

Other Applications. Shallow-penetration hardness tests permit the investigation of surface conditions, such as depth of the decarburization resulting from heat treatment, and depth of case in carburizing and cyaniding.

Since precipitation hardening is reflected in hardness changes, it is often studied with the aid of hardness tests.

The suitability of a specific composition of steel for an intended use is frequently governed by the hardenability, the evaluation of which requires the use of hardness tests. *See* "Hardenability Tests", in this Handbook.

A rather interesting application of the hardness test is for estimating the approximate carbon content of a steel from the measured hardness of the steel in the martensitic condition. Data of Burns, Moore and Archer,[4] converted to diamond pyramid hardness (DPH), and presented in Fig. 1, indicate the trend of this relationship for steels that contain between 0.10 and 0.60% C.

Principles of Indentation Hardness Testing. Since the hardness test yields much useful information, and because no one combination of test load and indenter size has been satisfactory for testing specimens of all sizes and all degrees of hardness, it has been necessary to devise many hardness scales. Regardless of which indentation hardness scale is selected, the test is usually performed by impressing into the specimen, which is resting on a rigid platform, an indenter of fixed and known geometry, under a known static load applied either directly or by means of a lever system. Depending on the type of test, the hardness is expressed by a number that is either proportional to depth of indentation for a specified load and indenter, or proportional to a mean load over the area of the indentation. Indentation area is measured either as contact area or as projected area. (The projected area is bounded by the outline of the indentation lying in the plane of the specimen surface.) Because an indentation is measured after either partial or complete removal of the test load, thus permitting elastic recovery, such a measurement does not represent the actual size of the indentation under load, but is a measurement of the recovered indentation.

Table I. Specifications for Hardness Indenters

	Brinell	Rockwell		Vickers	Knoop	Monotron
Material of which indenter is made	Hardened Steel or Tungsten Carbide	Diamond	Hardened Steel	Diamond	Diamond	Diamond
Shape of indenter	Sphere	Cone	Sphere	Square-Based Pyramid	Rhomb-Based Pyramid	Hemisphere
Dimensions of indenter	D = 10mm	θ = 120°	D = 1/16 in., 1/8 in., 1/4 in., 1/2 in.	θ = 136°	a = 130°, θ = 172°30′	D = 0.75mm

Five types of indenter in common use are listed in Table I. For hard metals, diamond indenters are preferable because they deform less than those made of steel. Hardness numbers determined by using cone and pyramid indenters are virtually independent of the test load, whereas those determined by using a ball indenter are not. This means that, for a given specimen, a hardness number based on the relationship between load and indented area, will vary with a change in load on a ball indenter, but will remain constant with a pyramid indenter; this characteristic of a ball test necessitates a change in ball diameter with change in load (as described under the Brinell Test) in order to use the same scale for measuring the hardness.

Common Methods of Making Indentation Hardness Tests

Brinell Hardness Test. The Brinell hardness tester usually consists of a hand-operated vertical hydraulic press, designed to force a ball indenter into the test specimen. The load applied by the instrument can be varied over a considerable range.

Standard procedure requires that the test be made with a ball of 10 mm ± 0.0025-mm diam under a load of 3000 kg for ferrous metals, or 500 kg for nonferrous metals. For ferrous metals the loaded ball is pressed into the test specimen for at least 10 sec; for nonferrous metals the time is 30 sec. The diameter of the impression thus produced is measured by means of a microscope containing an ocular scale, usually graduated in tenths of a millimeter, permitting estimates to the nearest 0.05 mm. At high hardness levels, when greater precision is desirable in the measurement of the diameter of the impression, a micrometer-slide comparator type of Brinell microscope measuring to ± 0.01 mm is recommended.

The Brinell Hardness Number (Bhn) is the ratio of the load in kilograms to the impressed area in square millimeters, and is calculated from the following formula:

$$\text{Bhn} = \frac{P}{\frac{\pi D}{2}\left(D - \sqrt{D^2 - d^2}\right)}$$

where P = Test load in kilograms,
D = Diameter of ball in millimeters,
d = Diameter of impression in millimeters.

Ordinarily calculation is unnecessary because tables are available for converting the observed diameter of impression to the Brinell hardness number.

The use of two loads (3000 kg for ferrous metals and 500 kg for nonferrous metals) and one size of penetrator, limits this test to relatively large specimens. For testing a smaller specimen, a lighter load and ball of smaller diameter may be used if the ratio of the load to the square of the ball diameter is the same as that in the test with a heavier load. Table II[5] shows the various combinations of diameter of the indenter and the load to be applied in order to maintain the correct value for each of four different ratios.

Rockwell Hardness Tests. A Rockwell test is made by slowly elevating a specimen against the indenter until a minor load has been applied, as indicated by an index hand on a dial gage. A major load is then applied by releasing a loaded lever system; the speed of descent of the lever is controlled by an adjustable oil dashpot. At the completion of the descent of the lever, the major load is removed and, with the minor load still acting, the Rockwell hardness number is read on the dial gage. This number is based on the depth of indentation less the elastic recovery following removal of the major load, less the penetration resulting from the minor load. Because of the reversal of the order of the numbers on the dial gage, a high number is associated with a shallow impression made in hard material, and a low number with a deep impression in soft material.

Table II. Combinations of Diameter of Indenter and Load for Brinell Test

Metal	Ratio[a] L/D^2	Load (kg) for Indicated Diameter (D) of Ball Indenter D = 1 mm	D = 2 mm	D = 5 mm	D = 10 mm
Steel and materials of similar hardness	30	30	120	750	3000
Copper alloys and materials of similar hardness	10	10	40	250	1000
Copper and materials of similar hardness	5	5	20	125	500
Lead, tin and materials of similar hardness	1	1	4	25	100

(a) L = test load. D = diameter of ball indenter. It is recommended that a designation such as "Bhn (10/3000/30)" be used to indicate ball diameter (mm), test load (kg), and duration of load application (sec).

Several different Rockwell scales, each associated with a particular combination of load and indenter, are necessary to cover the range of hardness encountered in metals. There are also two machines, the normal Rockwell tester for relatively thick sections, and the Rockwell superficial tester for materials too thin to be tested with the normal tester. Indenters include steel balls of diameters 1/16, 1/8, 1/4 and 1/2 in. and a 120-deg spheroconical diamond ("Brale") with a spherical apex of 0.2-mm radius. Major loads are 60, 100 and 150 kg on the normal tester and 15, 30 and 45 kg on the superficial tester. Both machines are capable of making precise measurements of depth; one scale division on the dial gage measures a vertical displacement of the indenter of 0.002 mm with the normal tester and 0.001 mm with the superficial tester.

The original, and most commonly used, Rockwell scales are B (1/16-in. ball indenter and 100-kg load) and C (spheroconical indenter and 150-kg load), both obtained with the normal tester. Because of the multiplicity of Rockwell scales, the hardness number must be designated according to the scale used; for example, as Rockwell B (R_B), Rockwell C (R_0) and so on. The various Rockwell scales are defined in Tables III and IV.

To obtain the best possible performance from a Rockwell tester, the following procedure is recommended:

1 The tester should be placed so that vibration does not seriously affect the readings of the dial gage.
2 For the minor load to be properly applied, the large needle on the dial gage should be at "set" within plus or minus five scale divisions. If the elevating operation results in the needle stopping within this range, but not on "set", no further adjustment should be made by means of the elevating screw, but the dial should be rotated to bring "set" under the needle.
3 On the normal tester, the dashpot, which controls the speed of application of the major load, should be adjusted so that the operating crank completes its travel in 5 sec with no specimen on the machine, but with the machine set up to apply a major load of 100 kg. In a similar manner the superficial tester is set for 7 sec with a major load of 30 kg.
4 The machine should apply the major load, that is, the operator should avoid any manual pressure on the crank after releasing the lever system. The major load is allowed to act until either the pointer on the dial gage suddenly slows down or the weight arm is completely free from control of the dashpot; the latter is preferred, because it is a clean-cut end point.* Within 2 sec after either of these points is reached, the operating crank should be returned gently to its starting position; snapping the crank to the starting position may cause an error of several points in the dial indication.
5 The performance of the machine should be checked frequently against standard test blocks supplied by the manufacturer. If the hardness value obtained differs from that inscribed on the test block, the machine should be adjusted according to the instructions supplied by the manufacturer.
6 Because the accuracy of the hardness determination depends on an accurate measurement of the depth of penetration, particular care must be taken to seat the indenter and anvil firmly. Any vertical movement at these points results in additional depth being registered on the gage and, therefore, means a false number.

Vickers Hardness Test. This test employs a square-based diamond pyramid indenter with an included angle of 136 deg between opposite faces; loads usually range from 5 to 100 kg. To make a test, the specimen is elevated to within about 1 mm of the indenter, and the lever loading system is set in starting position by means of a foot lever acting on a weight-and-cam mechanism that furnishes the motive power for the test. With release of the weight-and-cam mechanism, the indenter descends under the load, indents the specimen, and then returns to the starting position. The rate of descent of the indenter and the time the indenter is on the specimen are controlled by an oil dashpot, usually adjusted for a time cycle in the range of 10 to 20 sec. A buzzer system warns the operator if the specimen is not supporting the full load because of being too far from the indenter or not held rigidly enough for the size of the applied load.

* With the enclosed models, this end point virtually coincides with the completion of the travel of the crank.

Table III. Hardness Scales for Normal Rockwell Tester

The minor load is 10 kg; one scale division on the dial measures 0.002 mm vertical displacement of the indenter.

Scale Symbol	Indenter	Major Load, kg	Dial Scale	Application of Scale
B	1/16-in. Ball	100	Red	Materials of B 0 to B 100 hardness
C	Diamond	150	Black	Materials of C 20 to C 70 hardness
A	Diamond	60	Black	Extremely hard materials, such as tungsten carbide, which might chip indenter at higher load; also for hard sheet too thin for heavy loads.
D	Diamond	100	Black	Sometimes used on case hardened material
E	1/8-in. Ball	100	Red	For testing very soft materials such as bearing metals
F	1/16-in. Ball	60	Red	Substitute for the E scale(a)
G	1/16-in. Ball	150	Red	Phosphor bronze

(a) The E scale and the following scales may be more suitable for soft material in which, because of inhomogeneities, it is preferable to use a larger ball, making an impression of greater area and thus obtaining more of an average hardness. In such tests the smallest ball should be used that can satisfy the conditions, because of the loss of sensitivity as the size of the indenter increases.

Scale symbol	H	K	L	M	P	R	S	V
Ball diameter, in.	1/8	1/8	1/4	1/4	1/4	1/2	1/2	1/2
Load, kg	60	150	60	100	150	60	100	150

The red dial is used with all these scales.

The impression is measured through a microscope fitted with an ocular micrometer that contains movable knife edges; the distance between the knife edges is indicated on a counter calibrated in microns. The impression appears as a dark square on a light background. The length of the diagonal of the square is measured and used to compute the diamond pyramid hardness number (DPH), which is the load (kg) divided by the impressed area (sq mm). Although tables are supplied to convert the measurement of length to DPH, the following formula may be used:

$$\text{DPH} = \frac{1.8544L}{d^2}$$

L = Load in kilograms
d* = Length of diagonal of impression in millimeters

For ordinary testing, the range of loads is 5 to 100 kg; in this range a load of 10, 30, or 50 kg is usually employed. Theoretically, in this test the hardness number is independent of the load, but some slight discrepancies in this relationship have been observed; hence, it is advisable to report the load used.

Failure of the machine to check a standard block may be caused by:

1 Sticking of the plunger carrying the indenter
2 Sticking of the reciprocating bar that raises and lowers the loading lever
3 Too great lowering of the oil level in the dashpot
4 Zero position of the ocular micrometer being out of adjustment

The above description applies to the Vickers-Armstrong machine. Another machine designed specifically for the diamond pyramid hardness test is the Amsler-Vickers tester, which includes the main features of the Vickers test; namely, automatic application and removal of the load, the 136-deg square-based diamond pyramid indenter, and measurement of the impression with a microscope equipped with an adjustable ocular micrometer.

* For the Vickers-Armstrong tester, d is obtained from the ocular reading r, from the following relation:
$d = 0.002r$ or $0.001r$ (for 2/3-in. objective), and
$d = 0.005r$ or $0.0025r$ (for 1½-in. objective), depending on the constants of the ocular micrometer.

Table IV. Hardness Scales for Rockwell Superficial Tester

The minor load is 3 kg; dial has only one scale; one division on dial scale measures 0.001-mm vertical displacement of the indenter.

Scale symbol	15-N	30-N	45-N	15-T	30-T	45-T
Indenter	Diamond	Diamond	Diamond	1/16-in. Ball	1/16-in. Ball	1/16-in. Ball
Load, kg	15	30	45	15	30	45

N scales are used for material of such hardness that it would be tested with the C scale if of sufficient thickness.
T scales are used for material of such hardness that it would be tested with the B scale if of sufficient thickness.

Eberbach Tester. The Eberbach tester is a relatively recent development in the use of the DPH scale for testing "microhardness". The indenting unit employs a 136-deg diamond pyramid indenter loaded by springs and is readily substituted for the objective of any microscope. For making a test, a field is selected through the microscope; the indenting unit is then substituted for the objective of the microscope, and an indentation is made by bringing the specimen and indenter into contact by means of the focusing adjustment of the microscope. The microscope objective is then replaced and the indentation is measured through a micrometer eyepiece. The range of available loads is approximately 7.5 to 550 g. At present such testing appears to be qualitative rather than quantitative, but is a valuable tool for determining the relative hardness of microstructural constituents.

The Tukon Tester. The Tukon tester applies loads from 25 g to 50 kg and uses either the "Knoop" type of diamond indenter or the conventional square-based diamond pyramid indenter (Vickers) described under the Vickers Hardness Tester. The Knoop indenter is of pyramidal form having an included longitudinal angle of 172 deg, 30 min and included transverse angle of 130 deg, 0 min.

The Tukon tester is fully automatic, under electronic control in a synchronous cycle. The specimen to be tested is placed on a special micrometer stage that has two-way adjustment in a horizontal plane. The indentation is made by elevating the specimen against the indenter until the specimen resists further indentation, at which time electronically actuated contacts are opened, elevation of the specimen ceases, and the load remains on the specimen for a fixed period of time, after which the specimen is automatically lowered to clear the indenter, and then moved under a micrometer measuring microscope. Under the microscope, the Knoop impression appears rhombic in shape, with a ratio of long diagonal to short diagonal of 7.11 to 1. The long diagonal is measured and the Knoop hardness number is computed from the following formula:

$$I = \frac{L}{A_p} = \frac{L}{l^2 C_p}$$

where I = Knoop hardness number
L = Load (kg) applied to indenter
A_p = Projected area (sq mm) of indentation
l = Length of long diagonal (mm)
C_p = Constant for each indenter, supplied by manufacturer.

The hardness number, corresponding to a measured length l, for a given load, may be determined from a table supplied along with the tester.

When the square-based diamond pyramid indenter is used, the DPH formula is employed for calculating the hardness number.

Monotron Test. The Monotron test consists of measuring the load required for pressing a diamond indenter of 0.75-mm diam into the test specimen to a depth of 0.045 mm. Depth of penetration is measured under load by means of a compensated depth micrometer gage; a pressure gage indicates the load in kilograms applied to the indenter. The loading range is from 0 to 160 kg. The Monotron hardness is the load indicated on the dial gage when the 0.75-mm diam indenter is employed. Other Monotron scales are as follows:

Scale	*Indenter*
M-2	1-mm diamond ball
M-3	$\frac{1}{8}$-in. tungsten carbide ball
M-4	2.5-mm tungsten carbide ball

For testing materials of high hardness, such as tungsten carbide, it is customary to penetrate only 0.015 mm deep in order to avoid damage to the diamond; the load indicated is then multiplied by three to obtain the hardness number at a penetration depth of 0.045 mm. Such a procedure is possible because of the linear relationship between load and depth of penetration.

Bierbaum Microcharacter. This is a form of scratch hardness test rather than indentation. The apparatus consists of a diamond cutting-point in the form of a corner of a cube, a means of drawing the test surface under the diamond point, and a microscope with an adjustable ocular micrometer to measure the width of the cut. The load on the diamond is 3 g. The hardness number is expressed by the formula, $K = 10^4/\lambda^2$ where K is the hardness number and λ is the width of the cut measured in microns. This instrument is better suited for research work than for commercial testing.

Automatic Testers. This type of tester, either wholly or partly motor-driven, is used in production work.

Brinell Test. One adaptation[7] of the Brinell test is entirely power-driven. A 3000-kg load is used, one-half of which is applied as a preload to "set" the specimen and minimize the effects of surface conditions such as scale. As the remainder of the load is applied, a dial gage records penetration beyond the preload point. The dial numbers are not intended to be Brinell hardness numbers, but ■ position on the dial is empirically determined that corresponds to the Brinell hardness number of a satisfactory part. This is done by preparing a test surface properly on a representative product and obtaining the Brinell hardness number in the conventional manner, using the automatic machine to indent the specimen. A test is then made with the machine, on an unprepared surface of the specimen. The dial reading is assumed to correspond to the conventional Brinell hardness number with surface conditions taken into consideration automatically. Obviously, surface conditions must be fairly constant. Since this is only a comparative test, the results should never be construed as true Brinell hardness numbers.

Rockwell Test. In this version of the tester an electric motor, driving a cam, lowers and raises the lever, thus applying and withdrawing the major load. The time required for a complete cycle can be either 4 or 1¼ sec; the high speed is for hard specimens, the low speed for soft. It is questionable whether this tester gives true Rockwell readings. As in the conventional test, the minor load is applied by manual control. The dial gage indicates the hardness.

Portable Hardness Testers. *Brinell Meter.* This tester is constructed in such a manner that a small portion of a 10-mm steel ball projects through the base of the instrument, and within the instrument a bar of known Brinell hardness number backs up the ball. To obtain a hardness number, the tester is held in such a manner that the ball is between the test specimen and standard bar; the head of the instrument is struck a sharp blow with a hammer; then the diameters of the indentations in the specimen and bar are measured. With the aid of a table, the ratio of these diameters is used to determine the Brinell hardness number of the specimen.

The King Portable Brinell Machine. This machine is capable of making a standard Brinell test with either 500 or 3000-kg load on a 10-mm ball. The design provides a clamping device that enables the machine to be used in any position; the test head can be removed from the frame for mounting on a large planer or boring mill. The complete tester weighs 26 lb.

Scleroscope. This instrument measures the rebound hardness of a material by allowing a diamond-tipped tup to fall by its own weight and to rebound from the test specimen. The height to which the tup rebounds is taken as a measure of the hardness of the material. The tup operates within a vertical glass tube on which is inscribed a scale for measuring the height of rebound. A dial gage can be used for measuring and recording this height.

This test is used especially for measuring the hardness of smooth surfaces that must not be marked by an indentation. A rough surface will cause low readings.

File Hardness Test.* In defining the term "file hard", one should specify the hardening procedure used on the test block that the file cannot "touch". The surface of the steel article being tested is rubbed slowly but firmly with the sharp teeth of the file until the operator has determined whether or not the file will "bite", that is, whether or not the material is "file hard".

The test is, for the most part, limited to untempered hardened parts, and comparative testing within a given

* Condensed from E. T. Morton's "File Hardness Test", which appeared in the 1939 edition of this Handbook.

shop. The information derived from it is influenced by the following factors:

1 *Size and Shape of File.* These should be standardized as: (*a*) 6-in. Pillar Testing File No. 0 and No. 1 to be used on flat, oblong, and square test pieces; file No. 0 is suitable for hardened steel, file No. 1 for tempered steel. (*b*) 8-in. Pillar Narrow Testing File for hardened steel. (*c*) 6-in. Three Square Testing File No. 1, for testing an object of irregular shape in which there are crevices and grooves.
2 *Hardness of File.* As long as a file will cut a master test specimen, it is suitable for testing purposes.
3 *Speed of Filing.* The slower the speed, the more accurate the test.
4 *Pressure.* This will vary among operators, but should be kept as firm and as nearly constant as possible.
5 *Angle of Contact.* This should be kept as nearly constant as possible.
6 *Composition and Heat Treatment.* With steels of Rockwell C 60 or more, differences in composition and heat treatment are associated with apparent anomalies, such as the relative hardness of two materials being reversed with the file test as compared with an indentation hardness test.

Factors Influencing the Accuracy of an Indentation Hardness Test

Accuracy of Load Applied. Any tester supplied by a reputable manufacturer should apply loads in a stated range with negligible error, but wear and accumulation of dirt, which result in excessive friction, may impair the accuracy of the loading mechanism; therefore, it is advisable to service the machine regularly. It should be remembered that loads beyond the recommended range of a machine are not to be relied on for accurate testing.

Impact Loading. In addition to causing inaccurate hardness numbers, impact loading may damage diamond indenters. Such loading can be avoided by smooth and steady operation of the loading mechanism, when it is under manual control. When the load is applied under the control of an oil dashpot, the oil should be kept at the recommended level. A slow speed of applying the load is preferable to a fast one, since there is less danger of serious impact effects.

Duration of Load Application. Some metals exhibit high rates of flow under the test load;[8] consequently, to obtain consistent hardness results, it is necessary to control the duration of load application.

Condition of the Indenter. Flattening of a steel ball indenter results in error in the hardness numbers; the ball should be checked often for permanent deformation and discarded when such deformation occurs. Diamond indenters must be accurately ground and polished; chipping of such indenters causes inaccurate tests.

Condition of the Anvil. The anvil on which the test specimen rests must be clean and smooth; care should be taken not to bring the anvil against the indenter. When testing thin material, the hardness range of which is unknown, it is best to start with a light load in order to minimize the possibility of the indenter punching through the specimen and indenting the anvil.

Method of Measuring the Impression. When measurement of the diameter of the impression is required, the sensitivity of the ocular micrometer must be suitable for the size of impression. For most shop applications, Brinell impressions made with 3000 and 500-kg loads, are measured with sufficient precision at ×10 and ×20 magnification, with a millimeter scale the smallest division of which is 0.1 mm; for high-precision Brinell testing at hardness levels higher than about 480 Bhn, ■ carbide indenter should be used and the diameter of the indentation should be measured to ± 0.01 mm at ■ magnification of ×40 with a Brinell microscope of the micrometer slide comparator type. For the smaller impressions of the DPH test, using loads of 5 to 100 kg, an optical method that measures to plus or minus one micron is desirable; furthermore, with optical methods of measuring, in order to obtain a sharp image of the impression, the magnification should not be so great as to sacrifice good resolution of the image. Adjustable ocular micrometers should be checked against a standard length of stage micrometer.

The measurement of the depth of the impression is subject to error if there is any binding in the mechanism of the dial gage; furthermore, such a measurement requires a high degree of sensitivity in the dial gage because of the shallow depth of indentation.

Thickness of Specimen. The specimen should be thick enough so that no bulge or other marking appears on the surface opposite that of indentation. The recommended thickness of the specimen is at least ten times the depth of the impression. With Rockwell tests, the depth of penetration can be obtained from the dial gage; with a DPH test, the penetration depth is 0.143 of the diagonal length of the impression. Data in Table V should aid in the selection of a suitable hardness scale that will maintain the recommended relationship between specimen thickness and depth of penetration; the values of Table V are ten times the depth of impression as measured directly by the Rockwell tester and as calculated from measurements of diameter in other tests, assuming that the impression has the same contour as the indenter.

Surface Condition of the Specimen. The surface of the specimen on which the indentation is made should be flat and representative of sound metal; decarburized metal, pits, scale and grease should be removed. To obtain such a surface usually requires a filing, grinding or cutting operation. These operations result in a layer of disturbed metal, the hardness of which is not necessarily representative of the underlying metal; furthermore, the depth of the layer depends on the severity of the operation. This is particularly noticeable on metals of high strain-hardening capacity, as shown by Hull and Welton[9] who found that as the depth of finishing cut in machining increased, the depth of work hardening increased. Another possible effect of grinding and cutting is overheating the specimen to such an extent that the material for some distance below the surface is no longer representative. These surface effects result in erratic hardness numbers and so must be reduced by finer polishing until they represent only a small portion of the depth of indentation; the amount of reduction is controlled largely by the depth of indentation, which varies with load, size of

indenter, and hardness. However, if the size of the indentation is to be measured with a microscope, the surface finish must be capable of giving a well-defined impression, and may require continuing with a finer polishing procedure. There seems to be no established optimum degree of surface preparation for an accurate test; however, a few check tests on specimens of uniform material, but with different degrees of surface preparation, will usually determine the finish necessary to eliminate variation in hardness caused by these effects. A shallow indentation is more affected than a deep one. For many practical purposes, the 3000 and 500-kg Brinell tests are sufficiently accurate on a surface prepared by filing, followed by sufficient polishing on abrasive paper to obtain a good image of the impression in the microscope. With the lighter loads used in normal Rockwell and DPH testing, the surface finish should be at least the equivalent of 320-grit abrasive paper; and for 5 and 10-kg DPH tests and Rockwell superficial tests, the surface should

*For the 10-mm standard steel ball, no values of Brinell hardness are given higher than 500 Bhn. This is in conformance with the limitations established by the Standard Method of Test for Brinell Hardness of Metallic Materials (ASTM Designation E 10).

The values of scleroscope hardness number and approximate tensile strength are from the 1946 SAE Handbook. All other values are from ASTM Standard E 48-43T.

be as smooth as possible. For tests using light loads, such as Tukon tests, the best procedure requires a metallographic polish, after sufficient metal has been removed to get below the disturbed metal from previous operations that might have caused serious work hardening.[9]

The surface of the specimen adjacent to the anvil of the tester requires attention when a dial-gage measurement of the impression is to be used. Since scale, paint, grease and deep grinding marks result in sinking of the specimen when the test load is applied, such movement is recorded as added depth, thus giving a false hardness reading. Sinking of the specimen during a test that involves measurement of the diameter of impression, is not objectionable if the amount is not too great for the full test load to be applied to the specimen.

Shape of Specimen. For the greatest accuracy in any indentation hardness test, the test surface of the specimen should be flat and should be normal to the vertical axis of the indenter. A specimen that extends beyond the edge of the anvil must be supported so that it does not tip.

When a cylindrical shape is to be tested, a flat test surface should be prepared if possible, and a V-notch anvil should be used to support the specimen. If it is necessary to make a test on a curved surface, a hardness value based on measurement of depth is likely to be more in error than one determined by the measurement of the long and short diagonals of a DPH impression, taking the average hardness. Ingerson[10] has published correction factors that may help in determining the hardness of a curved surface.

For testing a tube, some form of internal support is necessary to ensure accuracy in hardness tests.

Locations of Indentations. The placing of an impression in relation to the edge of the specimen or to another impression, affects the accuracy of the result. According to O'Neill,[11] impressions should be at least 2½ diam from the edge of the specimen, and the distance between impressions should be 5 diam for ball tests and 2½ diam for cone and pyramid tests. Small cracks should be avoided, since they result in low hardness numbers as well as in damage to diamond indenters.

Uniformity of Material. If the impression area is not large enough, numerous impressions should be made in order to account for variations in the hardness number that are associated with structural inhomogeneity of the mate-

* For the 10-mm standard steel ball, no values of Brinell hardness are given higher than 500 Bhn. This is in conformance with the limitations established by the Standard Method of Test for Brinell Hardness of Metallic Materials (ASTM Designation E 10).

The values of scleroscope hardness number and approximate tensile strength are from the 1946 SAE Handbook. All other values are from ASTM Standard E 48-43T.

rial. Testing a material by making a large number of small impressions affords a method for establishing the degree of inhomogeneity of the material.

Advantages and Disadvantages of Different Types of Tests

The selection of a hardness test is usually determined by ease of performance and degree of accuracy desired.

The Brinell test is an old, established test that provides a means of studying the work hardening of metals, a property of considerable importance in relationships based on hardness, and on hardness versus tensile strength.[8,12] Because of the standard practice of using a 10-mm ball and 3000 or 500-kg loads, this test is limited to large specimens; however, the large indentation is an advantage when the material tested is not uniform; also, the surface does not need to be so smooth as that for smaller impressions. To make the Brinell test useful on small specimens requires changing the size of the load and ball in order to keep the hardness numbers on the same scale. Perhaps this is not a disadvantage, since other widely used tests change the indenter and load without keeping the same hardness scale. Because it is related to the diameter of the impression, the Brinell hardness number is less subject to errors of unrecovered vertical motion of the specimen than is a dial-gage hardness; however, using a microscope to measure the impression is less convenient than reading a dial gage. The standard practice of employing a steel ball makes hardness testing inaccurate above 479 Bhn (510 DPH) because of deformation of the ball—a disadvantage that can be overcome to some extent by the use of a tungsten carbide ball.

* For the 10-mm standard steel ball, no values of Brinell hardness are given higher than 500 Bhn. This is in conformance with the limitations established by the Standard Method of Test for Brinell Hardness of Metallic Materials (ASTM Designation E 10).

The values of scleroscope hardness number and approximate tensile strength are from the 1946 SAE Handbook. All other values are from ASTM Standard E 48-43T.

The Rockwell test, rapid and simple in operation, provides a means of measuring the hardness of small specimens. The hardest as well as the softest materials can be tested, since different scales of hardness may be applied, some of which are related empirically to one another with conversion tables. The hardness number is easily read on a dial gage, but it is subject to error if there is any unrecovered vertical motion of the specimen during the test.

The diamond pyramid hardness test is a relatively recent development when compared with the Brinell and Rockwell tests. Because of the constant angle of penetration, the DPH is theoretically independent of load and thus all hardness numbers are on the same scale; actually, this is true for loads of 5 to 100 kg. Furthermore, the diamond indenter is well suited for testing the softest as well as the hardest materials. Like the Bhn, the DPH is related to the diagonal of the impression and does not suffer from errors of unrecovered vertical motion of the specimen. The automatic loading feature of the machines designed for this test, eliminates errors from variation in rate and duration of loading and impact loading. Since the image of the impression is a square, it can be read more accurately than a Brinell impression, but it requires a better surface because of the small size of the impression. The optical measurement might be considered too time-consuming but, for production work, the Vickers microscope is equipped with an adjustable shutter that can be set for the desired hardness limits, thus eliminating adjustment of the ocular micrometer for each impression; an Amsler tester is available that projects the image of the impression on a ground glass for measuring purposes. Because of the shallow impressions, this test is well suited for measuring the hardness of thin as well as thick materials (*see* Table V). Some vertical motion of the specimen does not result in error—a feature that makes this test ideal for small sections that have odd shapes, since such specimens can be mounted in bakelite or in clamps for testing.

The Tukon tester, a recent development, is a precision machine used in testing surface conditions and specimens too thin to be tested with the machines that employ heavy loads. The Tukon tester is also well suited for testing the hardness of small parts such as are found in watches since, as in the Vickers test, specimens can be tested while mounted. With this test a new hardness scale has been introduced (Knoop hardness); its relationship to other scales has not yet been determined. Since the Tukon tester uses a pyramidal form of indenter, hardness numbers should be independent of load, but this does not appear to be true. When this machine is employed, the hardness of microconstituents can be investigated with either the Knoop

10	Diamond	5500 to 6950	

Hardness Testing at Elevated Temperatures

Both dynamic and static tests have been employed to measure hardness by indentation at elevated temperatures, but dynamic testing appears to have received more attention. In static testing, the load on the penetrator is applied slowly; in the dynamic test, loading is accomplished by one of the following: a falling weight, a released spring, or a blow from a hammer or pendulum.

Experimental difficulties are encountered with either type of test, as follows:

1 The surface of the test specimen must be protected from oxidation during heating. Protection may be obtained at relatively low temperatures with water, oil, or salt baths; at higher temperatures an electric furnace with a controlled atmosphere (such as purified nitrogen) may be used or the equipment may be designed to operate under reduced pressure (vacuum).

2 Because of the general tendency of metals to exhibit continuous flow under stress at elevated temperatures, it is necessary to maintain a constant time interval of indentation in static testing; otherwise, tests of different materials are not comparable. This effect of time is believed to be insignificant in a dynamic test, because of the instantaneous nature of the impact loading.

3 The dynamic test is subject to error from energy losses caused by rebound of the falling weight, friction along guides, and vibration of the machine and test specimen.

4 Because of the appreciable period of contact between the indenter and the specimen in the static test, it is desirable that the indenter and specimen be at the same temperature, since a cold indenter chills the specimen during the test. This limitation is not encountered in a dynamic test because of the very short duration of contact. Consequently, a steel indenter is suitable for dynamic testing but not for static testing, because the indenter will soften at the test temperature; hence, for a static test, a diamond indenter is preferred, although the sintered carbide ball may be satisfactory. The useful life of the diamond indenter at elevated temperature is a serious problem. According to Lysaght * the ordinary setting material of the diamond deteriorates at high temperature, but special setting material permits the repeated use of the diamond at 1200 F and short exposure to temperature up to 1500 F (total heating and cooling cycle, 5 hr, including 1 hr at temperature) in an atmosphere diluted with nitrogen. Under these conditions, the service life of the indenter is unpredictable.

The type of test to select depends on the application of the tested part in service. For instance, if plastic flow is considerable, a static test might produce more useful information. A dynamic test might be preferred where rapid deformation is encountered in service. Another consideration is the temperature of test desired; dynamic tests are possible up to 2200 F, whereas, at present 1500 F appears to be the limit imposed by the indenter on the static test.

Dynamic Test. Fetz[14] has published results of original experimental work and an extensive survey of technical literature that concerns this type of test. The method of Fetz appears to be typical of the dynamic test and consists of a drop hammer, operated by a foot release, sliding vertically along two polished steel front guides. A steel ball 10 mm in diam is fastened to the lower end of the hammer. After the sample has reached temperature, it is removed from the furnace, held on an anvil with tongs and indented by the ball attached to the falling hammer. The time interval between removing the sample from the furnace and striking it with the hammer does not exceed 1.5 sec and is usually less than 1 sec.

The hardness number has been expressed in different ways by different investigators, generally by one of the following relationships:

$$H = \frac{E_1}{V} \quad \text{or} \quad H = \frac{E_1 - E_2}{V}$$

where H = Dynamic hardness number
E_1 = Impact energy in mm-kg
E_2 = Rebound energy in mm-kg
V = Volume (cu mm) of indentation based on diameter measurement made at room temperature.

The dynamic hardness is sometimes expressed as a Brinell number obtained from correlation experiments conducted by the investigator. Because of variations in testing technique, such correlations do not permit quantitative comparison of hardness data obtained by different investigators, although qualitatively the same trends may be observed.

In order to have similar test conditions, it is recommended that the weight of the specimen and the impact energy be standardized. Also, the specimen should be of such a size that its heat capacity will minimize loss of heat during the time interval required for the test.

Static Test. Bishop and Cohen[15] have used the Rockwell tester and diamond Brale indenter up to 1100 F in a purified nitrogen atmosphere, without evidence of deterioration of the indenter. The furnace is designed to rest on the elevating stage of the tester and the specimen can be observed during heating and testing. A flow of purified nitrogen is used to prevent scaling. The indenter is heated to the temperature of the specimen. The furnace contains an anvil for supporting the specimen, and an extension member places the indenter within the furnace. An oil-trough seal is provided that allows either vertical or horizontal displacement of the specimen relative to the indenter, without affecting the protective atmosphere. Water flowing through copper coils cools the apparatus at the necessary points.

To make an indentation, the furnace and specimen are elevated with the Rockwell mechanism until the minor load has been applied; then the major load is applied and removed in the usual manner. The hardness number is read on the Rockwell C scale and is reproducible to plus or minus 0.5 of a number.

The Vickers hardness tester has recently been adapted to hardness testing[16] at temperatures up to 1700 F by the use of a vacuum furnace and an extension member added to the indenter piston for placing the indenter within the furnace. A standard Vickers diamond is employed and the impression is made in the usual manner after the furnace, specimen and indenter have come to equilibrium at the test temperature. The specimen is then cooled and the indentation is measured at room temperature. Means are provided for moving the specimen while at temperature in order to make several indentations on it.

Another method of static testing, employed by Harder and Grove,[17] is that of mutual indentation produced on two cylindrical specimens of the material being tested, under selected loads. This method appears to give satisfactory results up to 1475 F, but has the disadvantage of requiring specimens of a special shape.

Hardness Conversion Tables

Each of the instruments used customarily to measure the hardness of metals by the indentation method is best adapted to certain types of work. Brinell tests are especially suited to cast iron and to most pieces of medium to heavy section, but cannot be used for measuring the hardness of sheet metals. The Tukon tester has a field of application in very thin sheets, small parts, and measurement of microhardness; in this field the Rockwell instruments and most others are inoperable. Rockwell tests are indispensable for rapid production testing and are used on a wide range of materials.

Indentation hardness testers determine not a single fundamental property but a combination of properties; the contribution of each of these properties to the hardness number varies with the type of test. That is why no absolute conversions have been made from one hardness scale

* Communication from V. E. Lysaght, Wilson Mechanical Instrument Co.

to another. It is necessary to base hardness conversions on comparative tests of materials that have very similar mechanical properties. Many of the conversions now in use include a wide range of materials; consequently, the conversions may be inaccurate for specific applications.

Conversions based on a single class of materials have been developed for heat treated steels, nickel alloys, magnesium alloys, brass, aluminum alloys, and probably many others. However, conversions for steel and brass are the only ones that have been recognized by the technical societies. Others should be reviewed and published for general use if they are found reliable.

The reliability of hardness conversions is no greater than that of the original test values. Each type of hardness test is subject to certain errors. If the precautions cited above are carefully observed, the reliability of hardness readings made on instruments of the indentation type will be found comparable. Differences in sensitivity within the range of a given hardness scale (for example, Rockwell B) may be greater than between two different scales or types of instruments. When more than one range of load is available for a given instrument, the largest load should be used that is consistent with the dimensions and nature of the specimen and with the maximum allowable size of impression for the indenter. That is, use of superficial hardness scales, such as Rockwell 15-N and 10-kg DPH, should be confined to applications where higher loadings are not applicable—such as Rockwell A or C or 50-kg DPH. The scleroscope has been found less reliable than tests of the indentation type, and conversions to other scales are correspondingly uncertain.[18]

Tests have proved that even the most reliable data cannot be fitted to a single conversion relationship for all metals. The differences in physical or mechanical properties that influence the hardness values in this manner have not been fully determined. However, two factors have been found to contribute greatly to this behavior, namely, the modulus of elasticity and the capacity for work hardening. The modulus of elasticity has been shown to influence conversions at high hardness levels,[19] and there is reason to believe that at low hardness levels, conversions between hardness scales measuring depth and those measuring diameter, are likewise influenced by differences in the modulus of elasticity. Furthermore, work hardening has a very potent effect in most soft metals,[8,12] making it difficult to isolate the various factors that affect the conversion relationships.

Table X. Hardness Conversions for Aluminum Alloys and Copper in the Cold Worked Condition

Conversions for Steels Harder than 220 Brinell. Conversion Tables VI, VII and VIII, which were prepared jointly by the Society of Automotive Engineers, American Society for Metals, and American Society for Testing Materials, are based on extensive tests of carbon and alloy steels, mostly in the heat treated condition. They have been found reliable on virtually all alloy constructional steels and tool steels in the as-forged, annealed, normalized, and quenched and tempered conditions, provided the steels are homogeneous. Such materials as high-manganese steel, 18% Cr–8% Ni steel, other austenitic steels, and nickel-base alloys, as well as alloy constructional steels and tool steels in the cold worked condition, may not conform to these relationships with the same degree of accuracy as the steels for which they are intended. The values for scleroscope hardness number and approximate tensile strength are from the SAE Handbook and are not included in the original tables approved jointly by the three societies.

Precautions in Using Conversion Tables for Steels.

1 The values given are recommended for use in converting the results of one form of hardness test to another, only with respect to flat surfaces, and only when the foregoing test procedures and precautions are observed.

2 Attention is called to the limitation of use of the standard steel ball to hardnesses less than 500 Brinell. The Rockwell superficial hardness and diamond pyramid hardness tests require especially smooth surfaces for accurate results. In all tests, the specimen should be approximately ten times as thick as the depth of the indentation, to avoid anvil effect. (*See* Table V.)

3 It is very important that conversions from Brinell hardness to shallow-impression tests, such as Rockwell superficial and diamond pyramid hardness tests, be made only on materials that are of uniform hardness to a depth at least ten times that of the indentation. Such hardness conversions should not be made on surface-hardened, coated or decarburized surfaces.

4 Although the Rockwell hardness and Rockwell superficial hardness values in the tables are given to tenths of a point, in order to maintain exact relationships between the various scales, it is customary to report these values to the nearest point only.

5 In Table VIII, rows 3 and 4, the reader may note that a Brinell number of 627, determined with a carbide ball, corresponds to a lower DPH value than a Brinell number of 601 obtained with a Hultgren ball, because of the elastic flattening of the Hultgren ball. Therefore the DPH and Rockwell values in these rows are not inverted.

6 Experience has shown that, even under carefully controlled conditions, some deviations from the conversion relationships will occur.

Conversions for Metals Softer than 240 Brinell. For ferrous and nonferrous metals softer than 240 Brinell, a single set of conversion relationships inevitably introduces large errors because of the wide difference that may exist in the amount of cold working before testing, as well as the amount that occurs during the test itself.

The dependence of hardness conversions on the amount of strain hardening of the sample before testing, has been demonstrated by means of Brinell, DPH, Rockwell, and Rockwell superficial tests on a variety of ferrous and nonferrous alloys in the annealed and strain hardened conditions. As an example, annealed ingot iron and a cold rolled aluminum alloy each had a Brinell hardness of 66. The annealed iron had a Rockwell B hardness of 31 compared with 7 for the strain-hardened aluminum alloy. Thus a conversion relationship that is correct for iron would be 24 points Rockwell too high for the aluminum alloy. On the other hand, if materials have Brinell or Rockwell hardness values that are equal in the annealed state as well as after heavy cold deformation, these materials will have similar hardness conversion relationships for all degrees of strain hardening. This is true of yellow brasses and low-carbon steels and irons. The Wilson Chart No. 38,* part of which is reproduced in Table IX, is based largely on tests of these materials. It is for this reason that the following statement is published as a part of the Wilson Chart 38.

> "The indentation hardness values measured on the various scales depend on the work hardening behavior of the material during the test, and this in turn depends on the degree of previous cold working of the material. The B-scale relationships in the table are based largely on annealed metals for the low values and cold worked metals for the higher values. Therefore, annealed metals of high B-scale hardness, such as austenitic stainless steels, nickel and high-nickel alloys, do not conform closely to these general tables. Neither do cold worked metals of low B-scale hardness, such as aluminum and the softer alloys. Special correlations are needed for more exact relationships in these cases."

When the hardness level of a material is considerably different from that of yellow brass, as in aluminum and aluminum alloys, it is necessary to use specially prepared conversion relationships. Table X, based on tests of aluminum alloys and copper, and Table XI for flat rolled stainless steels of the 18% Cr–8% Ni type, are examples of conversions for alloys that have hardness ranges lower and higher, respectively, than the range for yellow brass. These tables are based on a limited number of data compared with Wilson Chart No. 38 (Table IX), and are included primarily to demonstrate experimental deviation from this widely used conversion table. For example, in Table X the 500-kg Brinell value of 66 corresponds to a hardness of 4 Rockwell B compared with 28 Rockwell B in the Wilson Chart (Table IX).

The dependence of hardness conversion relationships on strain-hardening characteristics can be demonstrated further by the Rockwell scales 15-T, 30-T, 45-T, F, and B, in which loads ranging from 15 to 100 kg are applied on a $\frac{1}{16}$-in. diam ball indenter.[12] (Fig. 2.) As higher loads are used, the increased strain raises the hardness by an amount that depends on the pretest capacity of the metal for strain hardening. An annealed metal of high capacity for strain hardening will harden much more in the test than will a cold worked metal. If both have the same hardness in a Rockwell 15-T test using a 15-kg load, the annealed metal will develop higher hardness in a Rockwell B test under a 100-kg load. In Fig. 2, an annealed iron and a cold rolled aluminum alloy have Rockwell 15-T hardness of 71 and 72 respectively. The Rockwell B hardnesses are 31 for the soft annealed iron and 7 for the strain hardened aluminum alloy.

In Fig. 2, lines representing the data from Tables X and XI are compared with the Wilson Chart line for the relationship between Rockwell B and Rockwell 30-T scales. In all other instances, lines have been drawn through the points for soft annealed metals (at the left) and strain hardened metals (at the right), disregarding chemical composition. Specialized hardness conversions more accurate than the generalized conversions now used for soft metals are suggested by these charts. Two approaches are, as follows: (1) By material classifications suggested by the Rockwell B versus Rockwell 30-T relationships of Fig. 2. (2) By strain hardening classification determined by the indentation contour as indicated in Fig. 2.

Method 1 requires organization of test data into specialized tables for specific classes of materials, and selection of the proper table based on knowledge of the class of material being tested.

Method 2 depends on knowledge of the state of strain hardening of the test piece. The limiting conditions can usually be identified by the appearance of the hardness in-

* Supplied by Wilson Mechanical Instrument Co., producers of Rockwell hardness-testing machines

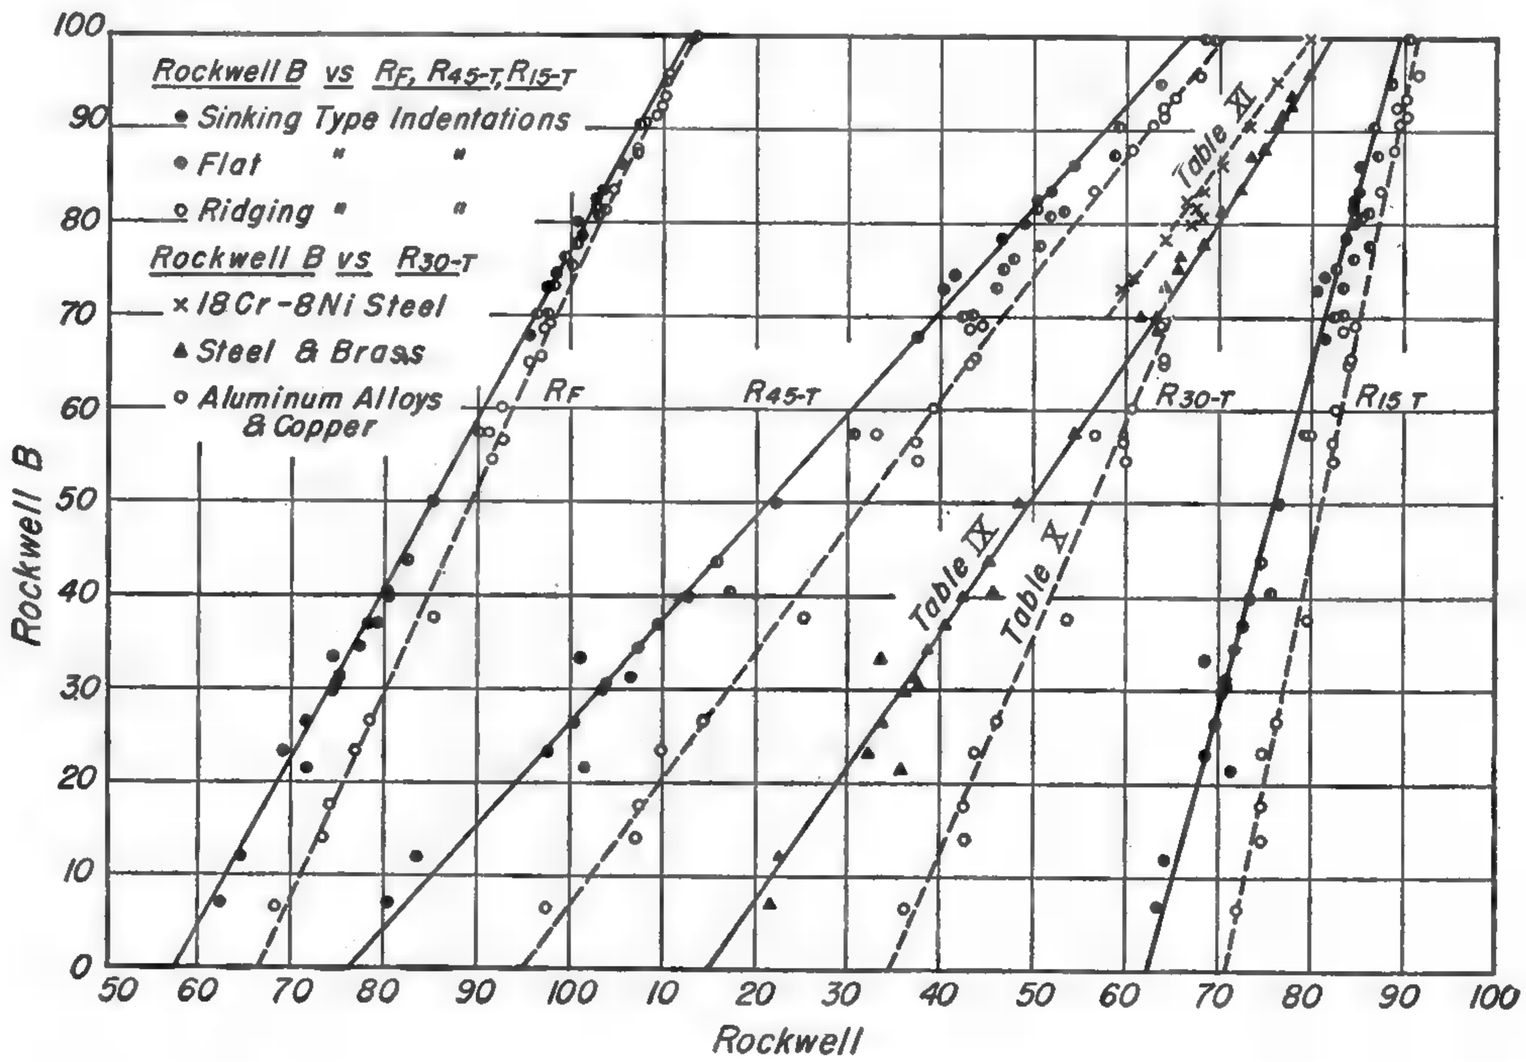

Fig. 2 Experimentally determined comparisons of Rockwell hardness tests

dentations themselves. Soft annealed metals have characteristic "sinking" type indentation contours when indenters of the ball type are used. On the other hand, heavily cold worked metals have sharp "ridging" type indentations. While annealed metals are being progressively cold worked, the indentation contours pass through a "flat" stage in which the lip of the indentation is neither rounded nor sharply ridged. The diameter of the indentation should approach 50% of the ball diameter in order to develop these characteristics in easily recognized form. A low-power magnifier is useful in observing Rockwell indentations.

The Meyer hardness test has been used to give a quantitative measure of the capacity for work hardening, thereby facilitating the selection of the proper conversion relationship in Method 2.[8,12] The Meyer constant n, representing the capacity for work hardening, is determined from the following relationship between load L and impression diameter d:

$$L = ad^n$$

The impression diameter is measured for two or more loads and the constants a and n are obtained, usually by a graphical method in which the variables are plotted on logarithmic graph paper.[20] Although 10-mm Brinell ball indentations are preferred, the $\frac{1}{16}$-in. and ⅛-in. Rockwell balls can be used.

The Meyer n constant has been found to vary from about 2.50 for dead soft annealed metals to slightly less than 2.00 for cold worked metals. The Meyer a constant is a measure of hardness level and is not related to work-hardening capacity. While it would be possible to establish conversions based on the constant n, the labor required in the determination of such conversions would not ordinarily be justified for hardness conversions alone.

The Tension Test

By Maxwell Gensamer*

THERE are only two methods of mechanical testing in which it is possible to keep the strains uniformly distributed throughout the specimen over a considerable range of strains; these are the tension test and the compression test. For materials that are even slightly ductile, the compression test provides no measure of ductility. Ductile materials do not fracture in compression, except through the action of parasitic tensile stresses developed in the skin after "barreling" has developed. The tension test provides tests for ductility, and through the circumstance that the load in the test goes slowly through a maximum, this test provides an easy and reproducible measure of strength, little affected by the testing conditions. Advantage can be taken of the uniformity of strain before "necking-down" begins, in order to obtain precise measurements of the relations between stress and strain, relations that can be used to calculate with fair precision similar relations for all other kinds of loading or straining. The tension test is relatively easy to adapt to high and low temperatures and high rates of straining.

The test is carried out in machines which vary widely in detail, but all consist of two essential members: (1) a device for straining the specimen, and (2) a device for measuring the resistance of the specimen to this straining.[1] When the stress-strain curve is desired, the circumstance that the strain is uniformly distributed over only a part of the specimen requires the use of a third member, (3) a strain gage, usually known as an extensometer, designed to measure the strain over only that part of the specimen in which strain is substantially uniform. After necking-down begins, with localization of the strain, the extensometer is useful only to indicate the final over-all elongation.

The devices for straining the specimen are usually of either of two types—mechanical screw or hydraulic. Screw machines are of two types—either rotating nut with translating screw, or rotating screw with translating nut. In both, the translating member is one of the crossheads, the so-called "moving crosshead". The stationary crosshead actuates the system for weighing loads. It is important, especially in compression testing, that these crossheads remain parallel throughout the travel of the moving crosshead, especially under load. Hydraulic straining devices are of two types—the packed-ram type and the lapped-ram type. In the packed-ram type, oil leakage is greatly reduced, but the friction of the packing prevents using the pressure in the cylinder as a measure of the load on the specimen. In the lapped-ram type, the pressure may be used as a measure of load, but provision must be made for recirculating the oil which is intentionally permitted to leak, so that friction may be reduced to a minimum. When the pressure in the cylinder is used to indicate the load on the specimen, it is important that effective aligning devices be employed to prevent misalignment of the piston in the cylinder; otherwise frictional errors will occur. The rate of motion of the moving crosshead can be varied easily and continuously over a wide range when hydraulic machines are used, but it is more difficult to reproduce a particular rate of motion than with mechanical machines.

Devices for measuring loads usually employ mechanical levers or hydraulic systems. In the mechanical machines, the moving poise system is losing favor, and the pendulum type is gaining in popularity. Although it sacrifices some sensitivity, the pendulum type gives a continuous indication of load. Numerous hydraulic systems have been devised; the most common of these are the Bourdon tube, the piston and pendulum, and the Bourdon tube combined with a calibrated helical spring. All of these can be quite accurate and sensitive; the Bourdon tube alone is more difficult to use in conjunction with recording devices. To avoid the frictional errors involved in measuring directly the pressure in the strain cylinder, a hydraulic capsule is fre-

Prepared for the Subcommittee on Mechanical Testing.

quently used, which makes the straining system and the weighing system independent. Hydraulic capsules may be employed with many types of straining devices, including the screw types.

Devices for measuring strain are too numerous to discuss in detail; they may be mechanical, optical or electrical. The most common mechanical devices are the dial gage, lever and pointer combinations, and wedge or cone types. Wedge or cone devices are used for instruments that have wide range and low sensitivity; the dial gage, for intermediate sensitivity; and the lever and pointer instruments, for high sensitivity. The optical and electrical instruments exceed the mechanical in sensitivity. The most popular optical system is Tuckerman's autocollimating modification of Marten's mirror system. The most popular and most adaptable electrical gage is the wire resistance strain gage; the magnetic gap extensometer is also in wide use.

The tension test may be arranged for great precision, in order to obtain data for the design of structures to operate within the elastic range; high precision is usually profitable only for relatively small strains, seldom greater than one per cent. For large strains, where forming characteristics or the capacity of a structure for absorbing energy are being considered, high precision is sacrificed for wide range and ease of observation. In the range of small strains, the data are greatly affected by the care with which the test is conducted. Observations along a single gage-line on the surface of the specimen will vary greatly around the specimen, unless care is taken to eliminate bending moments applied to the specimen by eccentric or oblique loading.[2, 3] The effect of these moments on modulus of elasticity measurements can be avoided by averaging the extension on opposite sides of a symmetrical specimen, but such averaging cannot prevent errors in the observation of the limit of elastic action. The stress at which small departures from ideal elastic action occur will appear to be lower if such deviations from ideal tensile loading are obtained. The stress-strain curve will be the more affected, the smaller the strain; at large strains, the specimen has become fairly well aligned. The tensile strength and ductility of ductile materials are seldom affected appreciably, even by considerable misalignment of the specimen, except when the specimens are thin sheet.

Misalignment is avoided by applying the load to a *straight* specimen at points on its centroid. So-called "self-aligning grips" seldom provide more than good first approximations to alignment, although these grips are adequate for tensile strength and ductility and, unless misused, generally satisfactory for determinations of yield strength when the yield strength is defined in terms of relatively large strains—for example, 0.1 or 0.2%. For stress-strain relations at small strains, means must be provided for centering the specimen in the grips until, upon loading, the strain can be shown by measurement to be uniformly distributed, within the degree of precision required by the application of the results. This measurement is accomplished by making simultaneous observations with at least three extensometers, located 120 degrees apart around a cylindrical specimen, or with four extensometers, one on each face, for rectangular specimens. When sheet specimens are being tested, misalignment may be so great that the stress-strain curve can be affected to several per cent extension; extensometers should be mounted on the *edges* of a sheet specimen to check the alignment for precise work at low strains.

Analysis of Tension Test Data for Small Strains.[4, 5] For strains measuring less than several per cent it is customary and satisfactory to plot the load per unit of original area, known as "stress", against the extension per unit of original gage length, known as "strain"; correction for the changing area and changing gage length is unimportant until large strains are reached. Such uncorrected curves have been plotted in Fig. 1, on the left, over a limited range of strains, for a typical alloy which exhibits no yield point, and on the right all the way to fracture for steel, which alone among alloys is usually characterized by a yield point. (Single crystals exhibit a sharp break in the stress-strain curve; fine-grained nonferrous alloys do not.

The *modulus of elasticity* is the slope of the stress-strain curve in the elastic range, at small stresses, where the curve is a straight line within experimental error. The *tangent modulus* is the slope of the curve at a particular stress or strain. The *secant modulus* is some particular stress divided by the corresponding total strain. The values of the tangent modulus and the secant modulus apply only to the stress and strain to which they refer.

The *elastic limit* is the stress beyond which inelastic action is obtained. In metals it coincides with the *proportional limit,* which is the stress at the point of departure from a straight line. These limits can be only approximated, for their values depend on the sensitivity of the strain gage used. The *yield strength* is much more useful, and is defined as the stress required to produce a given amount of permanent strain. It is tedious and unnecessary to determine the yield strength by measuring

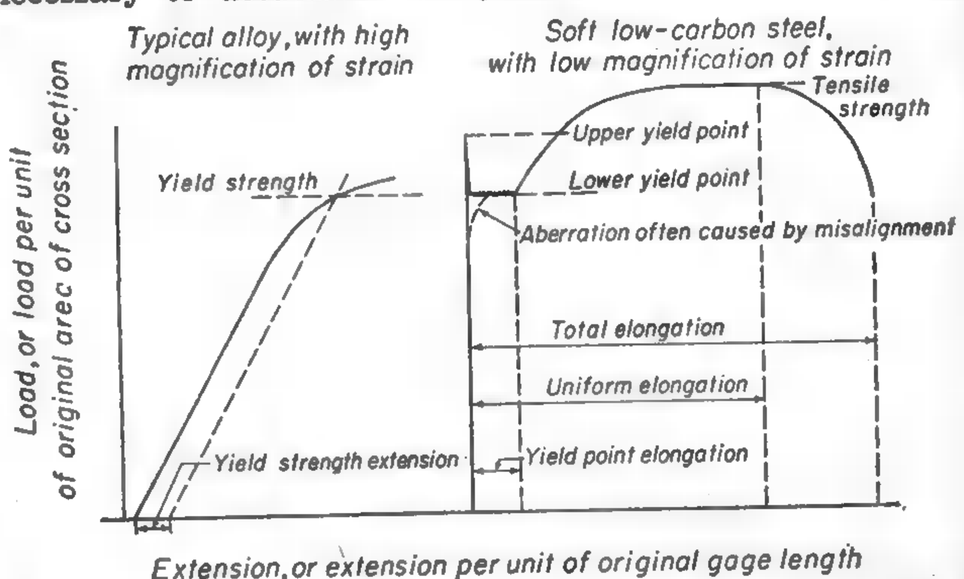

Fig. 1 Load-extension diagrams in tension. The load is usually load per unit of original area of cross section and the extension is usually extension per unit of original gage length. These have the same dimensions as stress and strain, with which they are often confused.

the permanent strain or set after removing the load. With all alloys, upon release of the load, the curve is a straight line from the point of release to zero stress (except for minute departures, unimportant in engineering work). This property makes it possible to use the "offset" method for determining the yield strength. Starting at the intersection of the stress-strain curve with the strain axis, the procedure is to set off on the strain axis a distance corresponding to the strain used in the definition of the yield strength (most frequently 0.2%, but often a smaller strain, and in every instance specified). If, from the point so obtained, a straight line is drawn parallel to the stress-strain curve at low stresses, the intersection of this line with the stress-strain curve is the yield strength. Johnson's apparent elastic limit was formerly popular but has now been superseded by the yield strength as measured by the offset method; Johnson's limit is the stress at the point on the stress-strain curve where the slope is two-thirds the modulus of elasticity. Sometimes it is specified that the extension for a given stress, known as the *proof stress,* is not to exceed a certain amount.

The yielding characteristics of steels which exhibit a definite yield point are described in terms of the upper yield point, the lower yield point, and the yield point elongation. The *upper yield point* is the stress reached before the sudden drop in stress. Up to this point the behavior is usually almost ideally elastic. The sudden drop in stress results in a sudden drop of the beam when a lever-and-poise type of testing machine is used. This pronounced drop, an easily detected departure from elastic action, is used to determine the "yield point by the drop of the beam". It measures the upper yield point, which is very sensitive to nonuniform loading; slight bending can eliminate the upper yield point, causing the curve to take the shape of the dashed line in the right half of Fig. 1. Even though it is widely used in the specification of ferrous products, there is no evidence that yield point by the drop of the beam is of any value as a material constant. The *lower yield point* is a material constant much less affected by the testing conditions, although it is rather sensitive to the speed and temperature of testing (much more so than are tensile strength and measures of ductility). Because the load varies considerably during yielding, it is necessary to take an average value; this introduces some uncertainty,

but not enough to be important. The value taken as the lower yield point is usually the mean stress during yielding immediately after the initial drop.

In dropping from the upper to the lower yield point, the steepness of the curve is determined entirely by a characteristic of the testing machine called the "spring constant" for the machine. It is impossible to observe a diminution of load with extension when the rate of diminution at constant rate of straining is *more* than the spring constant of the machine. A certain amount of motion of the crossheads is necessary to relax the load, and the ratio of the diminution of load to the motion of the crossheads required to produce it is called the "spring constant". A "soft" machine is one with a small spring constant; a "rigid" machine has a high spring constant. A "rigid" machine permits the observation of a steep drop in the load extension diagram, whereas a "soft" machine limits the observable slope under decreasing loads. The spring constant has no effect on the curve during an increase in load.

The *yield point elongation* is the percentage of increase in length to the point of resumption of rising load with increasing strain. At this point the specimen begins to strain uniformly, in contrast with the very nonuniform distribution of strain during yielding, observable through strain markings called "Lüders lines" or the "Piobert effect".

Analysis of Tension Test Data for Large Strains.[4,5,6] As the load increases, the deformation continues to be uniformly distributed until necking-down begins (except for the disturbances introduced by inhomogeneity of the specimen, and the "end effects" caused by the restraint of deformation in the vicinity of the grips or enlarged ends of the specimen). Necking-down occurs at that point on the stress-strain curve where the continuously diminishing slope of the curve reaches a critical value equal to the rate at which the stress would be increased by straining at constant load, because of the diminishing area. This critical value always occurs in direct loading when the strain reaches the value of the strain hardening exponent described below. During necking-down the load diminishes, although the true average stress (load divided by area at the point of least area) continues to increase. The maximum load that is reached divided by the original area of the cross section is the *tensile strength*. It is sometimes observed that the upper yield point is higher than the tensile strength. The point of necking-down, which fixes the tensile strength, is not the maximum stress that may be withstood without fracture. The *fracture stress* is the breaking load (lower than the load corresponding to the tensile strength, unless fracture occurs prior to necking) divided by the final area at the point of fracture.

As measures of ductility, the *reduction of area* at fracture and the *elongation* to fracture are used as percentage reduction of the original area and percentage increase of the original gage length. The percentage reduction of area at fracture is only slightly affected by the shape of the tensile test specimen. As long as the ratio of the width to the thickness does not exceed about 5 to 1, for rectangular cross sections,[7] the reduction of area remains the same as for circular cross sections. Rectangular cross sections diminish in thickness more in the center of the boundary surfaces than at the corners, so that the cross section after fracture is a figure bounded by curved lines; it is necessary to measure the greatest and the least dimensions in both directions and from these to calculate the area at fracture. Simple formulas are available for the calculation of areas from these data.[8] Reduction of area is unaffected by the length of the specimen except for end effects, if the specimen is short enough. The usual specimen (0.505-in. diam and 2-in. gage length, with the customary enlarged ends) is a little short of the length beyond which further increase in length has no effect on the tensile reduction of area at fracture; shorter bars may show less reduction of area.

Elongation to fracture is usually measured by fitting the broken specimen back together and measuring the distance between punch or scribe marks. When measured in this way, it is often referred to as "bench elongation". Elongation may also be taken from an autographic record of the load-extension diagram; the two should agree. Elongation is so much affected by the gage length over which it is measured that the gage length must always be specified unless it is very long.[9] Except for end effects, it can be shown that the elongation may be considered as made up of two parts—the *uniform elongation,* which the whole specimen suffers, up to the time when necking-down begins; and *local elongation,* which is a maximum at the center of the necked-down region and diminishes away from that point, gradually approaching a negligible value at a distance from the point of maximum elongation equal to several times the diameter. In long bars there are usually several points where necking-down begins almost simultaneously, so that finding a region of uniform elongation may be difficult. The elongation is always less near the ends of the bar. The standard specimen is not quite long enough to avoid this end effect, even at the middle of the gage length. The infinite-gage-length elongation refers to the uniform elongation; the zero-gage-length or infinitesimal-gage-length elongation refers to the elongation calculated from the reduction of area at fracture.

Reduction of area is usually measured with micrometer calipers, having anvils which have been ground to "points". These should have minute flat areas at the points, small enough to introduce no serious error when applied to the concavely curved surface of the broken specimen when the halves are fitted back together; or spherical points if the radius is sufficiently large. It is advisable to have some vise-like arrangement to hold the broken parts together during gaging. Elongation is usually measured with dividers, applied to punch or scribe marks. Generally these marks may be quite deep without affecting the results, but brittle materials and thin sheets occasionally break at deep marks with less than usual elongation. A gridwork of lines, applied by the photoengraving technique, obviates this effect and may be used to study the distribution of elongation over the specimen. Variation in ductility from specimen to specimen and from point to point, and variation with direction in the same specimen are often considerable, and are almost always greater than the variation of the other tensile properties. Tests taken transverse to the direction of greatest elongation in working are generally inferior in ductility, often considerably so.

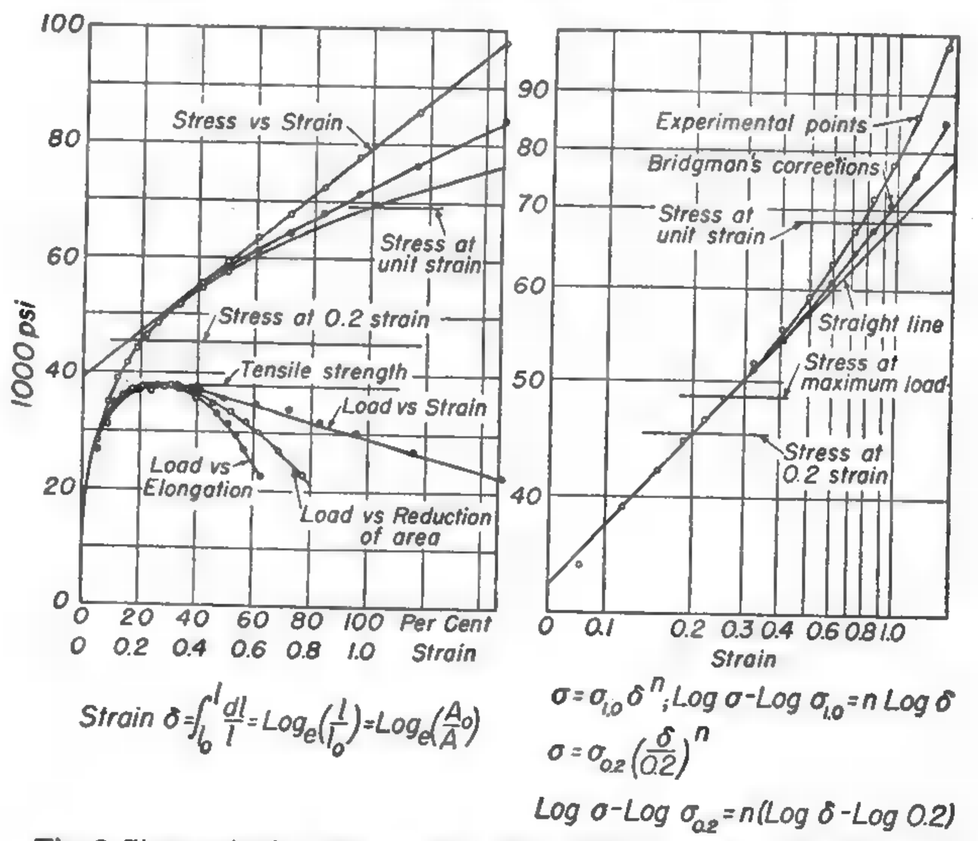

Fig. 2 Stress-strain curves variously plotted. To the left, load-extension, load–reduction of area, load–true strain, average stress—average strain, corrected stress (Bridgman correction)—true strain, and extrapolated true stress—true strain curves are shown plotted directly. To the right, the last three are shown plotted logarithmically. The slope of the log-log plot is the strain-hardening exponent; the stress for a strain of 0.2 has been called the flow strength, in this article.

Stress-strain curves in the plastic range require a treatment somewhat different from that used where the strains are only a few per cent. In Fig. 2 the data are for an iron alloy, and for plastic strains only. To the left, the data are plotted in several ways—stress against strain or load against strain. To the right is a plot of the logarithm of the stress against the logarithm of the strain. Experience has demonstrated that the part of the stress-strain curve in which confidence may readily be placed, is a straight

line when plotted logarithmically. Beyond the point where necking-down begins, there are departures from the straight-line plot for which quantitative corrections cannot yet be made. These departures result from the circumstance that simple tension no longer exists after necking-down begins, and also from the increase in speed of deformation, localized by this necking-down. It is probably fair to assume that the curve would be straight to the point of fracture if necking-down could be avoided, while maintaining the same speed and temperature of testing throughout.

It may be helpful to follow the plotting of a point on the final logarithmic curve, all the way from the original data to the final straight-line plot. If it were not for necking-down, which begins at the maximum load (or maximum in load divided by original area, which is what is plotted here) it would be possible to go from a load or nominal stress versus extension curve to a load versus reduction of area curve, by calculation. Until necking-down begins, the one curve can be calculated from the other, by using the fact that the volume or density of a metal is unchanged by plastic deformation, requiring constancy of the product of length by area. But after necking-down, this calculation is not possible, for the over-all extension depends on the *distribution* of deformation.

To obtain a true stress-strain curve the area must be *measured, after* necking-down begins. For each point then the *diameter* must be measured at the point where it is least, at the center of the necked-down region. From the *area* the *strain* may be calculated, using always the logarithmic strain when the strains are large. The logarithmic strain takes into account the fact that the gage length is changing throughout the test, and it may be regarded as the true strain; it is simply the integral of dl/l, instead of $\Delta l/l_0$, the conventional strain.[10]

Dividing the load by the actual area gives the apparent true stress. However, this needs correction because there are lateral tensile stresses in the necked-down region, which lead to higher average stress than would exist if simple tension prevailed; and, unless the test is run very slowly, the rate of straining may be high. Bridgman[11] has attempted to calculate the correction required by the presence of lateral tensile stresses, but his correction is apparently not sufficient; the corrected points still lie a little above the straight line in the log-log plot of stress versus true or logarithmic strain.

The fact that the log-log plot is a straight line means that all tensile curves are general parabolas, fitting equations of the form $\sigma = \sigma_{1.0}\,\delta^n$, where σ is the true stress, $\sigma_{1.0}$ is the true stress at unit strain ($\delta = 1.0$), δ is the true strain $(\ln \frac{l}{l_0})$, and n may be called the strain hardening exponent; n is the slope of the log-log plot. It is interesting to note that the rate of strain hardening, $d\sigma/d\delta$ obtained by differentiation of the above equation, is equal $\frac{\sigma}{\delta}n$, that is, the ratio of the stress to the strain multiplied by n; the greater n, the greater the rate of strain hardening. The constants which describe *completely* the whole course of the *corrected* plastic stress-strain curve are then $\sigma_{1.0}$ and n.

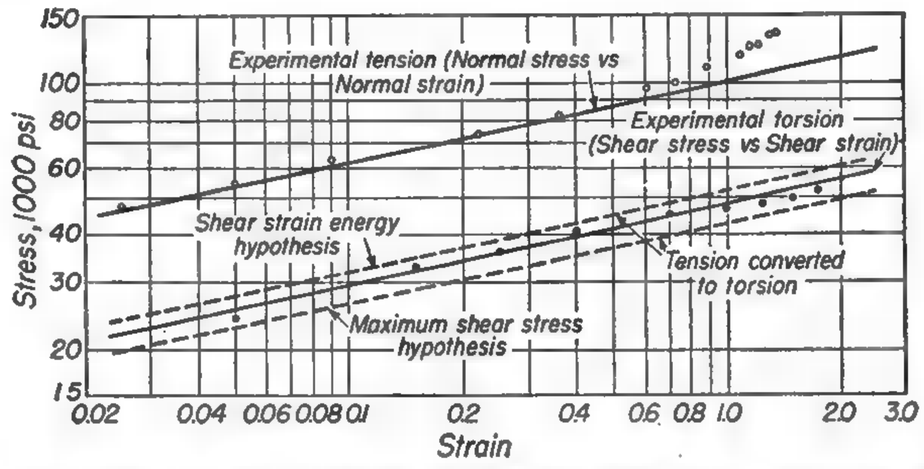

Fig. 4 Comparison of tension and torsion data. The dashed lines are the tension data converted by calculation for comparison with the torsion data. Within narrow limits the agreement between data taken in tension and in torsion is quite good if tension data beyond the point of necking-down are neglected.

It is advisable to discuss not $\sigma_{1.0}$, but the stress for a strain of 0.2, or $\sigma_{0.2}$. The reason for this is that the $\sigma_{1.0}$ value is influenced too much by how the line is drawn through the experimental points; the only reliable experimental points for steel center around $\delta = 0.2$. Below $\delta = 0.1$, the points are quite reliable *if* the specimen is aligned very carefully before starting the test, *and* if a correction is made for the elastic strain. But above $\delta = 0.3$, necking introduces uncertainties. Extrapolation from $\delta = 0.3$ to $\delta = 1.0$ is unreliable. On the other hand, the stress at $\delta = 0.2$ is extremely reliable and independent of the slope n of the line drawn through the points. The equation for the curve can just as well be written $\log \sigma - \log \sigma_{0.2} = n$ ($\log \delta - \log 0.2$), which is $\sigma = \sigma_{0.2}(\delta/0.2)^n$. Observe that the stress at the maximum load, which would be the tensile strength if the original area had been used instead of the actual area, is a point of no particular significance, since it does not come at a particular value of strain. The stress at $\delta = 0.2$ is the stress at the strain which is nearly average for the strain at maximum load—in iron about 20%, but varying from 10 to 30%. This stress at 0.2 strain may be called the flow strength, in the same way that it has been agreed to call the stress at a strain of 0.2% or 0.002 the yield strength.

The general applicability of tensile data is illustrated by Fig. 3, comparing stress-strain curves obtained in simple compression, simple tension, and two kinds of biaxial stretching: (1) balanced, when the strains in a sheet are the same in all directions, and (2) unbalanced, with a ratio of the strains of about 0.7 to 1, as determined in hydraulic bulge tests. The data have been converted to the stress invariant by use of the von Mises function, and to the strain invariant required to satisfy the law of constancy of volume and the assumption that the metal flows in the same way that a viscous fluid flows when acted upon by combined stresses. Neither of these methods of arriving at the stress and strain invariants is exact, but they do yield values almost

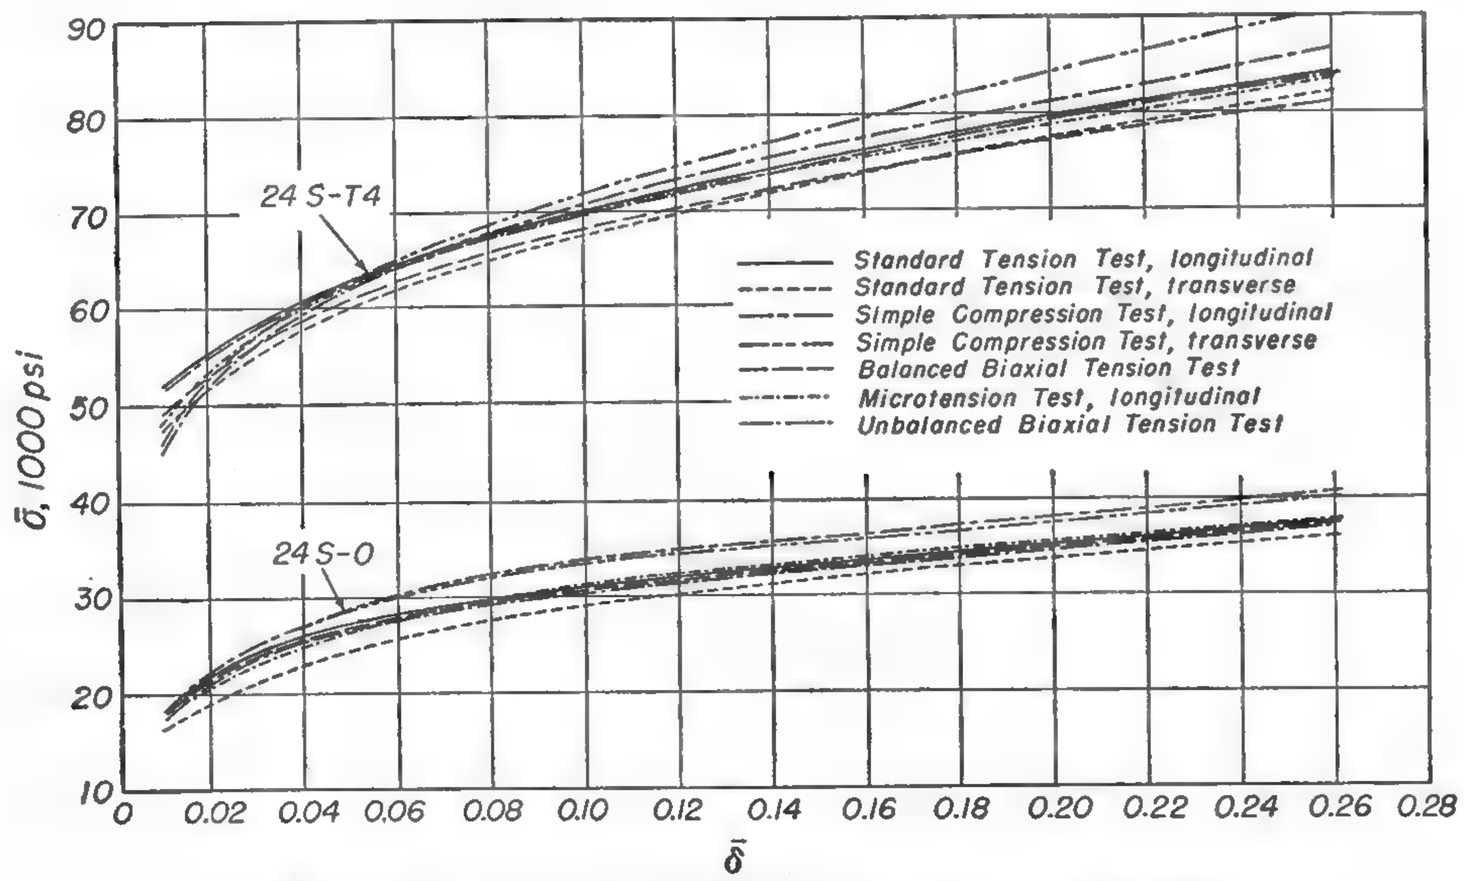

Fig. 3 Significant stress-strain curves for various methods of loading.

within the limits of experimental accuracy. It is nearly impossible to be sure that the curves of Fig. 3 do not coincide; hence, for practical purposes, we may use the tension curve to calculate the curves for other loading conditions, where the *average* values of the three principal stresses are not too different. It would not do to calculate in this way a stress-strain curve with superimposed high hydrostatic pressure.

The tension curve may even be used to calculate the stress-strain curve in torsion, when the properly corrected curve is used. This is shown in Fig. 4, taken from the work of Hollomon and Zener. The line through the tensile data, above, has been transferred by the von Mises or shear-strain-energy calculation, and again by the hypothesis of simple maximum shear stress in order to compare it with experimental data obtained in torsion, or twisting. It should be observed that if the *uncorrected* points obtained after necking in tension are ignored and if it is assumed that the data obtained in tension before serious necking apply to larger strains, there is good agreement between the tension data and the torsion data. In all ranges of strain, general experience shows that the torsion points fall between the values to be expected from the tension points by the application of the shear-strain-energy hypothesis and the maximum-shear-stress hypothesis. The spread between the two extremes is only 15%.

Compression Tests

By M. F. Sayre*

WITH metals, compression tests are much less commonly used than tension tests. In fact, only one of the many ASTM metals specifications calls specifically for compression tests as a requirement for acceptance of the material. It is usually tacitly assumed that metals are equally strong in tension and compression, or that if any difference exists, the compressive strength is the greater of the two. Tests for determining tensile strength are considered to give satisfactory indications of the quality of the material and of the allowable stresses to be used in compression as well as in tension.

In many instances this assumption is correct; in others it is not. In recent years there has been an increasing realization that, if valid design stresses are to be chosen, compression tests may be necessary, with the load acting in the direction in which the stress is to act in service. Consequently there has been a considerable increase in the number of compression tests being made, particularly on thin sheet material.

Compared with tension tests, compression tests have this disadvantage—they give somewhat less information. Under increasing compressive loads, specimens made of ductile materials tend to shorten in length and increase in diameter to an indefinite extent, so that no values equivalent to percentage elongation and percentage reduction of area can be determined, and ultimate strength has no particular meaning. A second disadvantage of the compression test is that, in order to obtain satisfactory results, somewhat greater care must be used in preparation of specimens, and the testing machine must be in somewhat better condition than is necessary for obtaining equally satisfactory results in tension testing. With present-day machine tools for preparation of specimens and with present-day testing machines, these requirements can be fulfilled without too much difficulty, so that compression testing can be carried on rapidly and in a routine manner.

The basic requirements for a satisfactory compression test are discussed below.

Alignment of Machine. The movable crosshead of the machine in which the test is to be made should move in a straight line at right angles to the stationary crosshead, without appreciable lateral motion and without wobbling. If the crossheads of the testing machine do not meet this requirement, it may be desirable to carry on the actual test in a subpress placed between the crossheads.

* Professor of Applied Mechanics, Union College, Schenectady
Prepared for the Subcommittee on Mechanical Testing.

A subpress as recommended in ASTM Method B9–47T is shown in Fig. 1. The hollow plunger in this subpress is guided by a rigid frame, so that it moves in a vertical direction. The load is applied through a central rod within this plunger. The side play of the rod is sufficient to allow

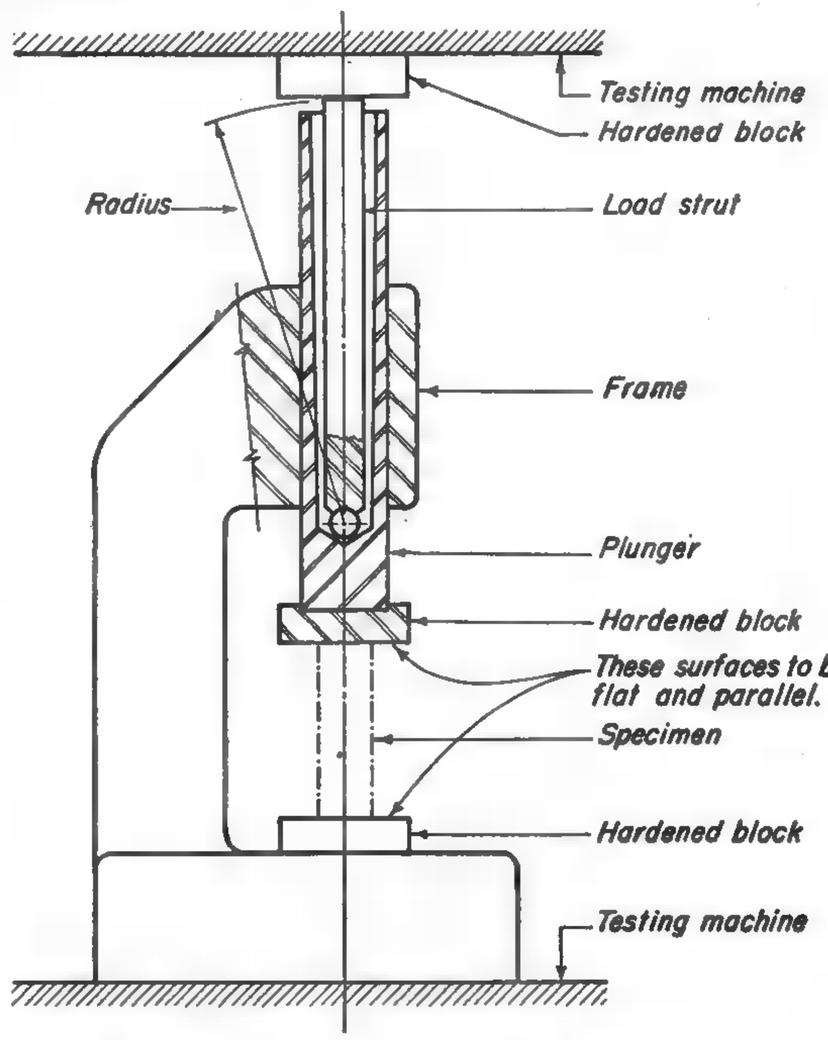

Fig. 1 Subpress recommended in ASTM Method B 9–46T

for any lateral movement or wobble in the upper crosshead of the testing machine, thus preventing jamming action between the plunger and its guide because of lateral forces. Since the load does not reach the plunger until it is below the guide, the plunger does not tend to increase in diameter and so does not stick in the guide, as a result of Poisson's ratio effect, while the load is applied. In testing machines where the movable crosshead is freely suspended from a ball-and-socket joint at the top of the machine, additional

side play is undesirable, and a modified subpress, with the load applied directly to the head of the plunger, may give better results.

Alignment of Specimens. The specimens used should have end faces machined plane and parallel, within very close limits. Details concerning dimensions of standard specimens for materials other than sheet are given on page 86, in the article entitled "Preparation of Test Specimens". Where reliable values for the properties of the material are desired, the test specimen should be at least

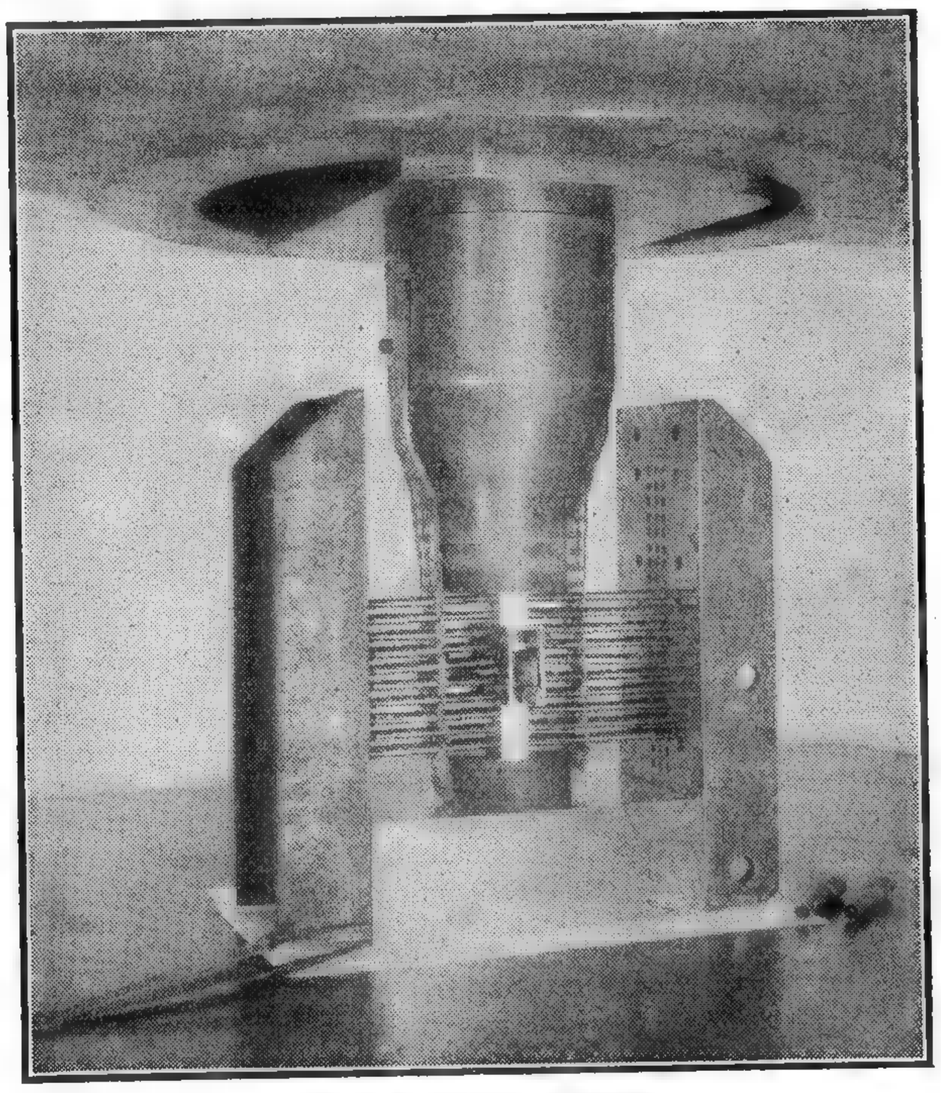

Fig. 2 Pack ready for test

three times as long as the diameter. Occasionally, where the dimensions of the stock from which the specimen is to be cut do not permit greater lengths (for instance, in compression tests of plate stock with the load applied at right angles to the face) short specimens may be used, with length about equal to the diameter. This procedure is followed in ASTM Specification B22–46T, for Bronze Castings for Turntables and Bearing and Expansion Plates for Bridges, which calls for cylinders 1⅛ in. in diam and 1 in. long. Results obtained from specimens of this shape will be comparable with one another but, because of the effect of end restraints, these results will show strength values higher than in tests of longer specimens.

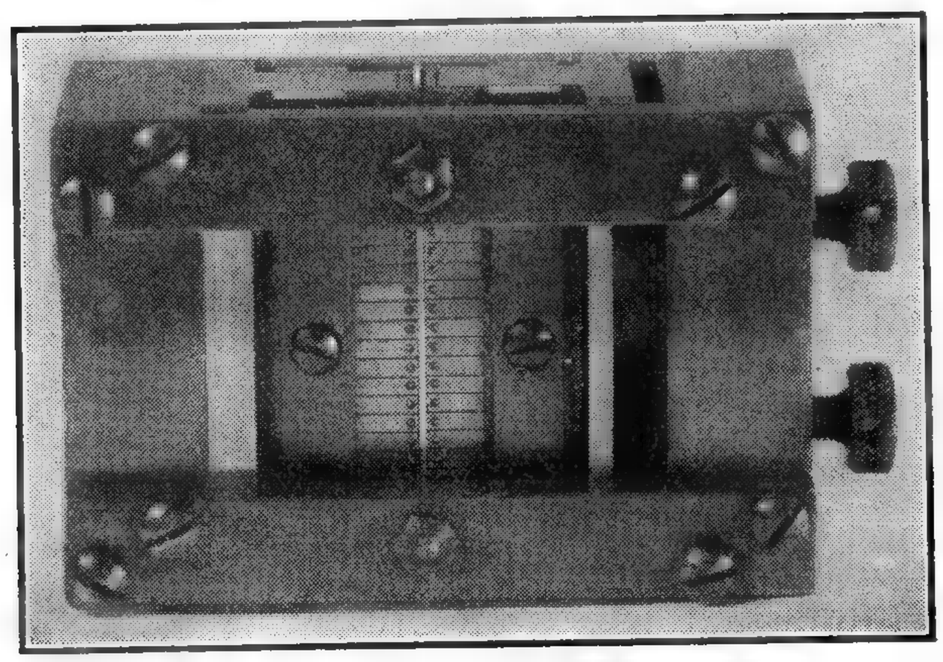

Fig. 3 Specimen in Montgomery-Templin fixture

Recently several different techniques have been developed by which satisfactory compression tests can be conducted on thin sheet specimens. In tests on thin sheet material, the specimens are supported laterally, either continuously or at close enough intervals to prevent buckling. The first methods used called for rows of very carefully adjusted steel pins, as shown in Fig. 2, or for rollers, as shown in Fig. 3, on each side of the specimen. It soon became evident that less elaborate methods were feasible. The problem is to provide adequate lateral support without introducing an undesirable amount of longitudinal friction, both initially and after the specimen has decreased somewhat in length and increased proportionately in thickness under load. The specimen must extend beyond the guides at the ends far enough to allow for this decrease in length but not enough to encourage the metal to buckle, and should extend at the sides far enough to support extensometers.

A fixture developed at the National Bureau of Standards is shown in Fig. 4. The tool steel guides shown are 0.46 in. wide by 2.20 in. long, and are held together by four bolts, which are intentionally made long and of small diameter so as to give a certain amount of elasticity. For sheet materials thicker than 0.020 in. the test specimen is made 0.50 in. wide by 2.25 in. long. With thinner materials (down to 0.006 in.) the overhang at the sides and ends is made

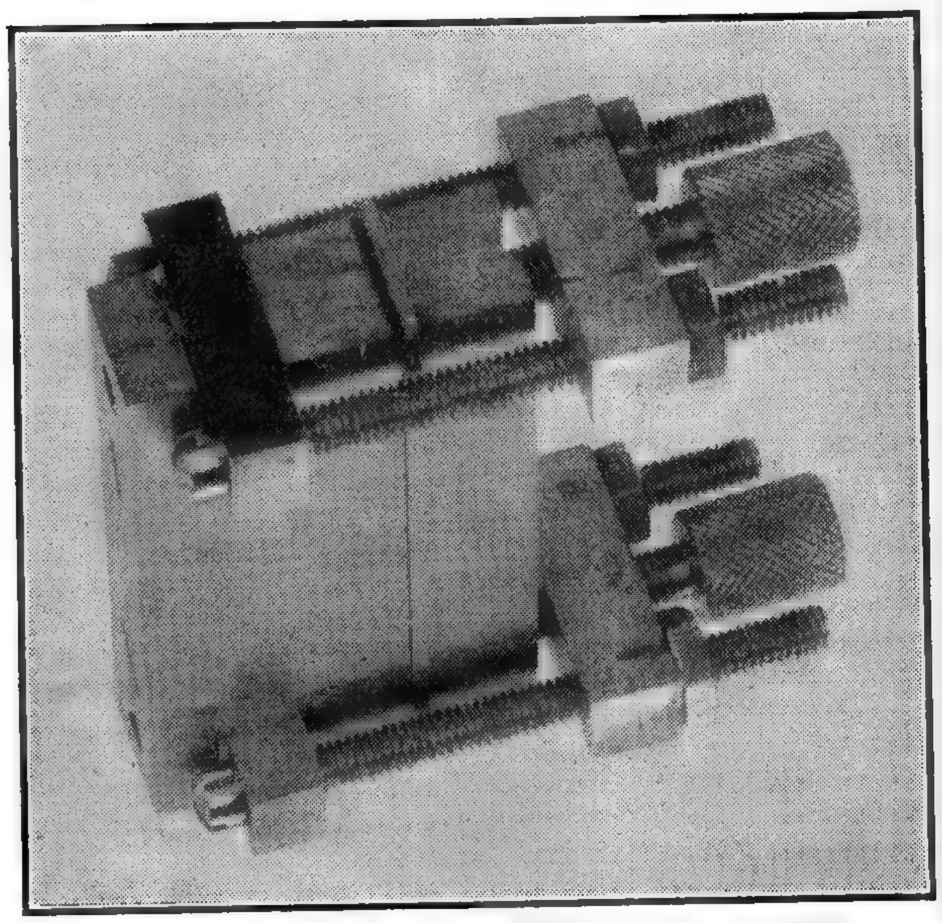

Fig. 4 Specimen between NBS lubricated steel guides

somewhat less. A thin film of heavy-duty lubricant for automobile wheel bearings is spread on the specimen. Then the specimen is placed between the guides and the bolts are tightened by trial until the guides will not slide down on the specimen under their own weight, but will slide smoothly if an additional force of not more than one pound is applied. Strains can be measured by using gages mounted on the projecting edges of the specimen. This fixture is intended primarily for use with a subpress, but good results have also been obtained by using it directly between the crossheads of a testing machine.

Alignment of Bearing Blocks. The bearing blocks used should have hardened steel faces that are plane and bear evenly on the end faces of the specimen. When the upper bearing block is made with a spherical seat, having the center of the sphere at the midpoint of the face of the bearing block, theoretically the block can be adjusted so as to bear evenly on the top face of the specimen, although the lower bearing block may be very slightly out of horizontal alignment, and the two faces of the specimen slightly out of parallel alignment. In practice this adjustment is not always easy to achieve. If the block is allowed to rest on the top face of the specimen while the crossheads are being moved together, the upper face of the bearing block may not line up exactly with its spherical

seat, and skew forces will be developed as the block moves laterally to seat itself. If the block is supported by springs so that it is held in contact with the spherical seat, swiveling the block while load is being applied, to the exact position that will give an even bearing on the specimen, will be difficult. In both instances, care should be used to make sure that the top face of the specimen centers accurately on the bearing block, and to avoid a tendency for the block to swivel as the load is being applied. However, the friction in the spherical seat is usually great enough so that the bearing block cannot be relied on to adjust automatically to the face of the test specimen as the load is being applied, and so that the bearing block will swivel jerkily if the specimen yields. This friction can be reduced by applying a forced oil feed to the bearing, but the practice is expensive and has not often been used.

Instead of employing the bearing with spherical seat, better results can be obtained by using test specimens with accurately parallel ends, and by adjusting the bearing blocks themselves so that their faces are parallel. This parallelism of the blocks can be checked with inside micrometers or dial gages, or by bringing the two faces lightly in contact with each other with no specimen between and by checking with feelers or by using Prussian blue for even contact. One method of making adjustment for lack of parallelism is to loosen the upper bearing block slightly so that it can rest evenly on the lower block, and then to grout the space between the upper block and the crosshead with plaster of Paris. While this is being done, the blocks should be under a moderate load in order to take up any slack elsewhere in the mechanism. An alternative method, developed at the laboratories of the Aluminum Company of America, uses a lower bearing block made of two hardened steel disks. Each of these disks is made with a very slight taper in thickness, so that when one is placed upon the other, with the thickest dimension of one opposite the thinnest of the other, the over-all thickness of the two is constant. As one of the tapered disks is rotated on the other, the assembly as a whole becomes a tapered disk. The rims of both disks are graduated to indicate the amount of taper produced and the direction of this taper. With these disks in zero position, the spacing between bearing blocks is measured at various points, and the disks are then rotated by known amounts until this spacing is made uniform. A single adjustment of this fixture will suffice for a whole series of compression tests.

As load is applied, the lateral dimensions of compression specimens increase because of Poisson's ratio effect below the elastic limit, and because of plastic yield beyond it. Near both end faces, this swelling tends to be restrained by friction between the specimen and the bearing blocks. If any lubrication is present—even residual oil from machining operations—the result is likely to be imperfect restraint and consequent variation among different specimens. To obtain consistent results, it is desirable to clean all bearing surfaces with a solvent, such as acetone, before testing, thus producing essentially complete restraint.

Speed of Testing. As in tension testing, speed of testing should logically be stated in terms of rate of increase of unit strain along the gage length of the specimen. For practical purposes this is not an easy unit to use, so the rate of increase of unit stress is used in its place for hydraulic testing machines and the free-running speed of the crosshead is used for machines of the screw type. Most of the compression tests made on metals are for research or investigational purposes rather than in connection with acceptance tests, and no standards of speed have been established, beyond an old ruling that the free-running speed of the crosshead should not exceed 0.05 in. per min. For short specimens this speed is likely to be too high. To obtain consistent stress-strain curves, it is desirable that about the same speed be used with successive specimens, and that the halts made for taking gage readings be brief and reasonably uniform in duration. Otherwise the short-time creep which occurs, once the elastic limit has been passed, may result in an irregular stress-strain curve.

Information Obtained From Compression Tests. For brittle metals, such as cast iron, and for nonmetals, such as building stone, concrete or brick, the only reading taken in a compression test is usually the maximum load in pounds. When divided by the original cross-sectional area, this reading gives the compressive strength of the material.

In acceptance tests for bronze castings (ASTM specification B 22–46 T) the requirement for class A material is that the deformation limit (which is defined as "that load which produces a permanent set of 0.001 in. in the given compression specimen", 1⅛ in. diam by 1 in. high) must reach 24,000 psi as a minimum; and that the permanent set in 1 in., under a compressive stress of 100,000 psi, must lie between 0.04 and 0.12 in. For class B the minimum "deformation limit" is 18,000 psi and the permanent set under 100,000 psi must lie between 0.10 and 0.20 in. For class C material, the only requirement is that the maximum compression under 10,000 psi shall not exceed 0.001 in. In essence, the requirements call for applying either one or two proof loads on each specimen, and measuring the change in length under each load.

Most other compression tests are run in order to obtain a stress-strain curve for the material in compression, both for its own value and for comparison with stress-strain curves in tension. In tests of high-strength aluminum alloys and alloy steels for aircraft purposes, it is necessary that this curve be carried at least up to the yield strength, which is defined as that stress at which the offset from the original straight stress-strain line corresponds to 0.2% strain. This curve must be sufficiently detailed to give values for the initial modulus of elasticity and for the slope of the tangent to the curve at various stresses above the proportional limit. These values are used in computing the buckling strength of parts subjected to compression under high stresses. To obtain the necessary accuracy, precision strain gages must be used, preferably reading on opposite sides of a specimen, unless previous experimentation has indicated that the stress distribution is sufficiently uniform for only one gage to be needed. It should be emphasized that, in any compression tests of metals, all strains should be measured between gage points on the specimen and not between the two bearing block faces, if accurate results are desired. Preferably the gage points should be located symmetrically with respect to the middle of the length of the specimen and not closer to the ends of the specimen than a distance equal to the width of the specimen.

The Torsion Test

BY THE SUBCOMMITTEE ON MECHANICAL TESTING*

TORSION tests provide a method for determining the modulus of elasticity in shear (sometimes called the modulus of rigidity), as well as for determining the shearing yield strength and the modulus of rupture or apparent ultimate shearing strength.

The torsion test is useful for testing such parts as axles, shafts and twist drills in the manner in which they are to be used. It offers advantages in the testing of brittle materials.[1, 2] At elevated temperatures the torsion test is of value as an index of forgeability.[3, 4] This test has also been used to determine values for the ultimate strength of cylinders subjected to internal pressure, utilizing that part of the torque-twist diagram lying beyond the elastic region.[5] Without uncertain correction, torsion test data are generally valid to larger values of strain than are tension test data.

A machine for making torsion tests consists essentially of (1) a twisting head, in which one end of the specimen

* Acknowledgment is made to F. M. Howell and F. G. Tatnall for their contributions to this article.

can be suitably gripped and by means of which a twisting moment can be applied to the specimen, and (2) a weighing head, in which the other end of the specimen can be gripped and by which the twisting moment, or torque applied by the twisting head, can be measured (Fig. 1). The gripping arrangements must be such that the axis of the specimen coincides with the axis of rotation. The deformation of the specimen is usually measured by a twist-measuring device or troptometer, which indicates the angular displacement of a point near one end of the test section in relation to a point on the same element of the specimen but near the opposite end of the test section.

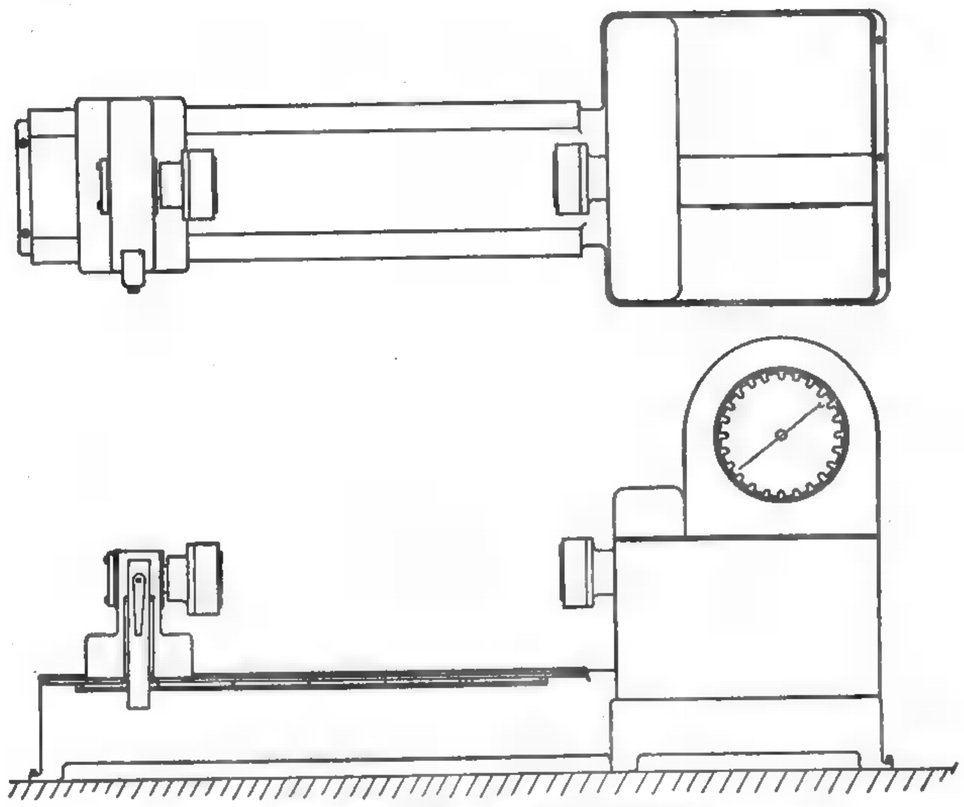

Fig. 1 Torsion-testing machine

Specimens that have a circular cross section are generally used for torsion tests. Solid specimens have the disadvantage that the stress varies from zero at the axis of the specimen to a maximum at the surface. A tubular specimen having a thin wall is generally preferred, because it provides more nearly uniform stress distribution throughout the cross section. For torsion testing, the use of thin-wall tubes is limited by those dimensions at which the tube will fail by collapse rather than by torsion.

The test specimen should be machined to a somewhat smaller diameter than the ends that are held in the grips, and a suitable fillet should aid in transition from one diameter to the other. The reduced section should be relatively short for the determination of ultimate shearing strength but, for the determination of yield strength and modulus of elasticity, a greater length is required. For the determination of ultimate shearing strength, suitable proportions for the reduced section are a length equal to about one half the diameter, and a ratio of outside diameter to wall thickness of 10 to 12; for the determination of yield strength and modulus of elacticity, the length should be at least 10 times the diameter and the ratio of outside diameter to wall thickness should not exceed 10.

The torsion test has not been standardized, primarily because there are few if any specifications that require torsion tests. The ASTM has published a "Tentative Recommended Practice for Torsion Tests of Cast Iron" (A260-42T) but none of the specifications of that society require that torsion tests be made.

When a cylindrical specimen, either solid or tubular, is twisted in such a way that the axis of twist coincides with the axis of the specimen, the specimen is subjected to pure torsion. The maximum stress occurs at the surface of the specimen. The shearing stress can be calculated by the following formula:

For tubes: $$S = \frac{16Ppd_1}{\pi(d_1^4 - d_2^4)}$$

For solid bars: $$S = \frac{16Pp}{\pi d^3}$$

where
S = shearing stress, in psi
P = force, in lb, at lever arm p, in inches
d_1 = external diam, in inches
d_2 = internal diam, in inches

This formula holds only as long as the strain is proportional to stress, but is commonly used for computing higher stresses and for determining modulus of rupture or ultimate shearing strength.

The total torsional deformation is measured as angular twist of one end of the gage length in relation to the other. In order to obtain the angular twist per inch of gage length, the total angular twist is divided by the gage length. The angular twist per inch of gage length can then be converted into shearing strain, in inches per inch, by multiplying by half the diameter of the specimen.

The modulus of elasticity in shear (sometimes called the modulus of rigidity) can be calculated from the following formula:

$$E_s = \frac{SL}{r\theta}$$

where
S = maximum shearing stress, in psi
L = gage length of specimen, in inches
r = distance from axis of specimen to the outermost fiber (half the diameter), in inches
θ = angle of twist, expressed in radians, in length L.

The yield strength is generally defined as the maximum stress developed by a torque producing an offset of 0.2% from the original modulus line, analogous to the method used for determining tensile yield strength. In "Tentative Recommended Practice for Torsion Tests of Cast Iron", referred to above, the yield strength is the maximum stress developed by a torque producing 0.001 radians per in. of angular twist beyond the line of proportionality. An offset of 0.001 radians per in. is the equivalent of a shearing strain of 0.0375% for the specimen, ¾ in. in diam, recommended by the ASTM for cast iron.

Notched-Bar Impact Tests

By S. L. Hoyt*

If it were possible experimentally to apply known triaxial stress systems as easily as to apply simple tension stresses, a great deal of confusion would be eliminated from discussion of notched-bar impact testing. Although the notched bar often provides triaxial stress components high enough to induce brittle failure in steels, no satisfactory method has ever been devised for measuring or computing the stress components in notched bars. There are convincing indications that a given geometry of notch does not impose the same stress system when used with different materials.

For this reason, it is evident that the data from the notched-bar test are subject to limited interpretation. The test can be expected to indicate only that a given steel is or is not brittle when tested at a given temperature with a notch of given form and severity. When interpreted

* Battelle Memorial Institute, Columbus, Ohio.
Prepared for the Subcommittee on Mechanical Testing.

within these limitations the comparison of results from one material with those from other materials can lead to a useful estimate of quality or to a correlation with the properties of other materials of supposedly similar composition. However, the limitations must be kept clearly in mind, and the test should not be misused.

The impact value is a simple evaluation of the notch toughness as a summation of load and deformation, and differentiates between different steels under the particular test conditions. The impact method is a positive method of securing a toughness value but has led to the false implication that the results correlate entirely with shock loading. However, while this is an impact method for determining energy absorption, it is not a test of impact behavior.

It is now quite generally recognized that tests of metal behavior under impact must be carried out at relatively high velocities before any peculiarity of behavior becomes evident. Typical "high-velocity tests" are ballistic tests of armor plate. In the field being discussed here, the notch actually dominates the test.

Impact Machines. Two types of machines are commonly used, the Charpy and the Izod, both of which employ the swinging pendulum. The conventional size of Charpy machine has a total available striking energy of 30 kg-m or 220 ft-lb. The specimen, supported at both ends as a beam, is broken by a single blow of the pendulum applied at the middle of the span. Ordinarily the specimen breaks at the notch, the two halves fly away, and the pendulum passes in between the two parts of the anvil. The height

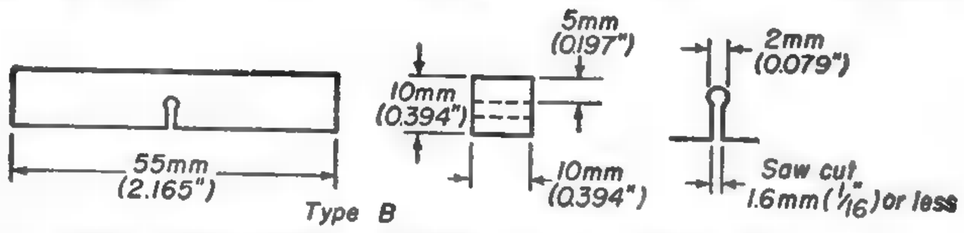

Fig. 1 Simple-beam notched-bar impact test specimen with keyhole notch, Charpy type (ASTM)

of the fall minus the height of the rise, gives the amount of energy absorption in deforming and breaking the specimen, plus friction losses and the energy of the flying parts, which is about 1 to 2 ft-lb. The instrument has a scale with moving pointer, which is calibrated in terms of energy to give the "impact value" of the test specimen. One or more specimens are broken to determine the impact value of the metal. Because of the sensitiveness of the test to variables, such as the machine finish of the

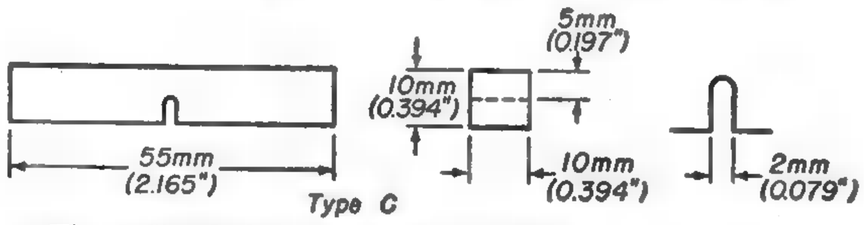

Fig. 2 Simple-beam notched-bar impact test specimen, Charpy type (ASTM)

specimen and the location and extent of nonmetallic inclusions, it is customary in steel specifications to require that three individual specimens should constitute a test. These may be appraised individually or assembled with other data for statistical analysis.

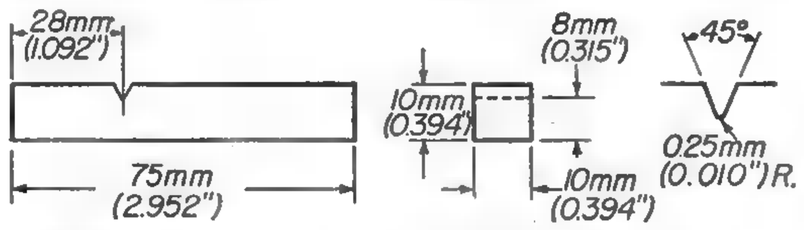

Fig. 3 Cantilever-beam notched-bar impact test specimen, Izod type (ASTM)

It is common European practice to report notched-bar impact test results in terms of energy absorbed per unit cross-sectional area. It should be realized that this expression does not permit translation of data from one type of test to another; consequently there appears to be little or no value in expressing results in this way.

The Izod machine is similar in principle but the test specimen is held rigidly in a vise, as a cantilever beam, with the center of the notch coincident with the upper face of the jaws. The capacity is usually 220 ft-lb. In this method, one half of the test specimen is broken off and the impact value is determined as before.[1]

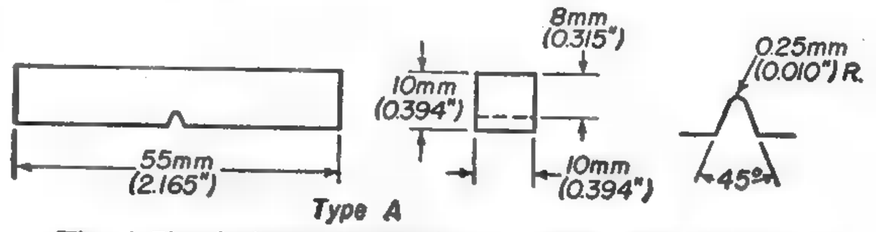

Fig. 4 Simple-beam notched-bar impact test specimen, V-notched Charpy type (ASTM)

Types of Specimens. In this country, two types of test specimens are generally used: the standard Charpy specimen (*see* Fig. 1 and 2) and the standard Izod specimen (*see* Fig. 3). However, a practice has spread of using a specimen of the Charpy type with the Izod notch. This specimen, known as the "V-notch Charpy specimen" is illustrated in Fig. 4. There should be no confusion in using the results of this method if they are labled "V-notch Charpy value". When a figure is reported as a "Charpy value", the first presumption is that the specimen was like that shown in Fig. 1 or 2, though it may have been like the one in Fig. 4. Since the Izod notch gives much higher values for tough steels, a high "Charpy value" (above approximately 50 ft-lb) may be assumed to relate to the specimen of Fig. 4. Results obtained in using one particular form of test specimen cannot be translated to another.

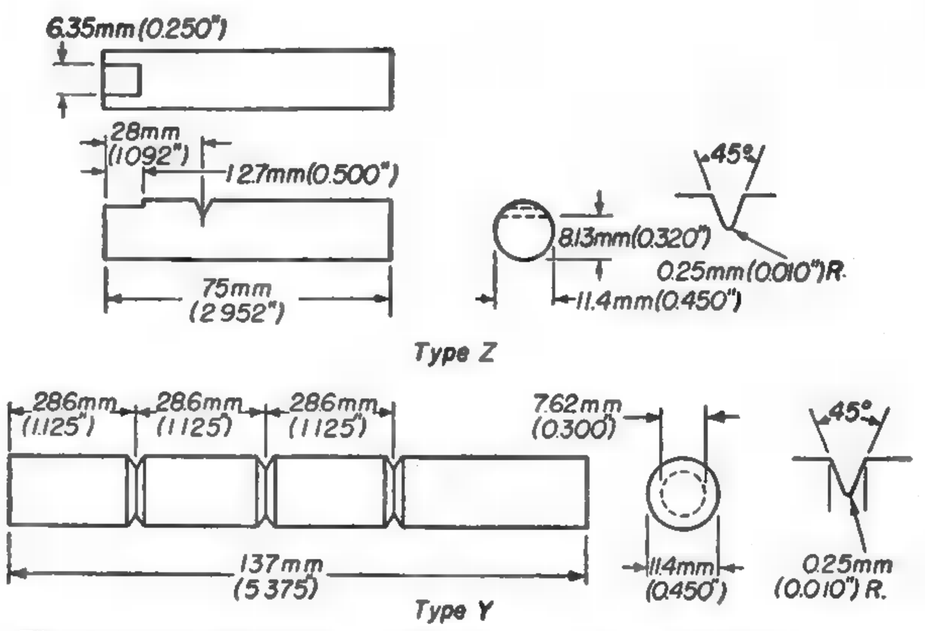

Fig. 5 Supplementary cantilever-beam notched-bar impact test specimens, Types Z and Y (ASTM)

Supplementary types of notched-bar impact test specimens are recognized by the ASTM, as shown in Fig. 5. These specimens, circular in cross section, have the advantage of lower machining costs. Attempts have been made to develop round specimens of the simple-beam (Charpy) type also. Although these specimens of circular cross section have been designed to give results equivalent to the corresponding rectangular specimens, such equivalence is not always obtained. Added difficulty is encountered in locating the specimen in the machine properly to maintain the relative position of notch and striking tup.

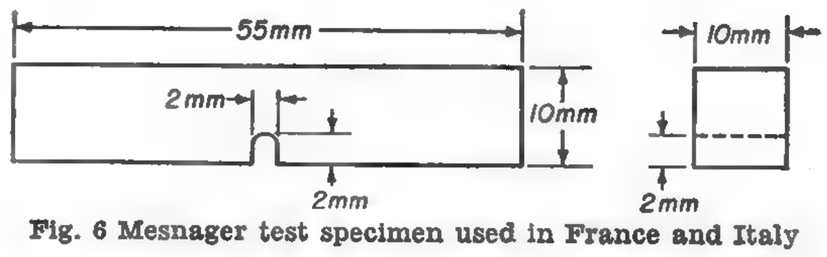

Fig. 6 Mesnager test specimen used in France and Italy

The "Mesnager" specimen is most frequently used in France and Italy, but the notch is too shallow for best results (Fig. 6). This specimen is broken in the Charpy machine. A number of types of specimens are recognized for making tension-impact tests (Fig. 7).

Perhaps the worst feature of practice in this field is that of testing V-notch Charpy specimens on the Charpy ma-

chine and reporting extra high impact values of about 80 ft-lb and more, even well above 100 ft-lb. In these instances, the test specimen has not broken (too shallow notch) but has been violently driven through the split anvil by the pendulum, meanwhile absorbing a large and unknown amount of energy. Obviously this situation results in absurd or fictitious values. Although the test data are unreliable in such cases, it is known at least that the metal has responded in a tough manner with that particular notch. A similar occurrence is possible in using the Izod machine. When the specimen is not broken by the blow, it rubs along the bottom of the tup, thereby absorbing considerable energy and falsifying the test results.

The notch of Fig. 1 is preferred by many because of the ease of making it and particularly because of the precision with which it can be reproduced. The hole is drilled with a No. 47 drill with a diameter of 0.0785 in. By placing the specimen in a fixture, this hole can be drilled tangent to the center line so that the depth of the section to be broken can be held to 5 mm or 0.197 in. The drilling operation leaves the scratches running around the hole, or in the most favorable direction to avoid causing low results in the test. The hole can be reamed out but that is seldom considered necessary. After the hole is drilled, a slot is opened to the surface by sawing, milling or grinding with care to avoid enlarging the hole. Cutting into the side of the drilled hole can be avoided by placing a copper wire in the hole while making the saw-cut. If the steel is too hard for drilling (about 400 Brinell or 40 Rockwell C) the notch can be made by grinding.

Test specimens that are to be broken in a hardened condition require a special technique. The hole cannot be drilled but, with suitable precautions, it can be ground to dimension. It is also feasible to drill the hole before hardening, insert a soft steel wire that will completely fill out the hole, and then heat treat the test specimen. This hole is subsequently opened to the surface.

The Izod notch, commonly used in Great Britain, is also quite widely used in this country. Its sharper root radius gives higher concentrations of stress than does the Charpy notch and its shallow depth gives a larger numerical spread between notch-tough and notch-brittle steels. On the other hand, reproducing the Izod notch requires greater care. This notch is virtually impossible to produce in hard steels. Furthermore, a great amount of work has shown that a shallow notch like the Izod is inadequate for the tougher steels and that as soon as the volume of deformed metal extends to the outer face, false impact values are obtained. The fictitious values that are obtained, particularly with V-notch Charpy specimens, have already been mentioned. However, this type of notched bar has been successfully used for the appraisal of considerable material, particularly for ordnance. In applications of this type, the properties of the material are such that the specimen always breaks under test.

Studies of the character of the machine finish in the notch have indicated that reproducible results may be obtained with some materials by using a milling cutter to make the notch, provided the milling cutter is periodically examined and kept in good condition. Some investigators advocate polishing the radius of the milled notch by using lapping compound on a wire of the correct radius, rotated by an electric hand drill.

Precautions Necessary for Reproducibility of Results. Three features of great importance are: making the notch correctly, locating the bottom of the notch properly, and placing the specimen properly in the machine. The other dimensions of the specimen should be held as shown. The accuracy which is usually maintained is plus or minus 0.001 in.; though if it will lower the cost of preparing test specimens, this can be increased to plus or minus 0.003 in. on harder steels and to plus or minus 0.005 in. on softer steels, without endangering the reliability of the results.

The impact machine should be known to conform to standard requirements, and to be of correct calibration. Frictional losses can be checked from time to time by permitting the pendulum to fall freely and then noting the decrease in the oscillations. The small fixture that is used to place the test specimen at the correct position on the anvil of the Charpy machine can also be used to check the zero position of the pendulum. The test specimen should be placed accurately on the anvil so that the tup of the pendulum will strike it opposite the notch. This placement can be properly made with the aid of the template. Furthermore, the anvil should be so designed that the test specimen clears the sides with no undue loss of energy from scraping.

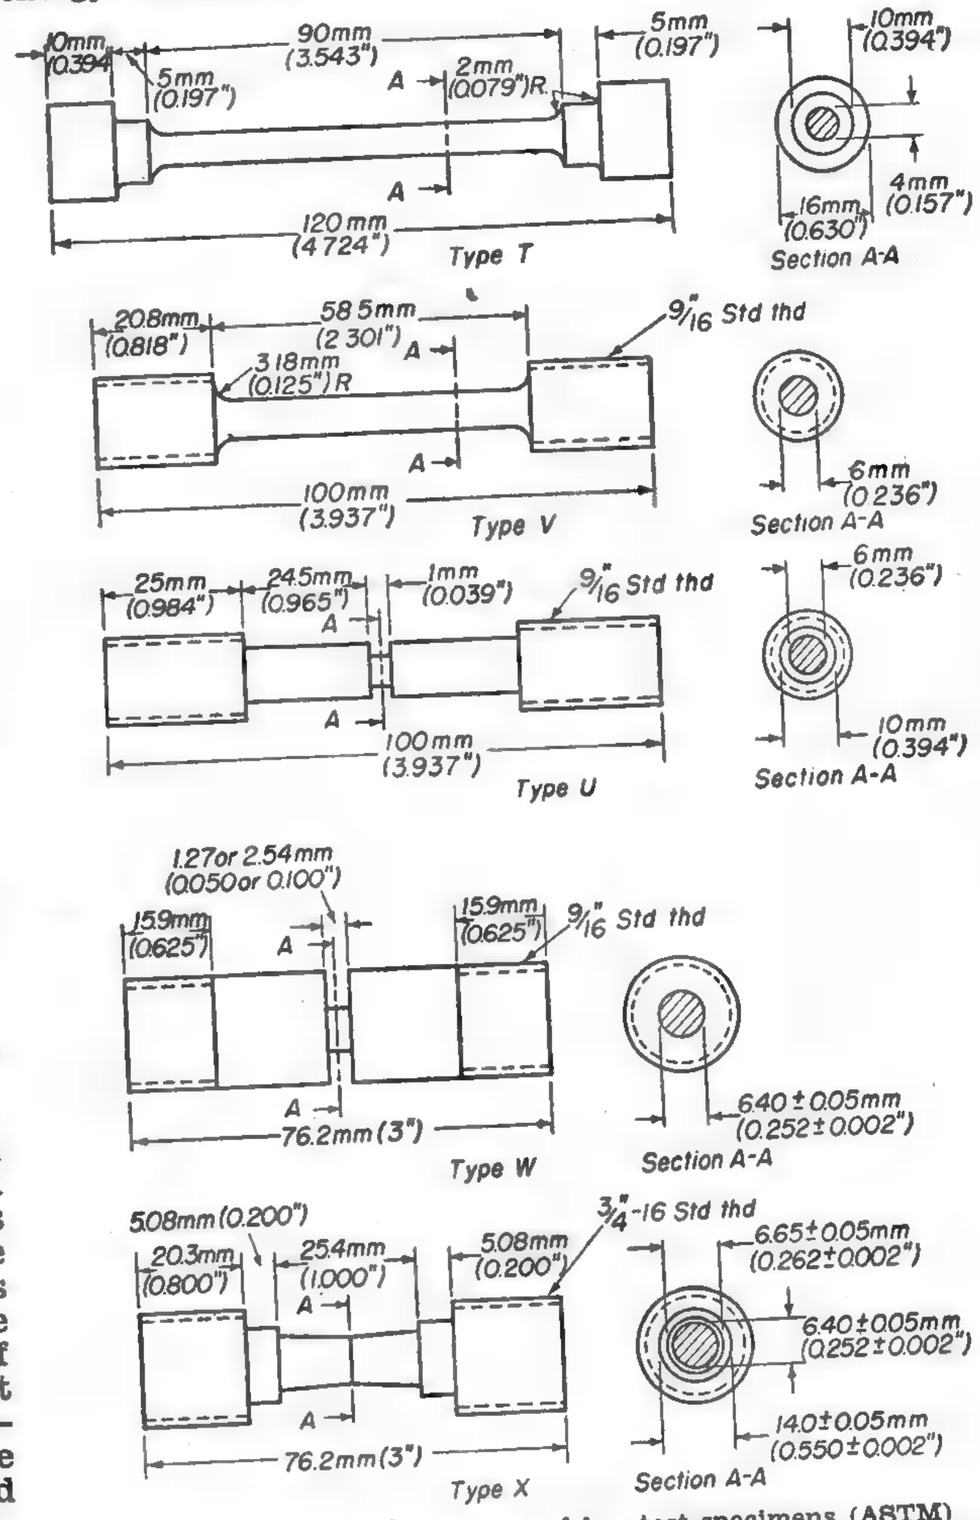

Fig. 7 Tension-impact notched-bar test specimens (ASTM)

The effect of variation of temperature in notched-bar testing is extraordinarily great. The laboratory temperature may vary as much as 30°F between summer and winter, and with some steels this is sufficient to affect the impact values greatly. To obtain reproducible results may require holding the temperature of the test specimen within a range not exceeding 10°F. The effect of temperature will be discussed at greater length in a later section.

Other factors that affect the consistency of the results are associated with taking the sample. Forgings and rolled sections have definite flow lines or fiber; nonmetallic inclusions are also drawn out in directions parallel to the direction of metal flow. If the length of the test specimen is parallel to the direction of the fiber, the impact value is higher—at times as much as twofold—than it is if the length is perpendicular to that direction. The direction of the notch in the test specimen may likewise have an effect on the impact value.

Heat treatment frequently alters the surface and affects the consistency of the test results. Usually this change is a decarburization, which increases the impact value, though it may be a carburization, which acts to lower the impact value. The discussion of such factors could be elaborated, but it is sufficient to say that every test specimen should be made by a procedure that insures having the metal in the desired condition. As a precautionary measure, at least 0.025 in. can be left on all faces for final

machining and grinding, and the notch can be made last.

Wide Specimens. It has been found valuable to test wide specimens for certain applications. A double-width specimen, shown in Fig. 8, ordinarily gives about double the impact value of the standard Charpy bar. Occasionally, however, the value is found to be no greater than that of the standard bar; and for certain critical service conditions such a material may not be desirable.

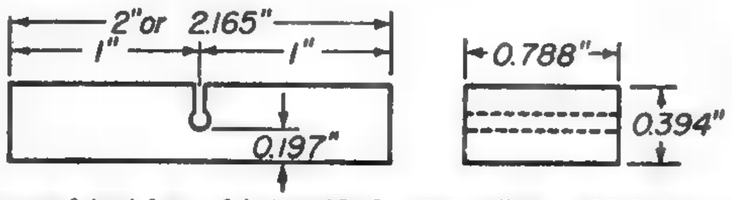

Fig. 8 Proposed test bar of intensified notch effect, which is the same as Charpy specimen except for being twice as wide

Effect of Temperature. Temperature has a pronounced effect of changing the energy absorption and fracture behavior of steel in a notched condition. This happens over a relatively narrow range and at approximately atmospheric temperatures for most ferritic steels that have not been heat treated. The sharpness of the change or "transition" from tough to brittle depends on the material and also on the notch geometry. Frequently the Charpy values will change from between approximately 25 and 30 to approximately 5 to 10 ft-lb over a temperature interval of 25 to 50°F, while the Izod values (V-notch) are changing gradually. With other steels, the two notches will show reverse effects.

Service failures corroborate the test results by pointing to the increased hazards of subnormal temperatures, and determinations of transition temperatures have come to be useful criteria of steel "quality" or applicability to the part in question. Size and shape (stress distribution) are important; a steel with a transition temperature of 30 to 40 F in the Charpy test may have a transition temperature above 100 F when tested as a large, rigid structure.

Transition temperatures of ferritic steels appear to be determined by the degree of oxidation, the amount of nitrogen and the extent to which it is "fixed" in a stable form, the coarseness of the structure, phosphorus and impurity elements, prior cold working or strain embrittlement, and structure. In other words, coarse structures and most active impurities raise the transition temperature and make the steel more susceptible to low-temperature embrittlement. Special attention must be given to deoxidation practice if it is desired to retain notch toughness at low temperatures. This factor of quality improves with deoxidation by manganese, silicon, and aluminum, or from rimmed steel to fine-grained, fully killed steel. See the article on "Properties of Metals at Low Temperatures".

Heat treatment is particularly effective; in fact, an effective liquid quench (complete martensitization) and a high tempering temperature put a hardenable steel in its best condition for low-temperature notch toughness.

The face-centered cubic, nonferrous metals[7] (copper, aluminum, nickel and others) remain notch-tough down to the lowest temperatures. This effect, which is presumably associated with the structure, recurs in the iron-base alloys or steels that are austenitic or face-centered cubic in structure. Examples are the stainless steels, such as 18-8, and the quenched Hadfield manganese steel.

Effect of Velocity. The effect of speed of straining is outside the scope of this article; however, it is found that increasing the velocity has the same embrittling effect as lowering the temperature.[3,4] This effect is relatively small, as compared with that of temperature, but has been demonstrated quantitatively.[5]

Nonstandard Tests. In technical practice, occasions arise that require the testing of materials and parts by using samples that do not conform to standards. There can be no set rule for such problems, but valuable advice can be had from the work of Tour.[2]

Interpretation of Test Results.[7] The interpretation of notched-bar test results necessarily involves certain strict limitations. Although steels are said to be notch-tough or notch-brittle, a given steel may behave in one way under one set of conditions and in another way under other conditions. Consequently, the broad problem of notched-bar testing is that of determining the severity of test conditions (notch geometry, temperature, and velocity) required to produce brittle behavior. If the service conditions are reasonably well understood, it should be possible to judge the adequacy of a steel. In important applications, this will involve a study of the service conditions and considerable testing of steel specimens, even including large or full-scale tests to bring in the size effect. Once the required level of notch toughness has been established, later testing can be simplified to a "go" or "no go" type. It may also be assumed that the steel composition, processing and treatment, as well as correct fabrication procedure, will have been established.

One of the best uses of the test is in comparing a steel with a standard known to be adequate for the service. The testing might include the effects of temperature, of specimen width, and of cold work or strain-aging, but the results would be interpreted in the following terms: adequacy of refining and deoxidation practice, steel composition and impurities, structure, homogeneity, heat treatment and so on. In such comparisons, the specimens of the material in question must be comparable in the other essential characteristics and properties with those that serve as a standard. With heat treated specimens, the grain size established prior to quenching must be carefully controlled, grain coarsening must be avoided, and the tempering must give the correct hardness and stress condition.

Notched-bar impact tests have been used as an index to the results of heat treatment. It has been noted that tempered martensite gives impact values superior to those obtained from other structures. It is sometimes extremely difficult microscopically or otherwise to distinguish between tempered martensite and tempered bainite. However distinct differences may be noticed in the Charpy results.

Creep Tests

By J. J. Kanter*

CREEP is a continuing change in the deformation or deflection of a stressed member. In regard to metals and alloys, creep is generally associated with a time rate of deformation continuing under stress intensities well below the yield point, the proportional limit, or the apparent elastic limit for the temperature in question. The creep may be an effect of consequential magnitude at normal temperatures as well as at elevated temperatures, depending on the material under consideration or the degree to which freedom from continuing deformation is sought.

* Materials Research Engineer, Crane Co., Chicago.

Prepared for the Subcommittee on Mechanical Testing.

Character of Creep. Most of the available information concerning the character of creep has been gained from observations of specimens under constant tensile load and

at constant temperature. Extensive studies have been made of the interrelations among strain, stress and temperature by testing series of specimens under various combinations of load and temperature. A creep test is generally conducted for sufficient time to establish the character of the curve of creep strain versus time at the particular constant load and temperature in question. Such a test, to be significant, may require from a few days to several years. Tests of less than 1000-hr duration are generally regarded as rather insignificant in establishing reliable creep rates.

In Fig. 1 are illustrated two typical tensile creep curves based on results actually obtained under different loadings on two different alloy steels at high temperature. The strain designated as "total creep" is the net plastic deformation accumulated over and above the elastic strain immediately incident to the application of load. The initial creep on a specimen not previously strained is invariably rapid, but as the straining progresses, the rate of creep decelerates until, after an appreciable period, a constant rate is approximated. This initial straining at a decreasing rate is often termed the first stage of creep.

The second stage of creep is the strain that occurs either at a constant rate or in asymptotic approach to a constant rate. The design of stressed members is usually based on the rate of second-stage creep strain. The useful life of a structure is for some purposes adjudged to be the lapse of time before the termination of the second stage.

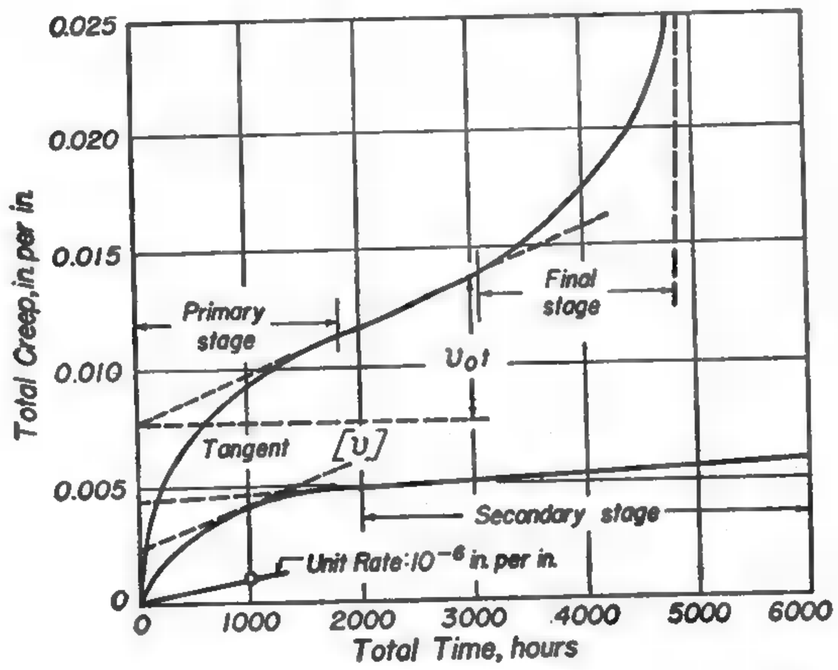

Fig. 1 Typical tensile creep curves obtained under different loadings for two alloy steels

In Fig. 1, the upper curve shows the second stage starting at slightly less than 2000 hr at a total creep of about 1% and terminating slightly beyond 3000 hr at a total creep of about 1.4%, where the rate of straining begins to increase. The lower curve shows no increase of rate up to 5000 hr, and tests are available in which the creep of metal specimens has continued in the second stage for several times this period. During the second stage of tensile creep, the cross-sectional area of the specimen remains sensibly unaltered, and thus the constant-load creep rate is usually reported, for practical purposes, as a constant-stress creep rate.

The third stage of creep is marked by an accelerating creep rate, leading to fracture. Although stress intensification and "necking" of the section contribute to the promotion of third-stage creep, studies of numerous materials have tended to show that this stage is ordinarily reached at deformations much smaller than those sufficient to produce rapid creep to fracture by stress intensification only. Such evidence is considered indicative of marked structural changes which strain, time and temperature produce in metals and alloys.

Creep-Testing Methods and Apparatus. The modifications of apparatus used in obtaining information concerning metals vary widely in form and purpose. Although creep has been studied chiefly under constant tensile load and temperature, numerous arrangements of apparatus have been devised for measurements in torsion, transverse bending, internal pressure, relaxation, variable loading and variable temperature. Ample descriptions of the equipment used for tensile creep testing up to 1931 are given by Tapsell.[1] Since the publication of the Tapsell book, a number of papers describing advances in tensile creep-testing technique have appeared in the publications of ASM, ASTM, AIME and ASME.

The ASTM has set up a recommended practice for creep testing[2] for the guidance of investigators seeking to evaluate the tensile creep characteristics of metals. No attempt has been made in this practice to prescribe a definite method of procedure or to specify apparatus, but rather to point out some of the possibilities, limitations and pitfalls of creep testing. It is recognized that creep investigation is still largely a subject for metallurgical research, and no hard and fast code of rules can be set up which might not prove detrimental to the best interests of progressive research. The tentative method of the ASTM attempts to cover only such fundamental considerations as the amount of extension, the effect of temperature, the tensile stress and the time. The ASTM method recognizes that since the characteristics which render a material resistant to extension under the conditions of test are not yet completely known, the only details of the procedure specified are those known to be important influences, and since others equally important may be discovered in the future, the recommended details of the method are largely advisory in nature.

Considerable latitude of practice is found among various investigators, in regard to the choice of test specimens. The gage lengths in use generally vary from ½ to 20 in., while diameters vary from 0.252 to 0.505 in. Longer gage lengths are preferred for delicacy of measurement where minute creep rates are of interest. For purposes of metallurgical comparison where the order of creep resistance is of primary concern, the 2-in. gage length is ordinarily employed. The use of this gage length not only simplifies the problem of specimen procurement, but also makes it possible to employ more easily constructed furnaces and simpler measurement techniques. Investigations of certain metal products are sometimes performed to advantage in apparatus designed to accommodate specimens in the form of strip, wire or tube.

Determination of the temperature of the specimen during the test is recognized in the ASTM practice as the most important single measurement in connection with creep testing, because small variations in temperature may produce large changes in creep rate. Care must be taken to insure accurate temperature measurement over the gage length of the specimen throughout the test. Reliable temperature measurements must be made at sufficiently frequent intervals to insure an accurate determination of the average test temperature.

It should be noted here that a great part of the creep data to be found in the early literature was obtained under conditions of test not acceptable under the ASTM practice. A confusion of creep values is to be found for certain compositions of steel. Though much of the discrepancy is traceable to differences of heat treatment and other manufacturing variables, a considerable part of the disagreement in the early literature must be attributed to lack of standardized technique and careful control of testing temperature.

Extension measurements are made through a number of devices, such as microscopes focused on targets within the furnace or extension arms extending beyond the furnace and actuating either optical levers or micrometer dial gages. Where total extensions are limited to the same order of magnitude as elastic extensions, it is important to have the elastic portion of the total extension accurately known.

The ASTM practice for creep testing, in recognition of the fact that much information pertinent to the intelligent evaluation of creep information has been lost through inadequate descriptions of materials used, recommends that essential information for identification of the materials tested be collected on a form, which provides not only a most complete description of the material, as to form, composition, and physical properties, but all kinds of grain size information, manufacturing data, and auxiliary test information. The code also adopts a tabular arrangement

for the reporting of the characteristics of the equipment used, intended to reflect the essential qualities of the measurements obtained.

In a carefully prepared preamble to the Joint ASME—ASTM Committee's compilation of available creep data,[3] the factors are summarized which experience indicates must be considered as having a possible influence on the creep characteristics of steels at high temperature. The recognized factors include melting process and practice, heat treatment, chemical composition, grain size, duration of test, number of tests and various other influences.

Significance of Creep. The first studies of industrial importance concerning creep in metals were published about 1922. They dealt with various steels and alloy structural members subjected to high temperatures in furnaces. These experiments served to demonstrate that commercial metallic materials, when used at elevated temperatures, underwent a steady rate of deformation under stresses well within the values allowed by good design practice and "safety factors" at that time.

As the temperatures of industrial processes steadily advanced and it was realized that troublesome deformations and even failure of equipment were being experienced at supposedly safe design stresses, the behavior of metals at elevated temperatures became the subject of critical inquiry. In 1924, realizing the industrial importance of these problems, the ASME and the ASTM established a standing research committee to study the effects of temperature on

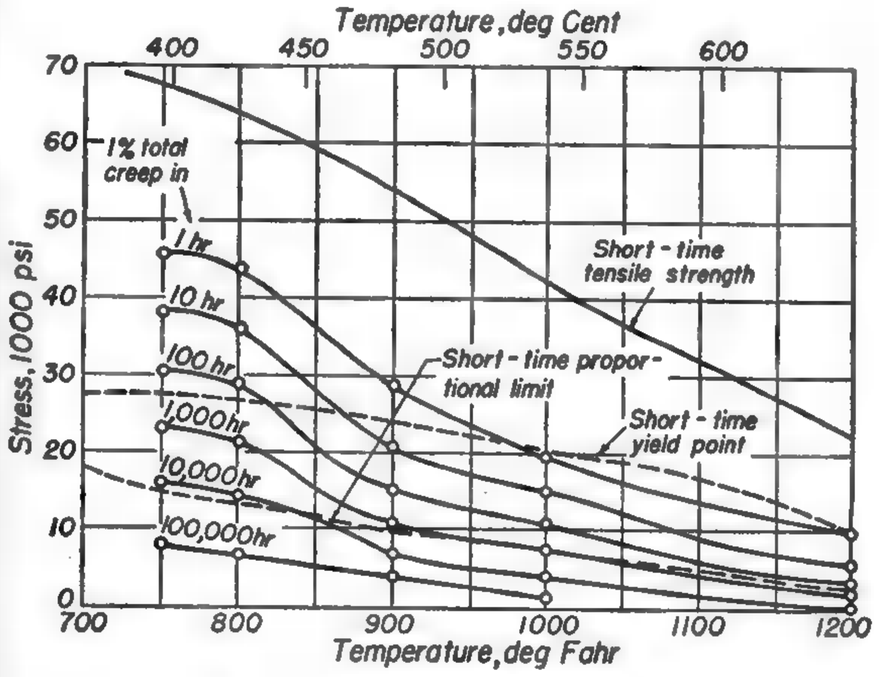

Fig. 2 Creep data for carbon steel

metals. This group has sponsored symposia, numerous reports and technical papers.

At first, it was felt that practical stresses, below which creep either did not take place or was of inconsequential magnitude, could be determined for the various materials at elevated temperatures. Creep investigations made from this point purported to show that proportional limits determined with sufficient delicacy might be regarded as "creep limits". Later investigations, in which refinements of creep measurements had been made, showed that considerable rates of creep could be measured at stresses well below the lowest proportional limits determinable by the most delicate means available. At the higher temperatures an increasing disparity was demonstrated between short-time tension test values and usable creep stress values, as illustrated in Fig. 2 by data for annealed cast carbon steel. It is now a commonly accepted fact that stress values from short-time tension tests are unreliable design criteria for applications at elevated temperature and that values determined by actual long-time creep testing are to be preferred. Although working stresses[4] based on tensile strength "safety factors" are still authoritatively used as bases of design stress for the temperatures at which creep is of inconsequential magnitude, the accepted basis of design for the higher temperatures is the selection of creep stress values.

Creep Strength. The practical aim of creep testing is ordinarily the determination of stress values, at temperatures of interest, upon application of which the amount of deformation occurring is limited to tolerance values over a period of time comparable to the anticipated working life of the member to be designed. Creep stresses, as so defined, are generally based on the rate of creep measured in the second stage and are justified as design values on the assumption that deformation during the useful life of the equipment is largely confined to this approximately uniform rate of creep. For some materials and purposes of application the deformation accumulating in the first stage must be taken into account. Constant-rate creep stress then becomes inapplicable and other values of creep stress are desired, based on the total deformation for the life period. The bulk of available creep stress data, however, have been determined in terms of either the constant creep rate or tangents to the time-deformation curve determined for some time of test chosen arbitrarily. An example of creep stress data for steel at elevated temperature is shown in Fig. 2, wherein a comparison is drawn with short-time values for tensile strength, proportional limit, and yield point.

Acceptability Tests for High Temperature. Since it is impracticable to make a long-time creep test on each heat of steel or heat treatment charge intended for service at high temperatures, considerable thought and study have been given to the development of some method of test which will assure that a particular lot of a given material has creep properties consistent with those dictated by the design requirement to which the material is to be applied. The requirements for such a test are that it can be performed within 24 hr, that it will detect off-color heats of material and that the conditions of reproducibility of test results, and correlation with creep data are such that mutual agreement can be reached between manufacturer and purchaser. Although a number of papers[5] have appeared concerning the development of such tests, it is too early to draw conclusions about the general usefulness of such tests for specification purposes.

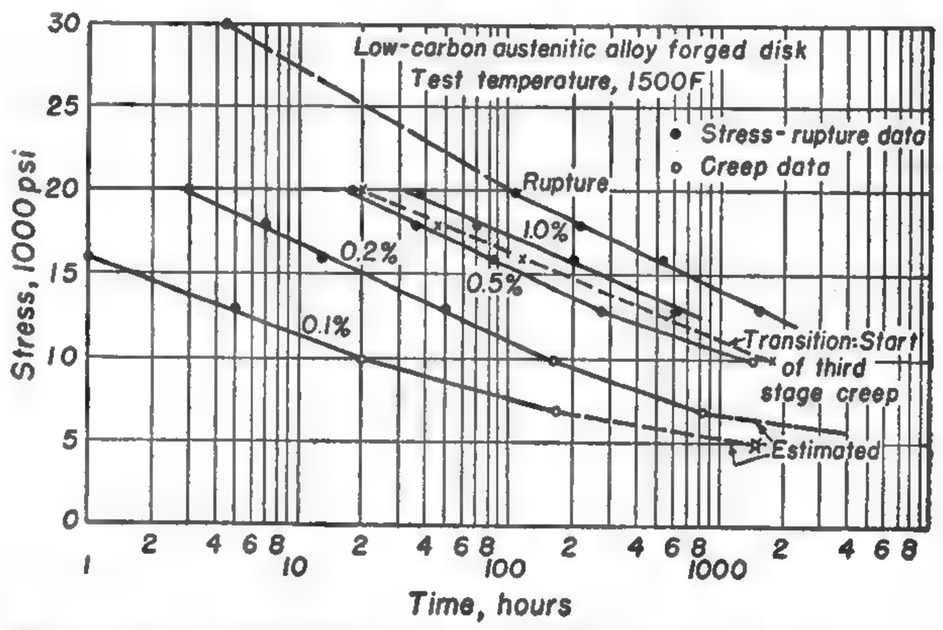

Fig. 3 Curves of stress versus time for indicated total deformations

Stress-Rupture Tests. Some high-temperature applications, such as turbosuperchargers, gas turbines, and jet aircraft engines, require materials to operate under rather extreme conditions of temperature and stress. In these applications the useful life may be of the order of several hundred or a thousand hours. In many of these applications, the permissible deformation is high or may not even be limited, and the only requirement is that rupture must not occur during the life of the part.

For evaluation of materials for this relatively short-time service, stress-rupture rather than long-time creep tests are used. For each temperature of interest, a series of tests is made over a range of stresses selected to cause rupture, over time periods from a few hours to several thousand hours. A log-log plot of the stresses versus the resulting rupture times for the tests usually shows a straight-line relation, except in instances in which surface or structural instability occurs, and in which a break in the straight line is observed. The data from stress-rupture tests are usually reported as the stresses for rupture in 10, 100, and 1000 hr, accompanied by the elongation measured at rupture.

In some instances, time-deformation characteristics are

not measured in stress-rupture tests, but these data may be obtained and, combined with creep test data, have been used to prepare design curves in which the relation between stress and time for certain total amounts of deformation ranging from 0.1 to as much as 5%, and the stress-rupture time curve are included on a single plot, shown in Fig 3. These design curves are very valuable to engineers for designing equipment for short life under extreme conditions when expected service life, temperature of operation, and permissible deformation are known.

Fatigue Tests

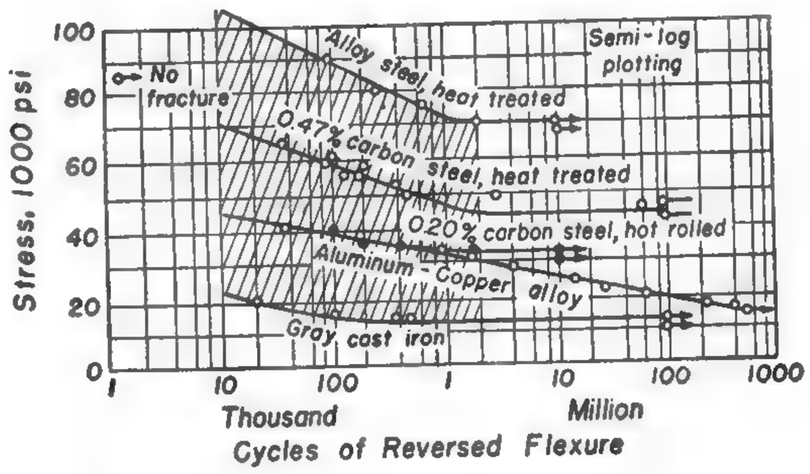
By H. F. Moore*

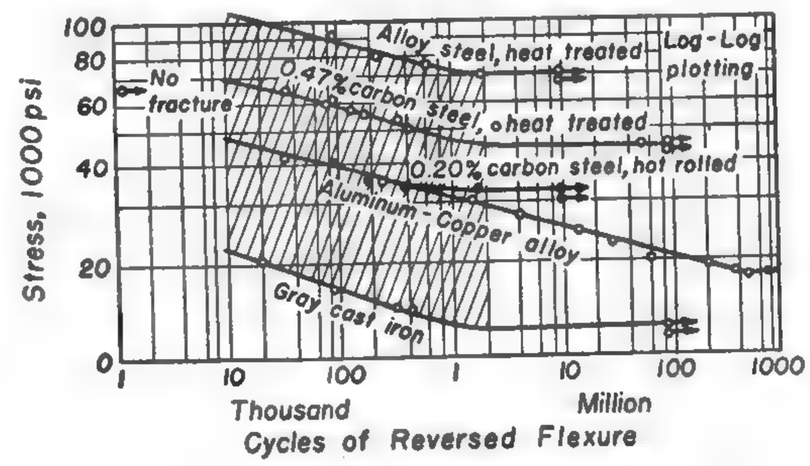
THE purpose of fatigue tests is to determine the resistance of a metal, or of a structural or machine part, to cycles of repeated stress. Metals are not perfectly homogeneous, but consist of crystals with planes of cleavage or slip oriented in many directions. When sufficient stress has been applied, slipping occurs on planes within the individual crystalline grains. At first this slipping may not be sufficient to cause harm. However, under ranges of stress sufficient to produce slip, continued repeated slipping, if sufficient in magnitude, causes minute cracks to form and to spread, gradually reducing the area of sound metal remaining in any cross section. One of the unsolved problems in the fatigue of metals is the exact determination of when and how, under repeated stress, harmless slip changes into harmful slip, causing the formation of a destructive, spreading fatigue crack. The end of such a crack is a minute area of highly localized stress, so there is a strong tendency for the crack to grow. The final fracture occurs with very little distortion or reduction of cross-sectional area. Formerly, the jagged appearance of the final fracture led to the natural but erroneous conclusion that the metal had "crystallized". It has now been determined that fatigue fractures start in the natural cleavage surfaces of the crystalline grains of a metal, or along crystal boundaries. Accordingly, the fracture has a "crystalline" appearance, but this appearance is the result of the fracture rather than the cause. The primary causes for failure of machine parts under repeated loads can often be ascertained by study of the fractures of the parts.

General Method of Procedure in Fatigue Tests. The method commonly used in fatigue tests consists in submitting specimens or entire structural or machine parts, to cycles of a known range of load of various magnitudes, and noting the number of cycles required for fracture, or for the attainment of a given specified "life" without fracture. The results of the test are plotted on a diagram (called the S-N diagram) in which maximum load or stress is plotted as ordinate, and the number of cycles for fracture as abscissa. The range of stress, or the ratio of minimum stress to maximum stress during a cycle, is stated. It should be noted that, for a cycle of partially or wholly reversed stress, the value is negative. The nature of the maximum stress should also be stated, whether tension, compression or shear.

In the United States, the stresses (or loads) are usually plotted to ordinary (Cartesian) co-ordinates, and the number of cycles of stress for fracture are plotted as abscissas to logarithmic co-ordinates. Cartesian co-ordinates for both ordinates and abscissas are sometimes used, and logarithmic co-ordinates for both ordinates and abscissas are frequently used, especially when it is not considered necessary to test for "life" beyond one or two million cycles. Which system to employ depends largely on convenience.

Figure 1 shows a typical set of S-N diagrams. The "endurance limit" of any metal is defined as the limiting stress below which the metal will withstand an indefinitely large number of cycles of stress without fracture. If the S-N curve becomes horizontal, the stress corresponding to the horizontal part of the curve is called the "endurance limit". If, however, the curve does not become horizontal, the term "endurance limit" is often applied to the stress





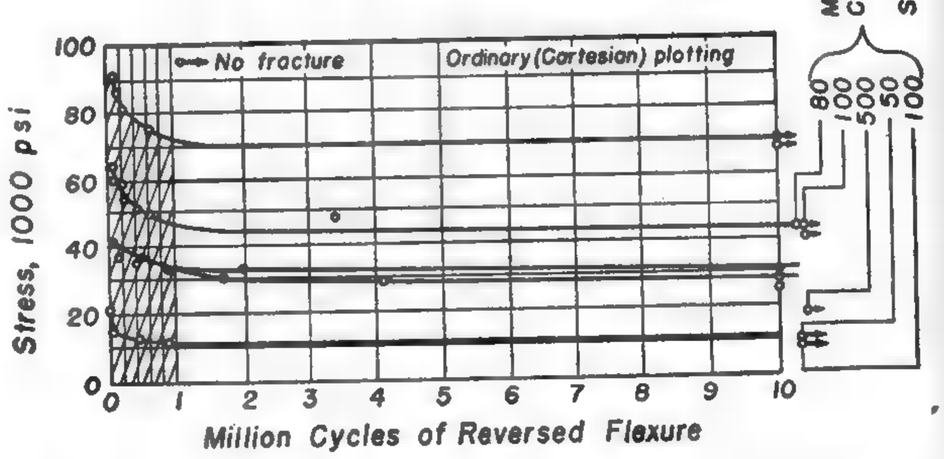


Fig. 1 Typical S-N (stress-cycle) diagrams for fatigue tests

corresponding to some specific number of cycles.* Table I presents data that are plotted in Fig. 1.

Apparatus for Fatigue Tests. Following are the essential parts of a fatigue-testing machine: (1) a drive for applying repeated cycles of stress to the specimen, (2) a means of measuring the maximum and minimum stresses applied during a cycle, (3) a counter for indicating the number of cycles of stress applied to the specimen, and

* Research Professor of Engineering Materials, Emeritus, University of Illinois, Urbana, Ill.

In this edition the articles on "Fatigue Testing" and on "Corrosion-Fatigue of Metals" have been combined. Several paragraphs in this article were written by R. L. Templin for the 1939 edition.

* In such instances, the number of cycles should be stated.

(4) a device for stopping the testing machine automatically when a specimen breaks.[1,2,3]

Figure 2 presents, in diagram, several types of fatigue-testing machines in common use. In all the machines shown, power is supplied by direct motor drive or by belt drive. When a specimen breaks in any of the machines shown here or when there is a marked increase in deflection or stretch, a latch is released, opening the motor circuit and stopping the machine. All the machines shown in Fig. ■ are fitted with revolution counters (not shown in every sketch) to indicate the number of cycles of stress.

Table I. Values of Endurance Limits for Different Numbers of Cycles of Reversed Bending Stresses for Five Alloys

Number of Cycles of Stress	Endurance Limit, 1000 psi: Cr-Mo Steel (heat treated)	Carbon Steel (0.47% C) (heat treated)	Carbon Steel (0.20% C) (as rolled)	Aluminum Alloy 24 S-T (age hardened)	Cast Iron, (tensile strength 31,600 psi)

(a) S-N curve horizontal

Figure 2*a* shows a rotating-beam machine, the most widely used type of fatigue-testing machine, known as the "R. R. Moore type". The specimen *S* is held in tapered chucks that are rotated by belt drive or by a directly connected motor. Two symmetrically placed loads are applied —one at *A*, the other at *B*—by the known weights *W* hung from an equalizer bar. As the specimen rotates, the weights set up cycles of completely reversed bending stress, and over the length *m* there is a uniform bending moment equal to $Wa/2$. The machine is equipped with ball bearings to minimize torsional stress caused by friction of bearings. The stress is computed by the common flexure formula.

Figure 2*b* shows a rotating cantilever-beam fatigue machine, a widely used type similar in principal to the rotating-beam machine shown in Fig. 2*a*. The weight *W* sets up cycles of reversed bending moment Wl at the critical section of the specimen. Rotating-beam machines for small specimens have been operated at speeds as great as 12,000 cycles of reversed stress per minute.

The machines shown in Fig. 2*a* and 2*b* are very simple and, if reasonably free from vibration, set up accurately measured stresses in round specimens. However, rotating-beam machines cannot easily be used for tests under any stress cycle other than complete reversal of stress. Such machines cannot be used to study the effects of surface conditions on the material from which the specimen is prepared, because the reduced portion of the specimen is machined below the original surface. For other than round specimens, rotating-beam machines can be used only at very slow speeds, because of the vibrations set up as a noncircular specimen revolves at a high speed.

Figures 2*c* and 2*d* show a vibratory fatigue machine. The specimen *S* is held in the jaws *J*, which can be moved up and down by screw *Q* to set up cycles of stress with various ratios of minimum to maximum stress. For partially or wholly reversed stress, the ratio of minimum to maximum stress in a cycle is negative. The magnitude of deflection of the specimen controls the total range of stress in a cycle and is determined by the adjustment of the variable-throw crank and connecting-rod *C*.

When the jaws are in any position that causes the deflection of the specimen to be greater in one direction than in the other, the stress cycle on the lower side of the specimen is not the same as on the top, although the total range of stress is the same. Under these circumstances, failure generally starts at the side that has the higher tension and the stresses on that side are the ones considered. Failure may start on the compression side in specimens that have unsymmetrical cross sections and in specimens that are under repeated direct axial stress; probably such failures start as shearing failures.

To determine the setup to produce a certain cycle of stress, the specimen itself is used as a dynamometer. The amount of force is computed that will be required for the desired maximum stress; the connecting rod is swung to one side, as shown in Fig. 2*d*; the required load is applied by weights *W*; and the deflection at some point along the length of the specimen is measured by the micrometer dial gage *D*. Then sufficient load is applied in the opposite direction by weights and a lever, to produce the desired minimum stress; the dial gage is read; and the connecting rod is attached to the specimen. The throw of the crank is adjusted by trial in order to give the desired total range of stress, and the vertical position of the jaws *J* is adjusted by the screw *Q*, until the desired ratio of minimum to maximum stress is indicated by the readings of the dial gage *D*, as the machine is turned over by hand.

At high speeds, corrections for inertial forces may be necessary. For making such corrections, the extreme dial reading should be noted while the machine is running;

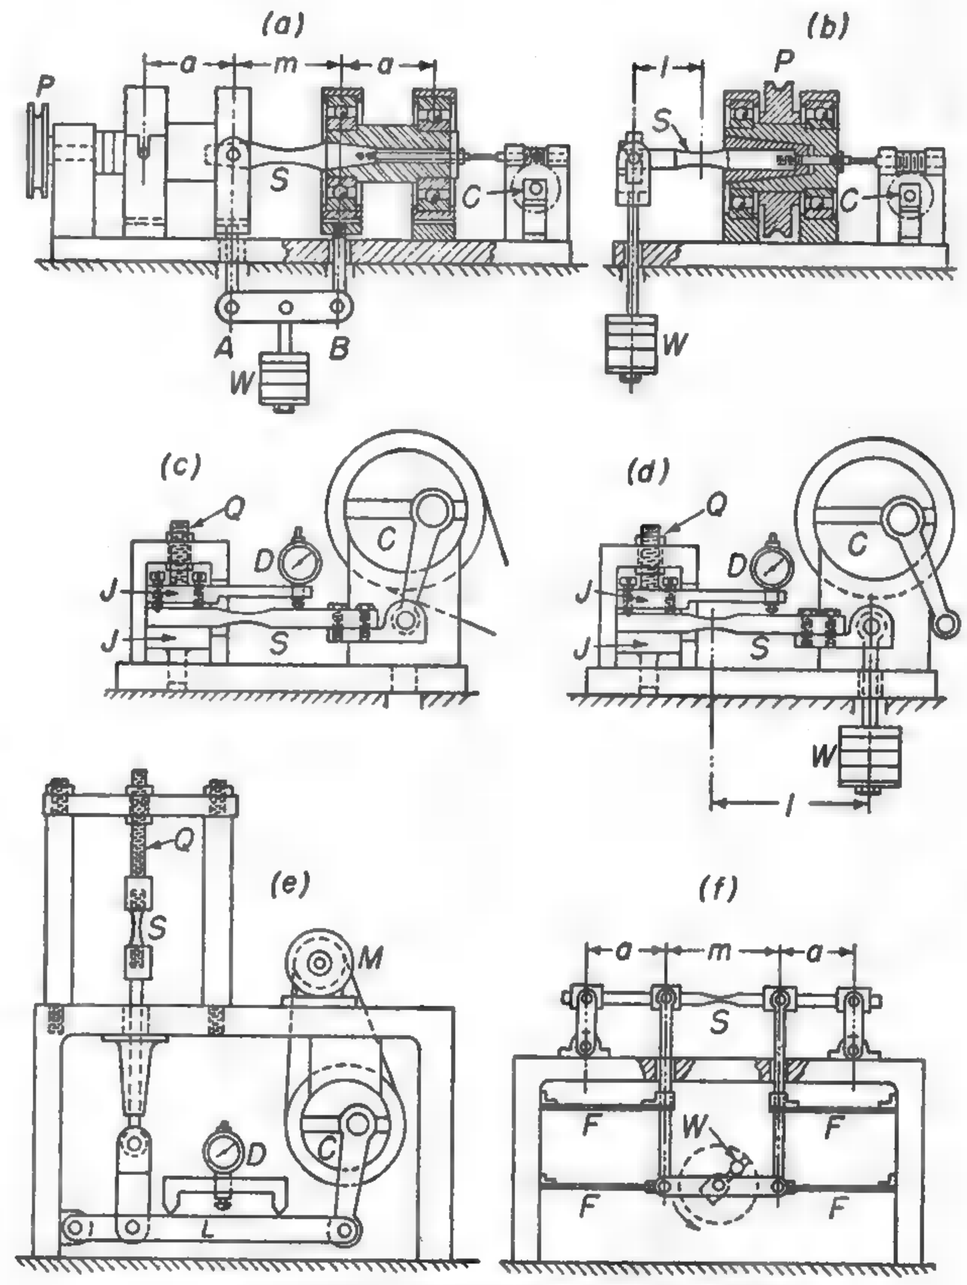

Fig. 2 Typical machines for fatigue testing

the plunger of the dial should be moved until it just touches the specimen at one extreme of its vibration. This reading is compared with the corresponding extreme reading when the machine is turned over by hand, and the change in force resulting from inertia can be estimated.

The vibratory type of fatigue-testing machine can be used for testing specimens with one surface in the condition that the surface of the metal will have in the machine or structural part. For example, a vibratory fatigue machine can be used to study the relative effect of rolled and polished surfaces on a structural part.

The plunger point of the dial gage *D* must be held out of contact with the specimen while the machine is running. In some machines, the force is measured by the deflection of a steel spring, attached to the specimen at one end and held in the jaws *J* at the other end.

Figure 2*e* shows a tension-compression (push-pull) fatigue-testing machine. The specimen *S* is pushed and pulled by means of the lever *L*, which is vibrated by the variable-throw crank and connecting-rod *C*. The maximum and minimum loads in a cycle of stress are measured by the deflection of the lever *L*, which is calibrated for deflection, and the deflection is indicated by the micrometer dial gage *D*. In some machines of this type, the load is measured by the deflection of an elastic ring attached directly to the specimen. The desired range of stress is obtained in a manner similar to that used for the vibratory machine shown in Fig. 2*c*, by adjusting the throw of the crank *C* and adjusting the position of the specimen by means of the screw *Q*. Under high speeds, inertial forces may be estimated, as for the machine shown in Fig. 2*c*.

Figure 2*f* shows a vibratory machine in which the vibrating force is supplied by means of the centrifugal force of a rotating weight *W*. If the weight *W*, the radius at which it rotates, and the speed of rotation are known, the force causing reverse flexure can be computed. As shown, the machine would set up cycles of completely reversed stress; but the steady force of a spring may be added to that of the centrifugal force of the rotating weight, and any desired ratio of minimum to maximum stress may be obtained during a cycle.

Alternating-current magnets have been used to set up cycles of repeated stress in a specimen. With magnetic excitation of cycles of stress, it is usually convenient, especially in large machines, to adjust the frequency of the exciting current, or the natural period of vibration of specimen and clamps, so that a condition of resonance is set up. During a fatigue test, the natural period of vibration will probably change slightly, and some system of control, usually electronic, is necessary in order to change frequency of current or to move weights to change the natural period of vibration so that resonance will be maintained up to the final stage of fracture of the specimen. A large fatigue-testing machine built by the Goodyear-Zeppelin Corp. is described in NACA Technical Note 637.

Fatigue-testing machines for cycles of repeated torsion, ordinarily operate by using a variable-throw crank and connecting-rod, in a manner similar to the crank–connecting-rod arrangement shown in Fig. 2*c*. Usually the maximum and minimum torsional moments that are set up are measured by the twist of a calibrated steel bar attached directly to one end of the specimen.

Test Specimens. Test specimens for fatigue tests may be classified in various ways. For this article it seems convenient to divide them into two classes: (1) specimens designed so as to avoid sudden changes of form known as "stress raisers", that is, sharp fillets, notches, keyways, screw threads, holes and the like, which set up high localized stresses; (2) specimens in which definite "stress raisers" are formed. The results of tests on specimens that have no stress raisers, give a measure of the fatigue strength of a metal under very favorable conditions; such data indicate the maximum fatigue strength that can be developed in a metal. The specimens with stress raisers are used (generally in connection with specimens that have none) to determine the sensitivity of a specimen to stress raisers. "Notch sensitivity" is the term frequently used. Sometimes stress raisers cannot be avoided in a machine part, and in some instances a metal of moderate strength (as shown by tests of "unnotched" specimens) but with a low notch sensitivity may serve better than a metal of higher "unnotched" fatigue strength and high sensitivity to stress raisers.

Figure 3 shows typical specimens for fatigue tests. Figure 3*a* shows the specimen commonly used for the rotating-beam machine of Fig. 2*a*. This is known as the "R. R. Moore type" of specimen. Figure 3*b* shows a notched specimen for use in the R. R. Moore type of machine in Fig. 2*a*.

Figure 3*c* shows an unnotched specimen for a rotating-cantilever fatigue machine like that in Fig. 2*b*, and Fig. 3*d* shows a notched specimen. Figure 3*e* shows a specimen for vibratory bending tests of sheet metal. Figure 3*f* shows a similar specimen in which a small hole acts as a stress raiser, for tests to determine notch sensitivity. Figure 3*g* shows one form of specimen for vibratory fatigue tests of plate metal or flats, and Fig. 3*h* shows another form; Fig. 3*i* shows a specimen for a vibratory bending test in which one surface (the top) is the as-rolled or the as-cast surface of the metal; Fig. 3*j* shows a specimen for direct tension-compression (push-pull) tests.

So that fatigue tests will develop the minimum variation in fatigue strength as a result of surface conditions, the surface of the specimen in the reduced section should be polished in a direction as nearly longitudinal (axial) as is feasible.[4]

The specimens shown in Fig. 3 are typical, but many other forms are in use. Wherever feasible, it is desirable to test actual parts. Many small parts, made in large quantities, can be tested easily in this way. Extensive

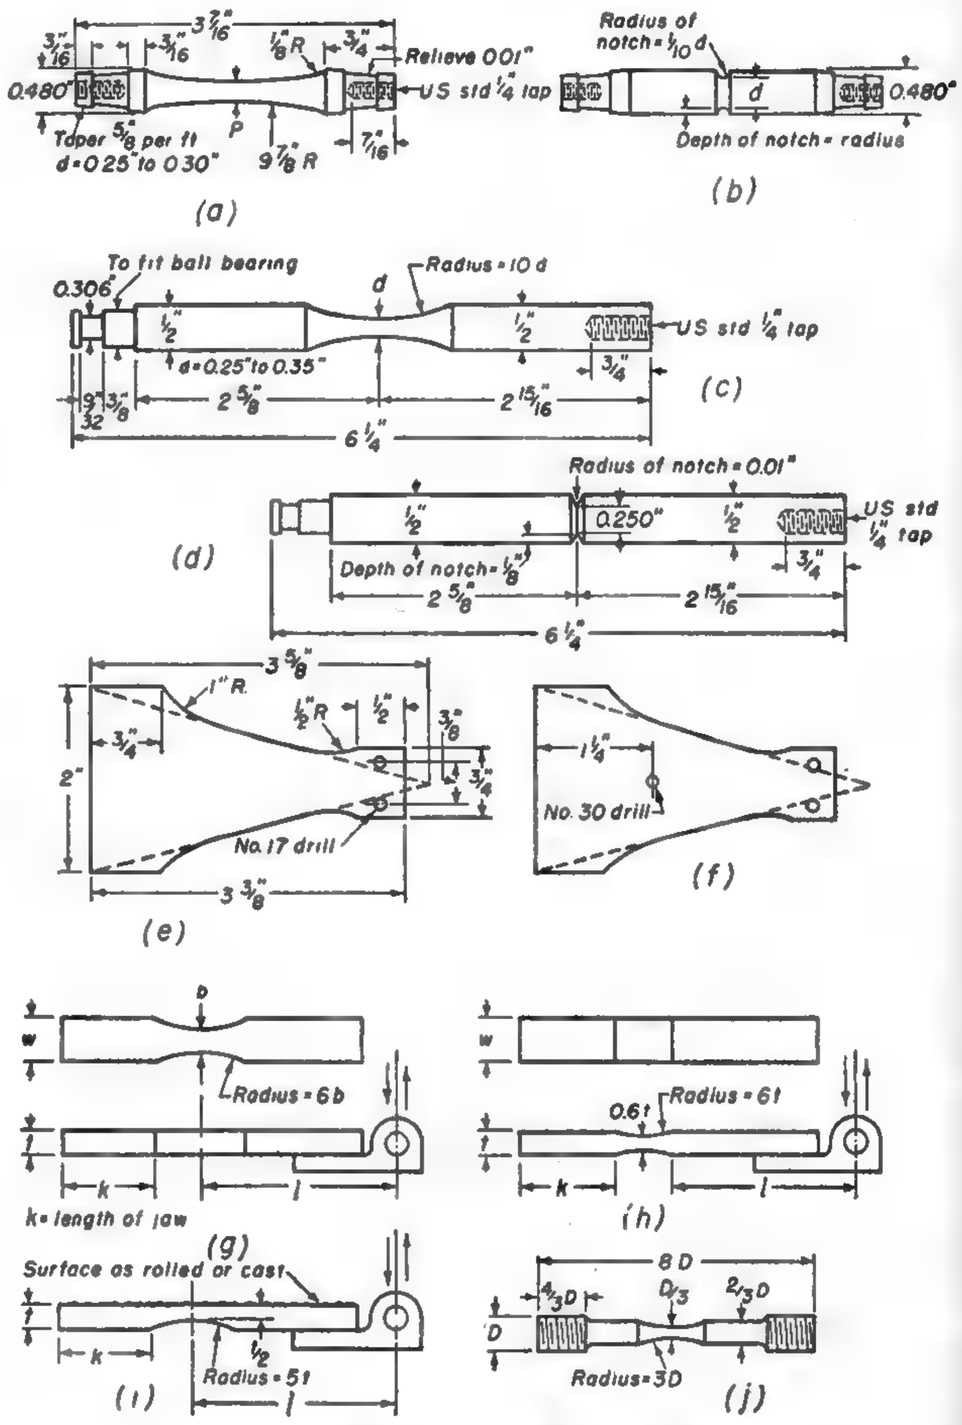

Fig. 3 Typical specimens for fatigue testing

The specimens shown in (*a*), (*b*), (*c*) and (*d*) are small specimens to be used in rotating-beam fatigue-testing machines (including rotating-cantilever beam machines). The specimen shown in (*a*) is used in the R. R. Moore type of rotating-beam fatigue-testing machine. The specimens shown in (*e*) and (*f*) are used for vibratory tests of sheet metal in the Krouse vibratory fatigue machine. The specimens shown in (*g*), (*h*) and (*i*) are for fatigue tests of plate, shape or bar material in vibratory machines. Since width and thickness will vary widely for different tests and for different testing machines, only general proportions are shown. Over-all length is not stated, because this will depend on the particular testing machine used, and on the size of stock available. The specimen in (*j*) shows general proportions for a tension-compression fatigue specimen. No standard sizes of fatigue specimen have been adopted; therefore, the specimens shown in this figure are to be considered suggestive forms rather than definite standards.

series of full-size fatigue tests have been made on springs, small shafts, bolts, and riveted, bolted and welded joints.

Number of Test Specimens Necessary for S-N Diagram. If the metal tested is of uniform quality throughout, a satisfactory S-N diagram *for one set of conditions* can usually be drawn from the test results for ▮ to 12 specimens. These specimens are tested under different maximum stresses, beginning with a maximum stress considerably higher than the estimated endurance limit for the maximum number of cycles to be used. Then each successive specimen is subjected to a stress smaller than that

applied to the previous specimen, until at least one specimen "runs out" without fracture at the maximum number of cycles required. The results for these tests are then plotted, and if the resulting S-N diagram shows only a small amount of "scatter" of results from an average line drawn to fit the plotted points, the test is regarded as complete. If there is considerable scatter, more specimens of the material in question are machined and tested. Then an S-N diagram is drawn to fit the test results.

If the maximum number of cycles prescribed is more than 100,000,000, more specimens will usually be required. If the purpose of the tests is not to determine the S-N diagram for the metal, but to determine the fatigue strength of machine or structural parts by tests of the parts themselves, the number of specimens required will depend on the purpose of the test. When tests are to be made under several different conditions, the number of specimens is, of course, increased. For example, it may be desired to study: (1) the fatigue strength of a metal under completely reversed bending, using unnotched and polished specimens, (2) the fatigue strength of notched specimens under reversed bending and (3) the fatigue strength of notched and of unnotched specimens under partly reversed bending, and under bending varying from zero to a maximum (one-way cycle of stress). For the tests of the unnotched specimens in reversed bending, from 6 to 12 specimens would be required. Tests of notched specimens (using only one type of notch) would increase the number to between 12 and 24. Tests of unnotched and of notched specimens under three different cycles of stress, would increase the total to between 36 and 72. If a thorough fatigue study of a metal were to be made, including all the above variables and others, such as specimens of several sizes, specimens with different notches or with holes or fillets, reversed and one-way fatigue tests in torsion, investigation of effects of surface condition, and corrosion-fatigue tests—if all these conditions were studied, the number of specimens required would be in the hundreds. The mechanical condition of the fatigue machine is important in obtaining consistent results.

Frequently, in tests of railroad rails and of structural parts, it is desired to know the resistance to a relatively few cycles of stress, for example, 100,000 cycles. In such instances it is not necessary to continue tests long enough to determine the endurance limit for indefinitely long life.[2] Tests that require up to 1,000,000 cycles of stress would give an allowance for length of endurance beyond the probable wide scatter of length of endurance for life under a given cycle of repeated stress. Under such circumstances, it is usually convenient to plot results on log-log paper since, above the endurance limit for indefinitely long life, the S-N diagram, plotted to log-log co-ordinates, is nearly a straight line ordinarily, and three or four points along this straight-line part of the S-N diagram locate the curve fairly accurately, even though the points do not indicate the stress at which this sloped line will change rather abruptly to a horizontal line.

Notes on the Use of Data From Fatigue Tests. When data concerning endurance limit are used, the number of cycles of stress employed as a basis for determining this value should be considered and stated in any report of results. For steel and iron, an endurance limit based on 10,000,000 cycles of stress is common. For nonferrous alloys, this number is usually higher, and for some of the light alloys 500,000,000 cycles is sometimes specified.

For many applications where repeated stress may occur, it is not necessary to determine the endurance limit for indefinitely long life. Instead it is more important to know the probable fatigue life at definite stresses above the endurance limit for indefinitely long life. However, in estimating the probable fatigue life of a part, it must be remembered that a slight decrease in stress causes a large increase in fatigue life, as measured by the number of cycles of stress for fracture. An examination of the S-N diagrams in Fig. 1, especially the shaded areas, will show this fact plainly. A "factor of safety" of two, for instance, on the basis of stress for a given fatigue life, would correspond to a "factor of uncertainty" of 10 to 20 on the basis of probable life for a given stress.[5] For example, if the estimated number of cycles of stress in a satisfactory life of a bridge member is 25,000, it would be unnecessary to determine the stress for an indefinitely large number of cycles; but it would be wise to determine the stress on the basis of a fatigue life of 250,000 cycles. As in most problems of design, the engineer must use sound judgment in applying the results of fatigue tests.

Because of the time and expense involved in making fatigue tests, various attempts have been made to devise accelerated fatigue tests; however, such tests frequently give misleading results. Regular long-time fatigue tests still seem necessary. No precise correlation has been found between fatigue strength and any other mechanical property; but probably yield strength, tensile strength and some type of ductility all have some effect on fatigue strength. Perhaps the closest relationship for the common structural metals is that between endurance limit and tensile strength.[1,4] The ratio between these two properties is called the *endurance ratio* and is sometimes reported.

The structure of a metal appears to have a definite effect on the resistance to repeated stress, but so far it has not been possible to express this effect in precise quantitative terms. Although relatively pure metals usually have lower endurance limits and lower tensile strength than alloys, their endurance *ratios* are frequently higher, perhaps because of greater uniformity in structure. The endurance ratio is higher also for annealed metal than for cold worked or for quenched metal. The greater ductility of annealed metal apparently aids in relieving any stress concentrations that may be present, possibly because annealed metal has very little residual strain, if any. Cold working by rolling, drawing, shot peening or other means, increases the yield strength of a metal considerably,[3,5] increases the tensile strength to a lower degree, and increases the endurance limit to a still lower degree. It is therefore apparent that the endurance ratio will vary with the amount of cold work. Superficial cold rolling or shot peening may be used to set up compressive stresses near the surface, which strengthen the metal against fracture by subsequent tensile stresses applied in service. Apparently there is an optimum degree of surface working above which the fatigue strength is decreased.

Since fatigue failure is far more likely to occur in a region of tensile stress than in a region of compressive stress, any residual tensile strain caused during heat treatment may seriously harm the fatigue strength. Under such circumstances, stress-relieving may be beneficial.

Effect of Range of Stress.[1,4,6] Most fatigue tests use cycles of completely reversed stress. From many results of tests made under cycles of tensile (or compressive) stress repeated but not reversed (one-way stress), and under cycles of tensile-compressive stress partially reversed, the following empirical formula has been found fairly reliable:[1,4]

$$S_{max} = S_e \left(\frac{3}{2 - r}\right),$$

in which r denotes the ratio of minimum stress to maximum stress during a cycle (r is negative for completely or partially reversed stress); S_{max} denotes the endurance limit for any given number of cycles of stress; and S_e denotes the endurance limit for the same number of cycles of completely reversed stress.* The direction (tensile or compressive) of maximum stress should be stated.*

For example, if the cycle of stress to which a part is repeatedly subjected ranges from a tensile stress to a compressive stress half as great ($r = -\frac{1}{2}$), and if the fatigue

* For aluminum alloys, the formula

$$S_{max} = S_e \left(\frac{2.25}{1.25 - r}\right)$$

agrees more closely with the results of fatigue tests.

* In another system of nomenclature, sometimes used, any given cycle of stress is considered to be made up of two components: (1) a constant mean stress, which is the algebraic average of maximum and minimum stress for a cycle (for example, this mean stress is zero for a cycle of completely reversed stress); and (2) a completely reversed stress equal to $\pm$ (maximum stress during a cycle − mean stress). Some recent writers define the endurance limit as the reversed stress component only, instead of defining it as the maximum stress during the cycle, as is done in this article. The two systems of nomenclature can be readily translated; see reference 1 (second item) and reference 6.

strength of the metal under completely reversed stress is 40,000 psi, then

$$S_{max} = 40{,}000 \left(\frac{3}{2-(-\frac{1}{2})}\right) = 40{,}000 \left(\frac{3}{2.5}\right) = 48{,}000 \text{ psi}$$

Under a cycle of stress varying from minimum tensile stress to maximum tensile stress four times as great as the minimum ($r = +\frac{1}{4}$).

$$S_{max} = 40{,}000 \left(\frac{3}{2-\frac{1}{4}}\right) = 40{,}000 \left(\frac{3}{1.75}\right) = 68{,}600 \text{ psi}$$

However, if this stress is greater than the yield strength of the metal, this result could not be used in design, because failure by yielding would probably take place before the stress of 68,600 psi was developed.

For various cycles of shearing stress, an empirical formula has also been developed.

$$S'_{max} = S'_e \left(\frac{2}{1-r}\right)$$

The symbols are similar to those given in the preceding formula. S'_{max} denotes the maximum *shearing stress* during a cycle (and also the maximum tensile stress under torsion). S'_e denotes the endurance limit for cycles of shearing stress completely reversed, and r denotes the algebraic ratio of minimum shearing stress to maximum.

Effect of Size of Specimen (or Part) on Fatigue Strength.[7] Tests at the University of Illinois showed endurance limits for steel specimens 1 in. in diam, which were about 20% lower than endurance limits for specimens of the same steel only ¼ in. in diam. Tests were made on 0.20% C steel, as rolled; on 0.35% C steel, as rolled; on 0.35% C steel, annealed; and on heat treated chromium-molybdenum steel. Tests at the Timken Laboratories showed very low endurance limits for steel specimens 6 or 7 in. in diam, but it is not certain whether these low values were caused by the size of the specimen or by the presence of defects in the steel. Fairly large defects are more likely to be present near a critical section in a large bar of steel than in a small bar.

Fatigue Tests at Low and Elevated Temperatures. A few test results have been reported for steels subjected to repeated stresses at low temperatures and, in general, these tests indicate that metals have higher endurance limits at temperatures below normal room temperature.

A considerably larger number of fatigue tests have been made at elevated temperatures. Earlier results were on carbon steels and stainless steels at temperatures as high as 1200 F, using a spring-loaded cantilever type of test machine. More recently, in studies of heat-resisting alloys for turbosuperchargers and gas turbine service, tests have been made at temperatures as high as 1500 F, using both fixed and rotating specimens of the cantilever type that gives completely reversed bending, in direct-stress test machines in which the stress was varied plus and minus from a mean tensile stress.

For plain carbon steel at temperatures above 1000 F, and for 18 Cr–8 Ni steel at 1200 F, the fatigue strength is higher than the stress that produces an appreciable rate of creep, and it is indicated that creep strength will be the controlling factor in design.

For the gas turbine alloys studied at 1200 F, the forged alloys had higher fatigue strength than the cast alloys, but in tests at 1500 F, the cast alloys surpassed the forged alloys in fatigue strength. Both at 1200, 1350 and 1500 F, the stronger alloys that were studied showed fatigue strength in excess of the steady tension stresses that will produce rupture in 1000 hr.

Effect of Overloading and Underloading on Fatigue Strength.[1,2,4] Occasional overloading of a specimen or of a structural or machine part may actually weaken the metal, if the overloading is repeated enough times. The application of repeated stresses above the endurance limit of the virgin metal does not always lower the endurance limit. The effect depends on the number of cycles applied in this overload stress. H. J. French and later investigators have recorded the existence of a "damage line", which may be defined as a line in the S-N diagram, separating the region containing conditions of stress and number of cycles that cause a lowering of the endurance limit from the region containing conditions under which no damage is done. Figure 4 shows an S-N diagram for which such a damage line has been determined by fatigue tests to fracture of many specimens that were subjected to various combinations of magnitude of stress and number of cycles of stress, applied before making the final test to destruction.

Understressing consists in subjecting a metal to a safe range of stress for many cycles of stress, before the metal is subjected to a fatigue test to fracture. This treatment sometimes increases the endurance limit of the metal,[1,4] in some instances as much as 25%.

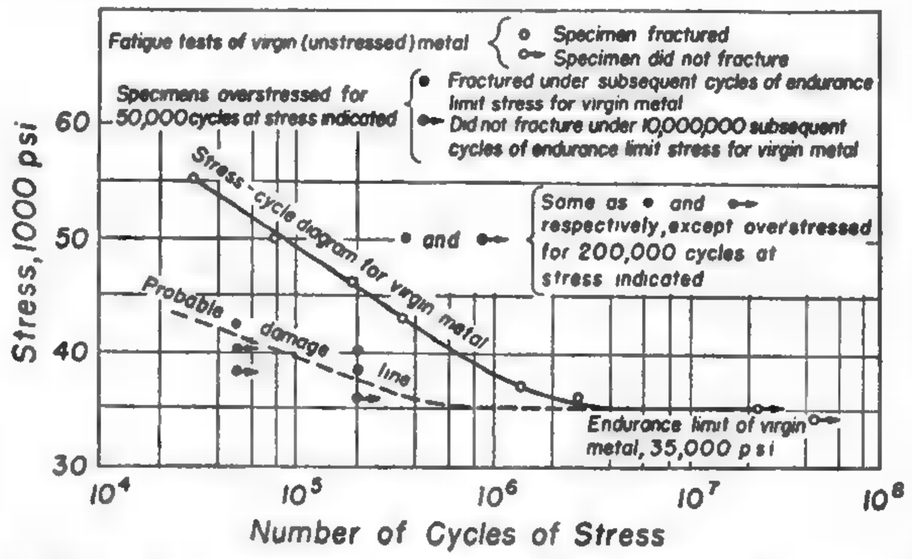

Fig. 4 Determination of "damage line" for a metal subjected to repeated stress.

The damage line is drawn *below* the results for overstressed specimens that failed under 10,000,000 subsequent cycles of stress equal to the endurance limit for virgin metal (35,000 psi), and is drawn *above* the results for overstressed specimens that did not fail. In actual determination of a damage line, many more overstressed specimens would be tested than the six specimens shown in this figure.

Effect of Corrosion on Fatigue Strength.[3,9] *Stressless Corrosion.* Many liquids and gases have a corrosive effect on most metals. The corrosion takes the form of a film, often only a few molecules thick yet able, in some instances, to give the metal beneath it a high degree of protection against further corrosion; also, the film on the metal usually has the power of self-healing, if cracked. Thicker films, which are characteristic of some metals under the action of a mild corrosive medium, usually lack this power of self-healing, and offer far less protection against the spread of corrosion, especially if the metal is being subjected to repeated stress, causing repeated strain on the film. Even when films do not stop the progress of corrosion, they influence the manner in which it proceeds, tending to localize attack at regions under cracks caused in the film by strain. This localized attack tends to produce pits in the metal, and to lower the resistance of the metal to stress, because of the intensification of stress that occurs at any notch or small hole in the metal. Oxide films are the most common on corroded metal, but phosphate and silicate films are sometimes found.

If an unstressed metal is exposed to corrosive agents or if, after being stressed, it is subjected to corrosive agents while the stress remains unchanged, the metal is said to be subjected to "static-stress corrosion", with a slight reduction in resistance to further damage under steady load, and a more serious reduction in resistance to cycles of repeated load. R. R. Moore's experiments on SAE 1045 steel that was corroded by a salt spray, without applied stress, showed an endurance limit 22% lower than the endurance limit of the same steel uncorroded. His experiments on duraluminum indicated approximately 35% reduction in endurance limit after static-stress corrosion.

Simultaneous Corrosion and Repeated Stress. *Corrosion Fatigue.* If a metal is subjected to a corrosive agent and at the same time is subjected to cycles of repeated stress, the protective film may be broken repeatedly. In steel, corrosion spreads through these cracks and forms relatively deep pits that act as stress raisers and greatly

reduce the fatigue strength of the metal. Almost all the common metals of construction are subjected to this action known as "corrosion fatigue".

In 1925 D. J. McAdam, Jr. began an extensive experimental study of corrosion fatigue. Even under pure water, the endurance limit may be reduced far below the limit recorded in air. In fact, no definite limit for endurance limit has been found for indefinitely long life under corrosion fatigue. In reporting the results in corrosion-fatigue tests, it is important to state the limiting number of cycles used in the test, and also the frequency of cycles of stress. In noncorrosion-fatigue tests, within wide limits, the frequency of cycles of stress is of very minor importance. In corrosion-fatigue tests under a low frequency of cycles of stress a longer time elapses for the corrosive action to accomplish its destructive work than in corrosion-fatigue tests run at high frequencies of cycles of stress; and the endurance, measured by number of cycles of stress, is consequently lower. Except in stainless steels, the endurance limit of alloy steels under corrosion fatigue (based on 10,000,000 to 100,000,000 cycles of stress) was found to be little, if any, above the corrosion-fatigue endurance limit for ordinary low-carbon and medium-carbon steels. The stainless steels were found to resist corrosion fatigue distinctly better than either plain carbon steels or other heat treated alloy steels.

In nonferrous metals, the effect of corrosion fatigue is so varied that no general statement can be made.

McAdam used two terms to express the amount of damage done by corrosion fatigue: "total damage", meaning the percentage reduction from the endurance limit in air, and "net damage", meaning the percentage reduction from the endurance limit of metal subjected to some definite period of "stressless" corrosion to the endurance limit of specimens that have been subjected to some definite routine of corrosion fatigue. From McAdam's data the following tentative relation is given between stress range and average rate of net damage: $R = CS^n$. In this equation, R denotes the rate of net damage in percentage per day, S denotes the range of stress in pounds per square inch during a cycle, and C and n are experimental constants. C is probably approximately proportional to the frequency for low frequencies, and nearly independent of frequency for high frequencies. Values of n vary from 2.6 to 5.7, as determined by Gough from McAdam's data.[9]

Interpretation of Fatigue Results. Several engineers have pointed out that the results of ordinary fatigue tests for small polished specimens, cannot be used directly, without modification, as a basis for the design of structural and machine parts that must be subjected to repeated stress.[10] This criticism is justifiable and where large numbers of small parts are produced, it is highly desirable to perform fatigue tests on sample parts rather than on conventional fatigue specimens. These tests should be made, if possible, under cycles of stress of the kind that the parts are expected to withstand in service (completely reversed stress, partly reversed stress, or stress repeated but not reversed, tension-compression load, bending load, twisting load, or a combination of these). The determination of the number and type of cycles of stress that a part will be required to withstand in service cannot ordinarily be determined in the laboratory; therefore, extensive field tests are frequently desirable. Often these field tests are conducted to determine exactly what stresses a part will be expected to withstand, and about how many of them must be withstood in a satisfactory period of service. Such field studies frequently involve the use of recording strain-measuring apparatus. The results should be considered approximations that may serve as guides, not statements involving a high degree of precision. In determining the magnitude of the "factor of safety" that must be used in designing a structural or machine part, usually the greatest problem is uncertainty concerning the corrosive mediums and the stresses that the part will have to withstand under reasonable service.

In laboratory fatigue tests on actual structural and machine parts, if a series of loads is used, of various magnitudes, the range of stress during a cycle may well show a ratio of minimum to maximum stress like that which will occur when the part is in service. Such fatigue tests of actual machine and structural parts are becoming quite common for springs, and are used, though somewhat less, for small crankshafts, crankpins, axles, lead sheathing for electrical cables, railroad rails, wire rope, welded joints, bolts and nuts, and many automobile and airplane parts. A considerable number of special-purpose fatigue machines are in use today, varying from machines to test a large number of small springs at once, to machines that have a maximum capacity of 50,000 to 200,000 lb, used for tests of wire rope, large shafts, axles, welded joints and the like.

For examining large parts and special pieces, the cost of preparing many specimens, and of conducting many tests, is prohibitive. Instead, fatigue tests of small specimens may be used as a basis for design, not only by considering their immediate results, but also (after further tests or relative estimates) by making allowance for the effects of size (and possibly of shape), of surface condition, of stress raisers (such as keyways, fillets, holes, grooves, notches, screw threads), of corrosive conditions, and of the ratio of minimum stress to maximum stress during a cycle to be expected in service. The details of the procedures used in fabrication will affect the fatigue properties of structural components.

Frequently the stress-concentration factor for a notched specimen or for a machine part can be determined by photoelastic tests of models or by mathematical analysis. The actual *strength-reduction factor,* because of the given notch or other stress raiser, may be determined by test, as follows: Make a series of fatigue tests on unnotched specimens with critical section the same in size and shape as the critical section of the machine or structural part being studied—or as nearly that size and shape as is feasible. Draw the S-N diagram for these tests. Next make a series of tests on specimens with the critical section the same except for a notch, or other stress raiser, and draw the S-N diagram. Then, for any desired number of cycles of stress, determine from the S-N diagram the ratio of endurance limit for unnotched specimens to endurance limit for the specimens with the stress raiser. This ratio is the *strength-reduction ratio* for the given size and shape of notch in the metal used, and for a given size of critical section.

The available data indicate that the actual *strength-reduction ratio* is less than the theoretical stress-concentration factor. This is caused, in part at least, by localized yielding at points of high stress concentration and the resultant lowering of the "high peaks" of stress there. In high-strength alloy steels, the actual reduction in strength of parts because of stress raisers, sometimes approximates the reduction indicated by the theoretical stress-concentration factor. For lower-strength steel and for cast iron the strength-reduction factor is distinctly less than the theoretical stress-concentration factor. Fatigue tests of notched specimens and of specimens with fillets, holes, or screw threads, are desirable, as well as tests of polished specimens without stress raisers. From such tests, some estimate can be made of the actual strength-reduction factor to be used.

To date (1947) the highest strength-reduction ratio that has been found in fatigue tests at the University of Illinois, is 3.85 at the root of U. S. Standard screw threads in bolts made of heat treated alloy steel. For similar bolts made of structural steel the strength-reduction ratio was 2.84.

In fillets and rounded notches, strength-reduction ratios as high as 2.5 have been observed, although strength-reduction ratios from 1.5 to 2.0 are more common. For cast iron, the strength-reduction ratios observed are lower than for steel, ranging from about 1.1 for soft gray cast iron, to about 1.6 for certain high-strength cast irons. This does not mean that gray cast iron is stronger than alloy cast iron, or that alloy cast iron is stronger than alloy steel. It does mean that the gain in strength to be expected from the use of alloy steel in parts with notches, grooves or fillets is less than would be indicated by comparative tests of unnotched fatigue specimens of alloy steel and of cast iron.

The designer must consider the effect of size on the

fatigue strength of the part that is being designed. If the diameter or thickness is more than ¼ in., 15 to 25% reduction in fatigue strength should be allowed, below the strength shown by tests of ¼-in. specimens with stress raisers similar to those in the part. For pieces with thickness or diameter greater than 2 in., adequate data are lacking, concerning the effect of size, although tests of specimens up to 2 in. in diam show a negligible increase in size effect above ¾ in. in diam.

The designer should consider probable surface conditions of any part that is being designed to resist repeated stress. A rough surface may reduce fatigue strength by as much as 25%, while cold rolling or shot peening, if performed properly, may *increase* the fatigue strength appreciably, in some instances as much as 25%. The designer should give careful attention to the possibilities of corrosion and corrosion fatigue, and should attempt to minimize damage by protective coatings or otherwise. If such protection is not possible, and corrosive agents are to be present while the part is undergoing repeated stress, a large reduction should be allowed—perhaps as high as 75%—in the fatigue strength of the part.

Of course, the preceding paragraphs do not tell the designer what actual stress conditions his machine part will be expected to withstand in service. That problem cannot be solved generally in the laboratory. It requires experience with other parts in similar service and sometimes requires field tests. However, if the applied stress to be withstood in service can be estimated with a fair degree of accuracy, the above considerations of size, stress concentration, strength reduction, surface conditions, range of stress in service, and corrosion, should enable the designer to use the data of laboratory fatigue tests of small polished specimens with safety and economy.

Bend Tests for Ductile Metals

By F. S. Mapes*

THE bend test is one of the simplest and least expensive of the mechanical tests used in evaluating the properties of metals. Before modern equipment and precise measurements were demanded, the bend test served as a guide to the ductility of metals and was particularly useful in control or acceptance testing where involved interpretations were unnecessary. For such purposes the test can be made without equipment for indicating the load and without close attention to details of procedure. Probably these factors alone justify retention of the bend test among more comprehensive and complex modern tests.

A rather large variety of bend test specimens and procedures have been used, as dictated by precedent, available testing equipment and the materials or products under consideration. Few standard procedures have been incorporated into specifications of Federal agencies and the present standards of the American Society for Testing Materials.

Frequently it has been stipulated that the bend test specimen be wrapped around a pin or mandrel of given diameter, but experience shows this to be impractical if not impossible, without the use of specially designed fixtures. Still other procedures require that the bend occur between rigid supports and under a loading nose. The more modern conception tends to favor the so-called "free bend" rather than a restricted or constricted bend, but not in testing full-section pipe, tubing and the like.

Many existing specifications require a 90, 120 or 180-deg bend of a prescribed specimen around a mandrel or pin of given diameter. The test specimens are usually rectangular in cross section, with rounded edges. When a press or compression-testing machine is used, a suitable means of support and loading, as shown in Fig. 1, should be provided. There are many modifications or variations in test procedure that will produce essentially the same bending result. The types of bend-testing fixtures can be used for pipe, tubing, rods or bars.

In the free-bend test, as prescribed by the ASTM method, the object is to make preliminary bends outside the actual test section and without introducing local stresses or strains in the section that eventually will have the greatest bending. Such initial bends, located at approximately third points along the specimen, should be equidistant from the center test section. These bends may be made by clamping the specimen in the jaws of a vise and bending the ends by hammering; or by setting the specimen on supports, as in Fig. 1, and loading at the third points. Where volume repetitive testing of this type is involved, an arrangement such as that shown in Fig. 2 is useful. This arrangement has the added advantage of

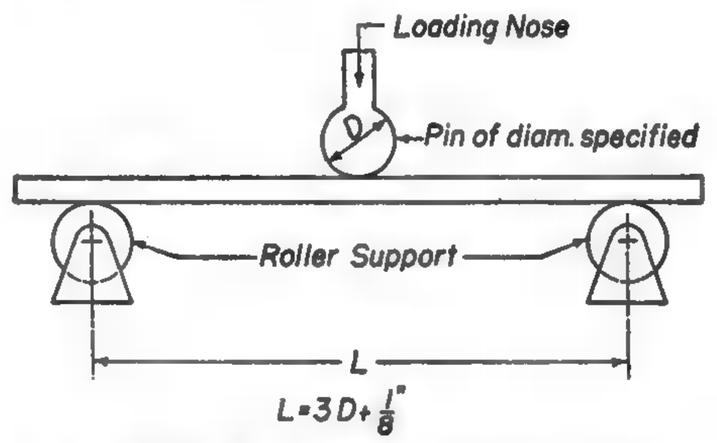

Fig. 1 Typical test fixture for restricted bend

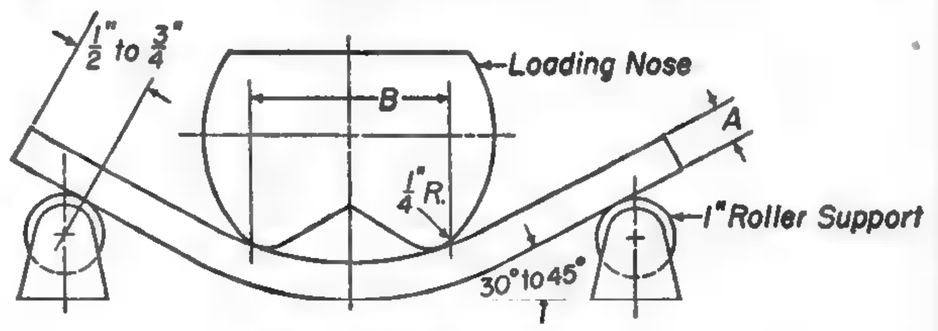

Fig. 2 Preliminary bend setup

* Schenectady Works Laboratory, General Electric Company.

producing the same angle of bend at each third point. The initial bend angles are not critical and may vary from 5 to 30 deg, depending on the material under test. It is recommended that the angles at each third point be as nearly alike as possible, to facilitate testing.

To complete the test, the specimen is tested as a strut by applying compression at the ends, in either a vise, a

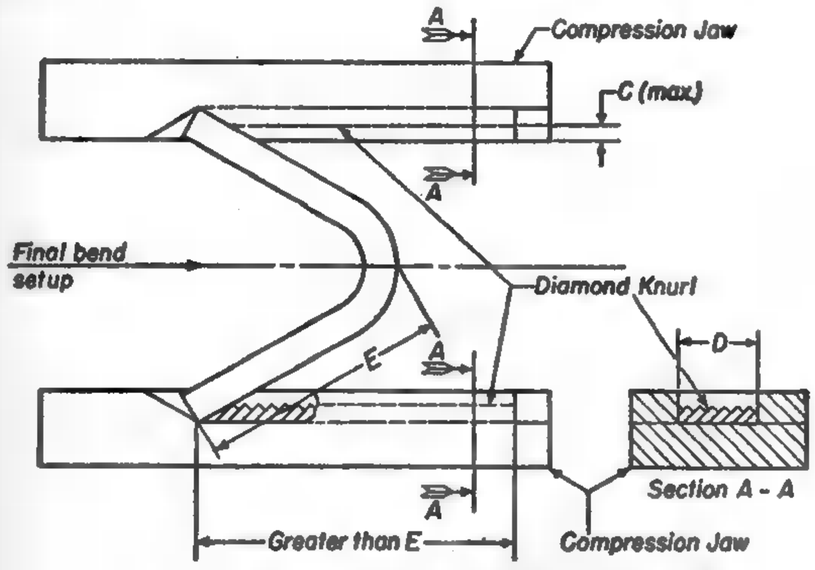

Fig. 3 Test fixture for completing free bend

press or a testing machine. Again, testing may be facilitated and the danger from slipping may be overcome by use of a fixture such as the one shown in Fig. 3.

In testing certain nonferrous alloys, procedures have been followed that are essentially the same as those already mentioned. When practicable, materials or products are tested in full section and restricted bend methods are ordinarily used. Figure 4 shows a method whereby test specimens are bent around dies of various radii to determine conformance to specification requirements or to find the minimum diameter of bend that the material will take without fracture. When testing round specimens, the dies are grooved to a depth equal to about one third the diameter of the specimen with a radius to fit.

As far as the restricted bend tests are concerned, the end point of the test is reached when, as required by material specification, the required angle of bend has been accomplished without rupture of the outer fibers, or when the bend has been sufficient to produce the required elongation in the outer fibers.

In the free-bend test, the evaluation is the measurement of elongation in the outer fibers at the time when rupture occurs or when the specimen has been flattened without failure.

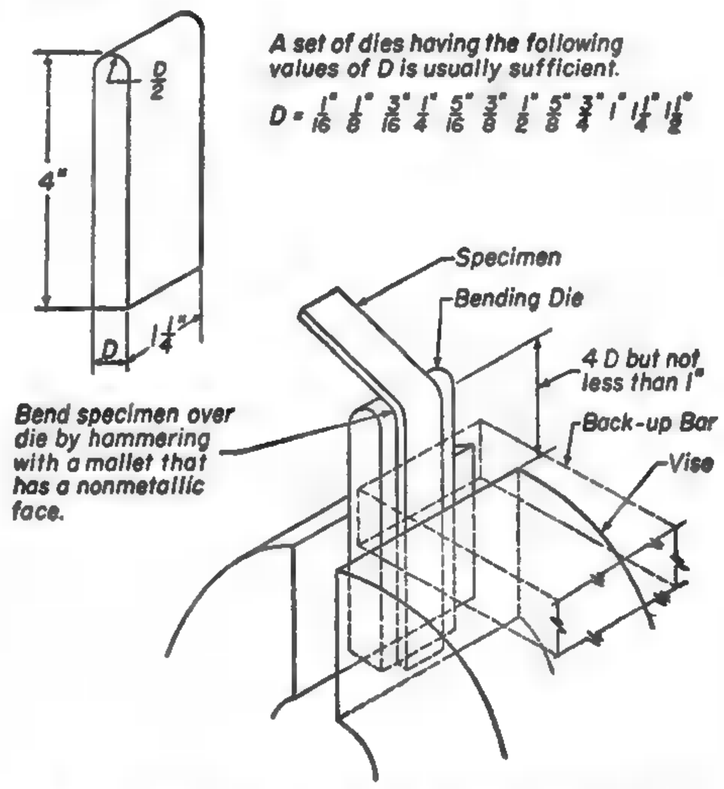

Fig. 4 Sketch showing die and specimen in vise

In bend tests, the speed at which bends are produced may or may not be important, depending on the material.

When elongation is to be measured, the gage length is laid out at the section of maximum bending and in the center third of the width of the specimen. A gage length of 0.3 in. is recommended for specimens ¼ to ½ in. thick, and a gage length of 1 in. for specimens more than ½ in. thick. Measurements of elongation are not generally required for specimens less than ¼ in. thick. Following completion of the bend, the final gage length is measured with a flexible scale or equivalent, or the radius at the outside of the bend may be measured and the elongation computed.

Bend Tests for Hard and Brittle Metals

By T. H. Gray*

THE transverse bend test is used for the evaluation of strength and toughness of hard and brittle metals such as hardened tool steels, sintered carbides and cast iron. Reliable tension tests become increasingly difficult to make as the hardness of steel increases to more than 600 Bhn, whereas the bend test involves fewer difficulties and is perhaps more significant at high hardness than at low. The utility of the bend test is increased further by the simplicity of the test specimen, which normally consists of a plain rectangular beam; by the ease of testing, since the test requires only that the beam be supported near the ends and loaded at the center; and by the rapidity of obtaining results, since the breaking load serves as a measure of strength. The amount of flexure of the beam under load may be utilized as a measure of ductility.

When the bend test is applied to materials of low ductility, such as cast iron, hardened tool steel, sintered carbides and even ceramics, there is naturally more scatter in the results than when ductile metals are tested. As much as 25% variation in strength has been observed between duplicate bend tests on hardened tool steel. For this reason it is desirable to make a sufficient number of bend tests on each lot or treatment to establish a mean value and the range of variation from the mean.

In practice, the bend test consists in supporting at two places a rectangular, square or round beam specimen of the material to be tested, and applying a concentrated load to the center of the beam until fracture occurs. The rate of loading is unimportant in brittle materials as long as it remains lower than the speed of shock loading. The breaking load, sometimes referred to as the "flexure" or "transverse breaking load", is often expressed in pounds, but a more satisfactory manner of presenting the strength of the material is to convert the load in pounds to a stress value. In this way corrections are made automatically for specimens that vary somewhat in size.

The highest tensional stress in the beam section determines rupture and is given by:

$$S = \frac{3\ PL}{2\ bh^2} \text{ for a rectangular beam,}$$

$$S = \frac{2.546\ PL}{h^3} \text{ for a round beam}$$

where:

P = concentrated load, in pounds
L = span, in inches
h = beam thickness, in inches
b = beam width, in inches

The point of highest stress is located at the intersection

* Research Laboratories, Westinghouse Electric Corporation, East Pittsburgh, Pa.

Prepared for the Subcommittee on Mechanical Testing

of the plane of load application, section *a-a* in Fig. 1*a*, with the bottom surface of the beam.

When rupture occurs within the elastic range of the material, *S* will represent the stress at the outer fiber (Fig. 1*b*). On the other hand, if the material possesses ductility sufficient to enable rupture to occur after plastic yielding (Fig. 1*c*) the actual stress is no longer *S* but some lower value, since the flexure formula is based on a stress distribution that increases linearly from the neutral axis to the outer fiber. For this and other reasons, rupture strength in bending, calculated as *S*, is often considerably higher than that in simple tension. Because of this, there is no established constant relationship between the two, although the bend test will usually rate specimens in the correct order with respect to tensile strength on materials of negligible ductility.

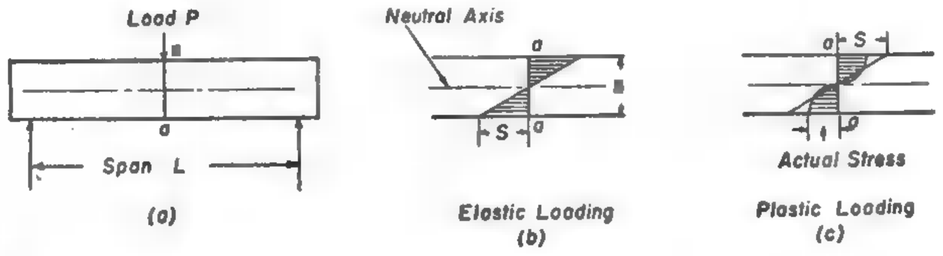

Fig. 1 Stress distribution in a beam under a concentrated bending load

The stress calculated by the preceding equations is called "bending stress" in this article, and the stress when rupture occurs is called "bending strength", obviously a more descriptive phrase for the textbook equivalent, "modulus of rupture". Though values of unit stress are reported, the need for specifying the dimensions of the specimen is not circumvented, since strength is influenced somewhat by specimen size, shape and span.

Bend Tests of Cast Iron. The transverse bend test functions satisfactorily as an acceptance test for cast irons, for which purpose it has been standardized by the ASTM.[1] For cast irons, both the loads and deflections are usually measured and the maximum load in pounds and the maximum deflection in inches are determined.

Square and rectangular bars are used, but both the ASTM and the British Engineering Standards specifications now include cylindrical transverse test specimens of several sizes and lengths. In the United States, three sizes of transverse test specimens are specified by the ASTM, as shown in the article on preparation of test specimens, page 86. In general, aside from the dimensions of specimens, lengths of span and maximum rates of loading, the ASTM leaves to the individual tester the determination of the type of supports, the rate of loading (below the maximum), the method of loading, measurement of deflection, and design of loading fixtures.

Table I. Comparison of Bending Strength and Tensile Strength of Cast Irons

Cast Iron	Bending Strength, psi	Tensile Strength, psi	Ratio of Bending Strength to Tensile Strength
1	79,200	38,800	2.04
2	100,900	54,200	1.87
3	82,700	43,000	1.93
4	87,200	45,000	1.94

Cylinders or knife edges are the recommended types of beam supports; the knife edges have a definite radius. The load is applied to the specimen at the center of the span, through a ball or cylindrical surface that usually has the same radius as the supports. The maximum rates of loading specified by the ASTM are such as to produce rupture in not less than 15 sec for the 0.875-in. diam bar, 20 sec for the 1.20-in. diam bar, and 40 sec for the 2-in. diam bar. These rates may be exceeded somewhat without affecting the results appreciably.

Other precautions should be taken in the performance of the standardized bend tests on cast irons, particularly in the preparation of the specimens. The general practice has been to cast the test bars to size, but it has been recommended[2,3] that they be cast oversize and machined to final size, for several reasons. Machining removes the surface irregularities (which act as stress raisers) inherent in the casting of iron. The presence of blowholes, pinholes and cracks is more clearly revealed. An additional advantage is the elimination of elliptical sections that occur frequently in the casting of cylinders.

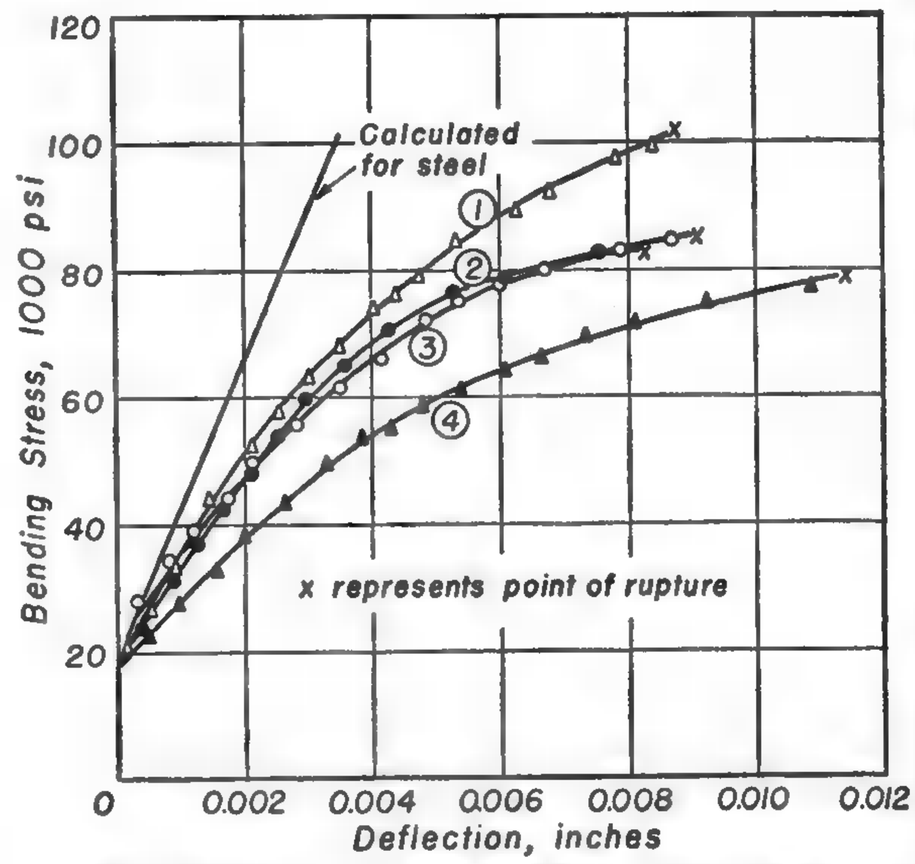

Fig. 2 Bending stress versus deflection of cast irons

The measured cross section of the specimen should be used rather than the nominal size, in determining the strength of cast irons, because the use of the nominal cross section introduces errors in the comparative values of strength. For this reason, as well as for purposes of standardization and for comparisons of test results, it is highly advantageous to use standard specimens and of as few sizes as possible.

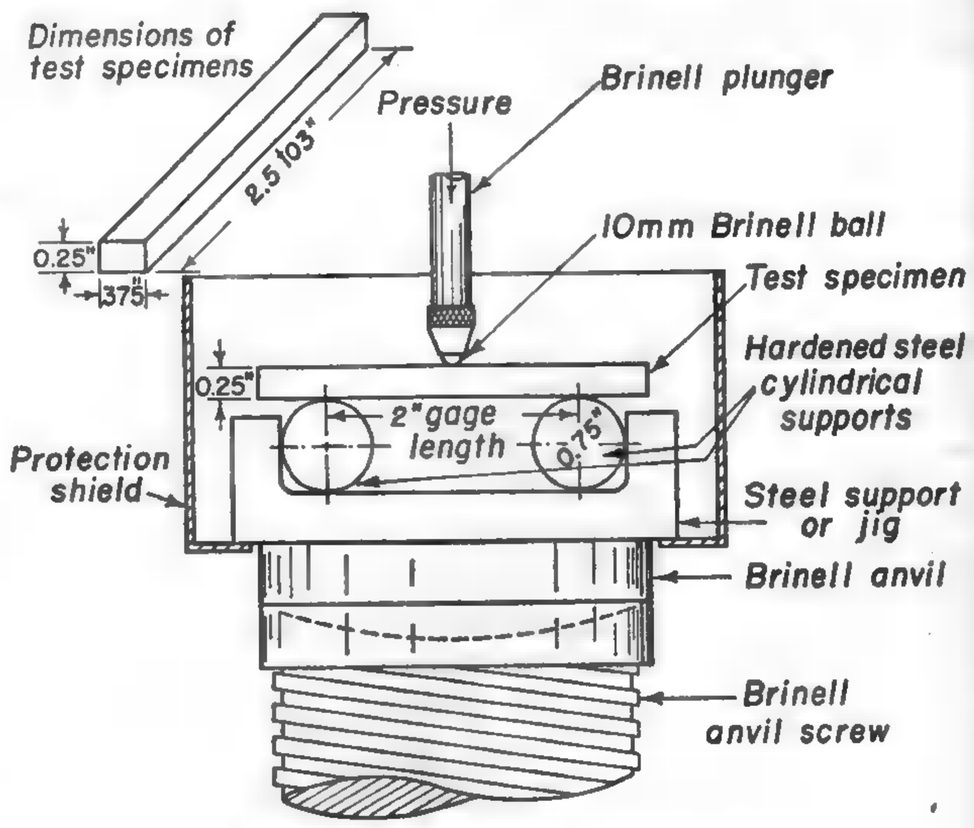

Fig. 3 Fixture for bend tests of hardened steels

It is not possible to limit the number of sizes of test specimen to one, since it is desirable that the size of the specimen should conform closely to the thickness of the actual casting because of the effect of different rates of cooling on the strength of cast irons.

To demonstrate the effects of such variables as heat treatment, microstructure and composition, it is often advantageous to use much smaller specimens than are specified by ASTM for bend tests on cast irons. Smaller specimens are preferably square or rectangular in cross section to facilitate testing. Satisfactory test results, shown in Fig.

2, have been obtained on cast-iron bars, 0.5 in. sq and 2.5 in. long with a 2-in. span. The load was applied to the bar through a 10-mm Brinell ball, by means of a Brinell tester. The values in Table I illustrate that these bend tests rate the cast irons in the same order of strength as tension tests, provided sufficient care is taken in the preparation of specimens and in performance of the tests.

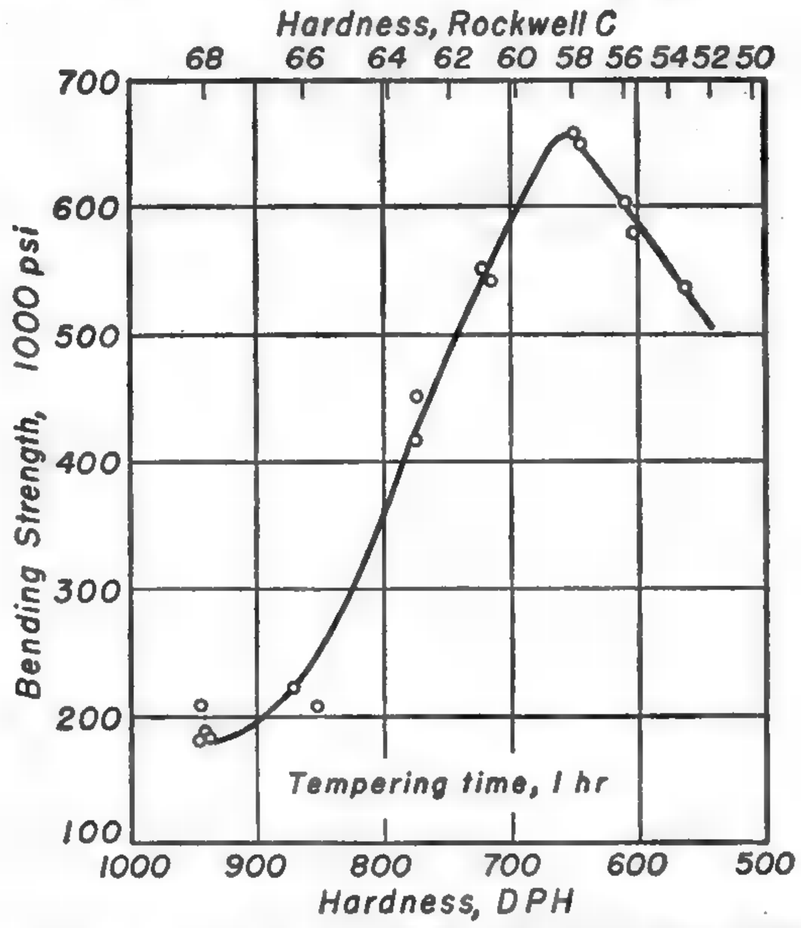

Fig. 4 Results of tests on 1.1% C tool steel, quenched in brine from 1475 F and tempered at 70 to 350 F

It is recognized that there is no definite factor for a general correlation between tensile and bending strengths, particularly since failure may occur in the elastic range in one instance, and after appreciable plastic flow in another. However, if the ductility varies inversely with strength, a fairly good correlation exists, as noted in the values in Table I.

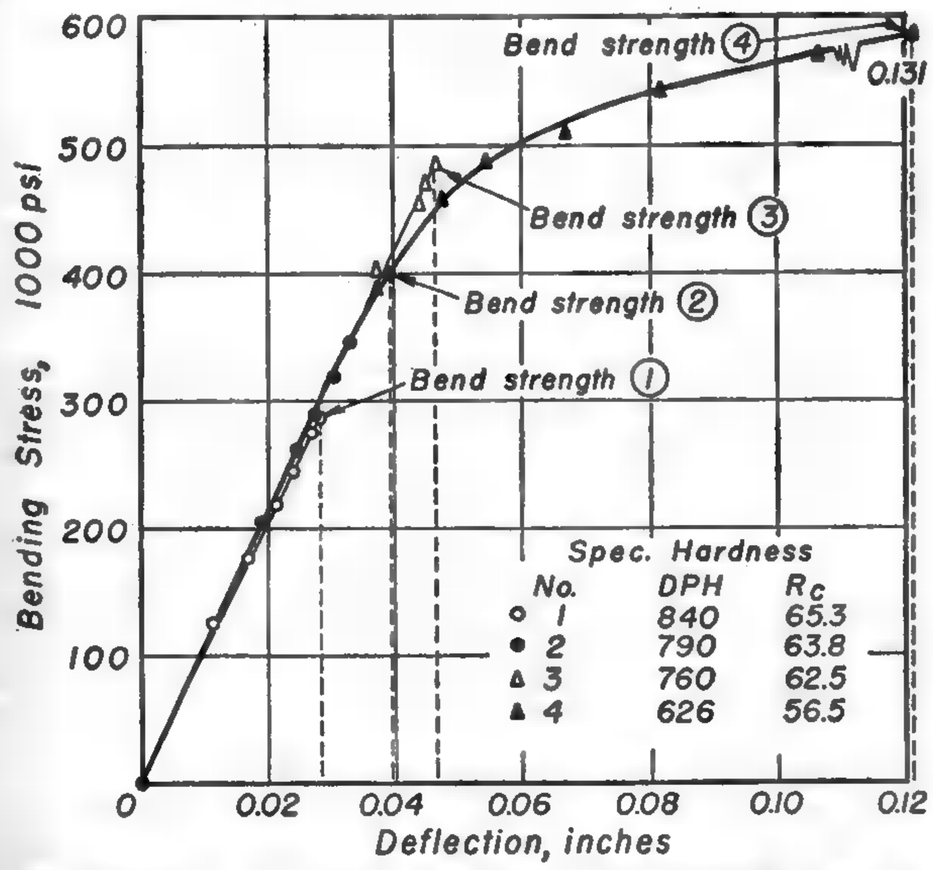

Fig. 5 Bending stress versus deflection of Cr-Mo-Si tool steel, 0.88% C, 1.1% Cr, 0.4% Mo, 1.43% Si. Dimensions ¼ by ⅜ by 3 in. Gage length 2 in.

Bend Tests of Hardened Steels. If bend tests are carefully conducted, they offer some advantages over other types of tests for evaluating the breaking strength of hardened steels of negligible ductility. Comparisons of strengths are more readily obtained than with the tensile test, and the bend test is more sensitive to slight variations in properties than the standard Charpy and Izod impact tests. Since many tools are stressed in bending, bend tests may provide a direct measure of the resistance of tool steel to failure in service.

There have been no attempts to standardize the bend testing of hard steels; consequently test specimens of various shapes and dimensions have been employed, as well as several testing methods. The test specimens and

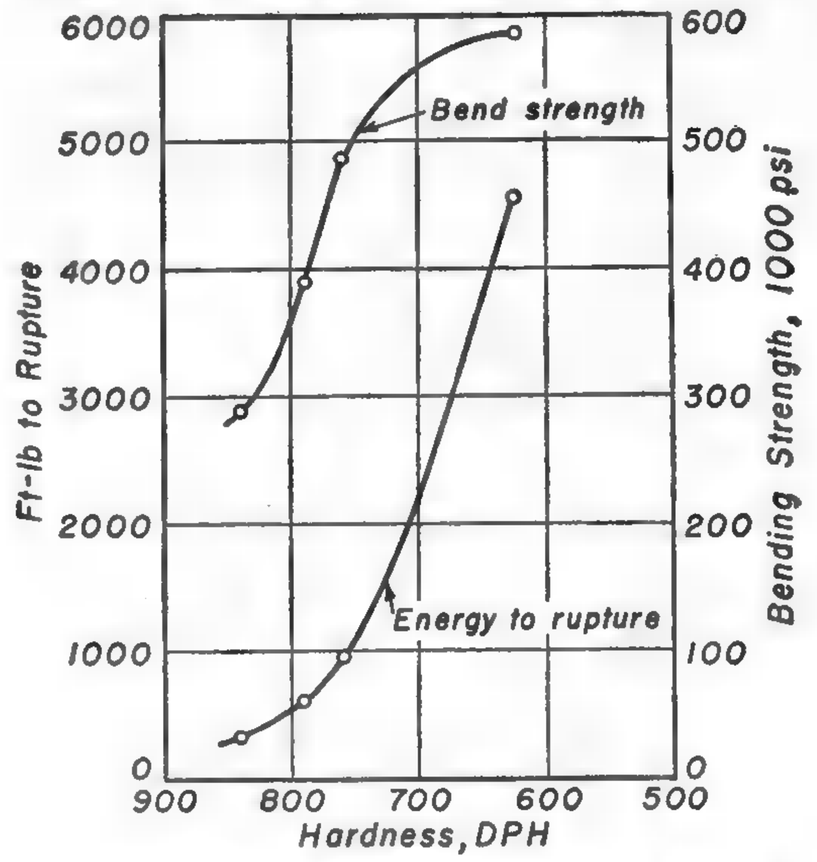

Fig. 6 Foot-pounds required to rupture Cr-Mo-Si tool steel in bending (0.88% C, 1.1% Cr, 0.4% Mo, 1.43% Si). Dimensions ¼ by ⅜ by 3 in. with a 2-in. span

fixtures are much smaller than those specified for cast irons and much shorter spans are used. The sizes of specimen tested range from 21/32 in. in diam, 7 in. long[4] to 0.072 in. in diam, 2 in. long.[5] Many tests have been made on rectangular bars ¼ by ⅜ by 3 in.,* with a 2-in. span.

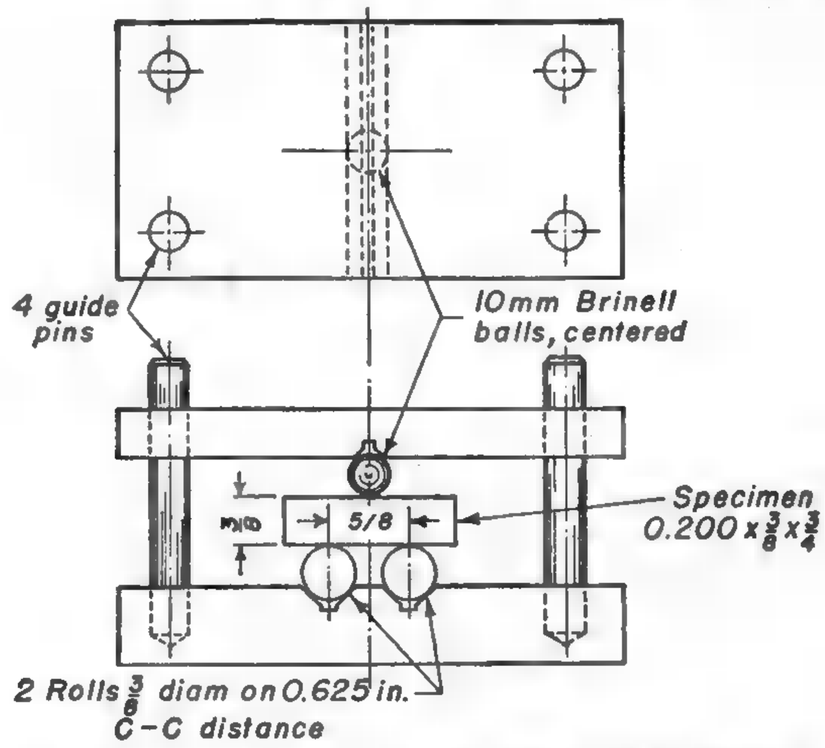

Fig. 7 Apparatus for determining the bend strength of sintered carbides. (Firth Sterling apparatus)

$$S = \frac{3PL}{2bh^2} = \frac{0.9375\,P}{bh^2}$$

S = bending strength, in pounds per square inch
P = breaking load, in pounds
L = C-C distance between supports
b = width of specimen, in inches
h = thickness of specimen, in inches

A fixture for performing bend tests on these specimens is shown in Fig. 3. The bars of this size should be surface ground to ± 0.001 in. of their final dimensions before testing, and the edges should be chamfered. The tolerances can

* Research data, Westinghouse Electric Corporation

be increased for larger specimens. Decarburization should be avoided or removed by careful grinding after hardening.

Testing fixtures consist of two supports for the beam specimen (either knife edges with a definite radius on the bearing edges or two hardened steel cylinders), a jig for holding the supports and test specimen, a means for protecting the operator from flying fragments, and a mechanism for applying the load. Loading with a ball at the center of the span yields more consistent results than loading with a knife edge or roll. Any of the usual laboratory testing machines that apply a load may be utilized conveniently for performing the bend tests.

The magnitude of the beam deflection can be measured conveniently by placing one end of an extension bar above or under the test specimen midway between the supports, and placing the other end of the bar under a dial indicator. An electric strain-gage can be placed very easily on the under side of the specimen for the same purpose. As a rule, deflection measurements are not made, since the failure of a fully hardened steel bar often occurs within the elastic range.

Typical results of bend tests on a hardened tool steel containing 1.1% C are shown in Fig. 4. As-quenched steels contain an appreciable amount of residual stress. Presumably because of these stresses and the inability of the hardened steel structure to accommodate itself to the load, the strengths at full hardness are low and the failures are brittle, with the specimens often shattering into fragments. Relief of these stresses and increased plasticity, resulting from tempering treatments, reduce hardness and greatly increase the bending strength of the steels. The shear component in the fracture of bend-test specimens also appears when the steels have been tempered to a hardness less than that for maximum bending strength, and shattering no longer occurs.

When deflections of the beam under the load are measured in conjunction with the bending stresses, curves similar to those of tensile stress versus strain are obtained, as illustrated in Fig. 5. These curves indicate that hardened and slightly tempered steels, of 760 DPH (62.5 Rockwell C) or more, rupture while they are still being deformed elastically.

The energy required to produce rupture, a quantity commonly accepted as an indication of toughness, can be obtained from Fig. 5 by computing the area under the curves up to the point of rupture. In Fig. 6 are shown values of energy in foot-pounds required to rupture hardened Cr-Mo-Si tool steel tempered to different hardnesses.

Bend Tests of Cemented Carbides. Bend tests have been applied with varying degrees of success in evaluating qualitatively the resistance to breakage of sintered carbides. Cursory attempts to standardize the test have been made by several manufacturers. Some have maintained that the size of the test specimens should correspond to the size of carbide products in service, so that a closer correlation can be made between the results of bend tests and service failures. As a result, many different sizes of test specimens have been used.

Several producers have tentatively accepted a carbide test specimen 0.20 by 3/8 by 3/4 in. with a 5/8-in. span. The bars are surface ground to within ±0.001 in. of their final dimensions; the grinding wheel moves longitudinally to avoid transverse scratches. One example of test apparatus, illustrated in Fig. 7, shows a specimen mounted in a jig ready for testing.* In this particular procedure, a 10-mm sintered carbide ball is used to apply a concentrated load slowly to the center of the test bar, by means of a hand-wheel on the testing machine. Typical values of bend strength range from 200,000 to 400,000 psi.

Mechanical Testing of Sheet Metals

By John R. Low, Jr.*

SHEET and strip products are almost invariably subjected to cold forming operations of one type or another in the process of fabrication, and therefore must be examined for "forming quality" as well as for the usual mechanical properties essential in structural materials. As a result of this additional requirement and of the wide variation among the types of forming operation to which a sheet may be subjected, a great many technological tests have been devised, simulating certain specific types of forming operations. Most of these special tests have not proved generally useful as routine testing methods and will therefore not be described in this article. A list of the more important of these special tests will be found on page 130, with references to the original articles in which they are described. At present the most widely used tests for sheet metals are the tension, indentation hardness, bend, and Olsen or Erichsen "ductility" tests. In addition to these, the "tear-length" tests for directionality, the Tour-Marshall bend test for strip, and a number of cup-drawing tests (small-scale deep drawing of cylindrical cups) are in more or less common use.

Tension Testing of Sheet Metals. The general features of the simple tension test are described in the article on "The Tension Test", page 105; and the ASTM sheet-metal specimen employed universally is described in the article on test specimens, page 86 in this Handbook. Three results of tension tests are normally reported for sheet metals: the yield point or the yield strength, the tensile strength, and the elongation in 2 in. The yield point may be determined by the so-called "drop-in-load" method, the divider method or the low-magnification autographic method, all of which are described in the article on "The Tension Test". The drop-in-load method is usually limited to the testing of steel sheet in the annealed condition, which exhibits a true yield point.

All three of the above-mentioned methods for determining yield point may be influenced by the skill and judgment of the operator, the care used in preparing the specimen, the speed of testing, and similar factors. Despite such possibilities for variation in the results, these measures of the yield stress have proved useful when a great many routine tests are required for purposes of control. When a more precise measurement is required, it is customary to determine the 0.2% offset yield strength by using sensitive strain gages.

No special comment is required concerning the determination of the tensile strength of sheet specimens, but the

* Chief, Division of Metallurgy, The Pennsylvania State College, State College, Pa.

Prepared for the Subcommittee on Mechanical Testing.

measurement of elongation deserves mention, as well as the influence of specimen shape on the value obtained. It is common practice, particularly with specimens of 2-in. gage length, to reduce the width at the center of the gage length deliberately by a few thousandths of an inch in order to be certain that fracture will occur midway between the gage points. It is not always recognized, however, that some materials are quite sensitive to the amount of such tapering or "waisting" of the specimen and that the elongation values obtained may be appreciably influenced by seemingly unimportant variations in the amount of taper from the ends of the gage section to the midpoint.[1]

Up to the present time no adequate method has been devised for the measurement of reduction in area at fracture for sheet specimens. In testing the heavier gages of the less ductile materials, the method suggested by MacGregor[40] for plate specimens may be used, but the measurements required cannot readily be made with adequate precision in the more common lighter gages (less than 0.062 in.) or in the ductile materials where considerable necking occurs. For this reason, reduction in area is almost never reported in tension testing of sheet metals.

Compression Testing. In compression testing, the ratio of the length of the specimen to the least cross-sectional dimension must not exceed a certain minimum value (usually 3 or 4) if buckling is to be avoided. This requirement is easily met in metal products with heavy sections, but, in the testing of sheet and strip, the required use of extremely short specimens would add greatly to the experimental difficulties of the test. For this reason a number of test methods have been devised which, by one means or another, provide sufficient lateral support in a fairly long specimen, without introducing frictional forces great enough to influence the test results appreciably. These methods are used only to determine the compression yield strength and cannot be used to obtain stress-strain data much beyond yielding.

In the "pack" method[33, 34] a number of samples are pressed together and the top and bottom surfaces of the pack are carefully machined parallel. To avoid the necessity of machining a large number of samples for each test, and the tedious adjustments inherent in the pack method, several special fixtures have been developed for testing single sheet thicknesses. Two of these [35, 36] simply use flat plates pressed against the specimen surfaces and depend on lubrication and careful adjustment of the pressure to minimize frictional effects. In a third method,[37] the lateral support is provided by a series of small rollers pressing against the two flat surfaces of the specimen.

The so-called "cylinder method"[38] consists of forming a small cylinder by rolling a sample of the sheet and joining the edges by soldering. The results obtained through the use of this method appear to be reliable, provided the proper cylinder diameter–sheet thickness and length-diameter ratios are employed to obtain simultaneous yielding all around the periphery.

Hardness Testing. The Rockwell test is almost universally used for testing the hardness of sheet steel. The particular load and indenter combination varies with the material and the thickness of the sheet to be tested. For example, the standard B scale is used for 0.033 in. and heavier steel sheets, the F scale for thickness between 0.025 and 0.033 in., and the Rockwell superficial tester for thickness less than 0.025 in. (*See* "Hardness Testing", page 93, for definitions of hardness scales.) Pack hardness testing of several sheets piled on top of one another is sometimes resorted to for purposes of comparison, but this practice is not recommended since the values obtained are frequently unreliable and cannot be correlated with the results of tests made on a single thickness, using lighter loads.

Erichsen and Olsen Type of Ductility Tests. The general principle of the Erichsen type tests (commonly called "cupping" or "ductility" tests) is illustrated in Fig. 1. The sheet is held between two ring-shaped clamping dies while a punch, usually hemispherical, is forced against one side of the sheet until fracture occurs. The height of the dome thus produced is measured by a dial gage, with plunger resting on the top surface of the sheet during deformation, or by measuring the movement of the punch. This "depth of cup", usually reported in thousandths of an inch (Olsen) or hundredths of a millimeter (Erichsen), is taken as measure of the ductility. Some machines are also equipped to measure the punch force applied, and a sudden drop in pressure on a gage is taken as the end point of the test; otherwise, the end point is determined by observing the sheet and noting the first appearance of fracture. Besides measuring ductility, this type of test is used also to detect surface roughening of the deformed sheet, resulting from large grain size.

Since Erichsen[2] first described a machine of this type, there have been numerous proposals for modifications of the original design. Most of these later cupping tests differ only in details, such as the die or punch dimensions, the shape of the specimen (round or square), or the method of clamping the sheet. These later modifications are the Olsen test,[3] the Guillery test,[4,5] the Persoz test,[6] the Avery test,[7] and the Amsler test.[8] The clamping dies and punch may be actuated hydraulically or by means of a screw.

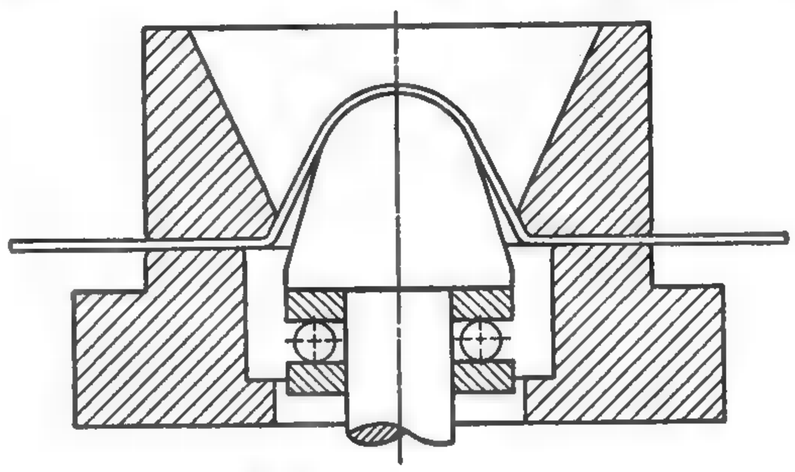

Fig. 1 Vertical section through Erichsen tester

Although it is generally agreed that the cupping test is unsatisfactory in many ways, nevertheless it is frequently included in routine testing programs. It has the advantage of being rapid; no special preparation of the specimen is required; it does indicate the general condition of the material and will indicate wide variations in ductility. Besides the conventional quantitative measurements of cup depth and maximum pressure, a qualitative evaluation of the drawn surface texture and the location and character of the break is sometimes used by experienced operators to determine the suitability of the product being tested for a particular application. On the other hand, it has been shown repeatedly[9] that test results on the same lot of material may vary widely from operator to operator or from machine to machine. This lack of reproducibility is caused, in some measure, by variations in clamping pressure, by the smoothness of the clamping dies or the punch, and by the amount of lubricant applied to the sheet surface. In addition, a variation in the speed of testing or failure to stop the test at precisely the same end point each time will contribute to this lack of reproducibility. More recent machines apply the clamping pressure hydraulically and automatically maintain it at a fixed ratio to the punch pressure.

The test results are sensitive to variations in gage.[10,11,12,13] The depth of cup increases approximately linearly with thickness (approx 0.6 mm per 0.010 in.) and various formulas and graphical methods have been devised for correcting for this factor.[11,13] The width of the specimen also affects the results; the depth of cup increases as the width of the specimen decreases, because of a "drawing in" of the edges under the clamping die.[10,12]

Bend Testing. The bend test, in one form or another, is one of the oldest applied to sheet metals, and is still one of the most widely used, despite the fact that no standard method of procedure has been accepted. At the present time bend tests range all the way from simple hand bending of a corner of a sheet to the quantitative measurement of resistance to bending in such machines as the Tour-Marshall flexure machine for thin sheets.

In general, the bend test is used either to determine forming limits, that is, minimum bend radius without failure for a 90-deg or 180-deg bend; or to determine the

yield point in bending, where this value must be controlled within narrow limits—for example, in light-gage sheet to be formed in high-speed automatic machines. For the determination of forming limits in bending, it is customary for the testing laboratory to design and construct the necessary tools, which are then used in either a Universal testing machine or in a hand brake. One of the most common bend test specifications requires that the material be capable of being bent flat upon itself (180-deg bend, zero radius) without rupture. In making this particular test, it is common practice to clamp one end of a strip of metal in a vise having either square or rounded jaws and to start the bend by hand or with pliers. After the strip has been bent slightly more than 90 deg, it is removed from the vise and either squeezed or hammered flat, after which the bent edge is inspected for cracks.

Cup-Drawing Tests. While not in general use for routine testing, the drawing of small cylindrical cups from flat circular blanks is sometimes used as a method of evaluating the forming quality of sheet materials.[41,42,43] Most commonly, cups of a given diameter are drawn, using a series of blanks having progressively increasing diameters. As the blank diameter is increased, a limiting size is found above which the material fails in drawing. This limiting blank diameter is then taken as a measure of the forming quality of the material being tested. Tests of this type may be carried out by using small laboratory presses such as the Wazau,[14,15] AEG,[16] or modified Erichsen[10] machines. Certain investigators advocate the use of commercial presses, in order to insure that the drawing speed will equal that used in full-scale drawing operations.[41,42]

Tests for Mechanical Anisotropy. In the series of processes for hot and cold reduction and annealing required to produce metals in sheet form, there is a strong tendency for preferred orientations of the individual crystals to develop. Consequently, sheet materials frequently exhibit a variation in mechanical properties if the direction of testing in the plane of the sheet is varied. This variation of properties, particularly resistance to plastic deformation, causes irregular flow during forming. The most common example is formation of "ears" in drawing cylindrical cups.

One test for evaluating the so-called "earing" tendency or "directionality" is the tear-length test.[10] In this test, two parallel slots are made in the edge of the sheet, the tab thus formed is gripped in a pair of pliers or a slotted key, and a triangular-shaped piece is torn from the sheet. The direction of tearing may be parallel to the rolling direction or at 45 deg, or at 90 deg, and any variation in the length of the triangular piece thus removed is an indication of anisotropy. (See Fig. 2.) Where equipment is available, laboratory scale cup-drawing is frequently used for this same purpose. Recently Baldwin[39] has shown that the ratio of the change in thickness to the change in width in the tensile test may be used for determining "earing tendency". The value of this ratio is compared for test specimens cut in several directions in the plane of the sheet.

Stretcher-Strain and Fluting Tests. The nonuniform type of plastic flow associated with the yield point behavior typical of annealed low-carbon sheets results in the formation of shallow, irregular depressions in the surface of the sheet in many stamping operations. Such surface markings, called "stretcher strains" or "Lüders lines", are highly undesirable where a smooth surface is required, and it is generally necessary to eliminate this behavior by temper rolling the sheet lightly (1 to 2% reduction) or by roller leveling. Another objectionable feature of a sheet exhibiting a yield point is the "fluting" which occurs when such a sheet is bent around a mandrel. Instead of forming a smoothly curved surface, such materials conform to the curvature of the mandrel by forming a series of sharp kinks separated by plane surfaces.

The tendency to stretcher strain, which may be detected in the tensile test, is directly proportional to the amount of yield point elongation. An Olsen or an Erichsen test of a specially prepared specimen may also be used to detect stretcher-straining. The specimen illustrated in Fig. 3 is prepared by drilling a hole at the center of the standard square specimen and then cutting a slot from one edge into the central hole. The specimen is deformed in the usual manner and the localization of deformation at the edge of the hole makes it possible to detect even a very slight tendency to stretcher strain.

Fluting tests are usually conducted by bending the sheet to be tested to successively smaller diameters around a series of mandrels or in bending rolls. The smaller the diameter of the cylinder to which the sheet can be bent without fluting, the less the fluting tendency.

Additional Sheet-Testing Methods. A great many special purpose tests have been devised, usually to evaluate deep drawing or forming quality, but they are not in general use. A number of these are listed below, together with references to the papers in which they are discussed: drawn wedge or Sachs test,[14,17,18,19] wedge-cup test,[18,20,21,22] K.W.I.E. hole expansion test,[8,22,23,24,25] fluid pressure cup test or Jovignot test,[8,10,26,27,28,30] slotted strip test,[31] and stretch-drawing test.[32]

Mechanical Testing of Bars, Plates and Shapes

By A. P. Spooner* and F. M. Howell*

FOR both ferrous and nonferrous materials, the mechanical test most frequently specified for bars, plates and shapes is the tension test. Hardness and bend tests are also often used.

Ferrous Materials

Bars. For testing hot rolled bars, the section size of the tension test specimen is normally the same as that of the bar, provided such a specimen does not exceed the capacity of the testing machine; usually an 8-in. gage length is used. Machined test specimens of standard size (0.505 by 2 in.) are used for larger sizes and generally for heat treated steel.

Occasionally, in conjunction with the tension, bend and Brinell tests, notched-bar impact tests of the Charpy or Izod type are made on heat treated bars.

To ascertain special properties, ordinarily in connection with research investigation, other tests are used, such as compression, torsion, shear, deflection, damping, torsional impact, weldability, machinability, wear resistance, drift, cavitation, tests at elevated temperatures, short-time tension tests and long-time tension tests (creep, relaxation and rupture), tests at low temperature such as impact and tension, fatigue tests, and special hardness tests such as Rockwell, scleroscope, Vickers, file, Monotron and microcharacter.

The mechanical testing of bars in the untreated condition is usually confined to the tension or bend test or both. For untreated bars, the carbon range and often the manganese range is not specified, although sometimes a maximum figure is given. For annealed steel with standard chemical limits, Brinell hardness is limited to a specified maximum value. Both maximum and minimum values of tensile strength or hardness may be specified for quenched and tempered or normalized and tempered bars, but the range should be equivalent to at least 0.3-mm diam of Brinell indentation.

The close relationship between hardness and tensile strength is shown in the hardness conversion tables in this Handbook. Since the two properties cannot be controlled independently, only one needs to be specified.

Test specimens taken from bars are almost always cut out in a longitudinal direction, that is, parallel to the axis of the bar. Usually the size of stock precludes the cutting of specimens in any other direction. Machined test specimens are cut from the center of small bars. However, when bars of larger sizes are to be tested, the specimens are taken midway between the center and the surface. There is no distinct dividing line determining from which of these two locations a specimen should be cut for testing a given bar. In bars larger than 1 to 1½ in. in diam, the test specimens are usually cut from the midway point.

The end-quench hardenability test may be applied to alloy steel bars containing between 0.20 and 0.60%C. With standard chemical ranges, either maximum or minimum hardenability can be used. When limited by both a maximum and minimum standard hardenability range, wider latitude than standard is required for the composition. When working to a minimum and maximum standard hardenability range, more uniform response to heat treatment is obtained than when using the standard chemical ranges. The end-quench hardenability test is not satisfactory when applied to carbon steel.

Plates and Shapes. Because plates and shapes are almost always used in the as-rolled condition, the tests applied to them are usually fewer and less complicated than tests applied to bars, in which properties are frequently enhanced by heat treatment.

Tension and bend tests are commonly specified by the trade to determine the suitability of plates and shapes for the intended purpose. The conventional tension test specimen is cut approximately 18 in. long by 2 in. wide, and is machined over the gage length to a width of 1½ in. With this specimen, percentage elongation is measured in 8 in.

When structural materials such as beams, angles and universal plates are to be tested, the coupons are cut parallel to the rolling direction, which is ordinarily the direction of the major stresses.

Sheared plates of first quality are usually tested in the same manner as the structural material, although in some specific instances tests are required in the transverse direction, at right angles to the major rolling direction.

The standard test specimen, 0.505 by 2 in., may be used when the material is so thick that the load required to break the conventional specimen is beyond the capacity of the testing machine. Extensometers are used only occasionally in testing plates and shapes.

In the bend test, a standard test coupon is bent cold to certain prescribed limits, depending on the hardness and thickness of the material. The bend test furnishes information concerning the suitability of the material to withstand forming by the fabricator.

The homogeneity test is specified for the higher grades of plates, particularly steel for use in fireboxes and high-pressure installations. This test is made by nicking and breaking a piece of the broken tension test coupon and examining the fracture for cavities and segregation.

Other tests that have a restricted application include hardness and low-temperature impact tests. Low-temperature impact tests are occasionally specified by fabricators of pressure vessels. The Charpy Keyhole specimen is the commonly accepted standard.

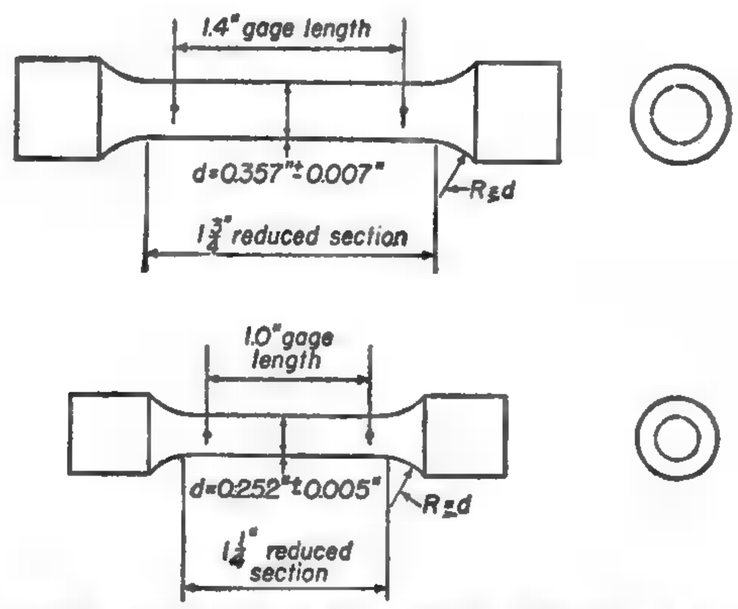
Nonferrous Metals

The tension test is used much more than any other for evaluating the acceptability of nonferrous rods, bars, shapes and plates. The bend test, next in importance, determines suitability for forming. Occasionally hardness tests such as Brinell and Rockwell are required.

Tension Tests. Rods, bars and shapes are tested in full size when practical. When a machined test specimen is necessary it is permissible to remove enough material from the test section of the specimen to meet the limitations of the testing machine. It is also permissible to machine a specimen to the form and dimensions of the standard tension specimen ½ in. in diam (*see* Fig. 3 of the article on page 87) or to a smaller size proportional to this specimen. Examples of specimens of smaller size are shown in Fig. 1. The gage length for the measurement of elongation is often 2 in. regardless of the size of the specimen; but to minimize the effects of specimen size on results of elongation, the gage length should be four times the diameter or distance across flats of the test section (in octagonal, hexagonal or square cross sections). For rods, bars and shapes as large as 1½ in. in diam or thickness the axis of the test specimen should coincide with the axis of the piece. For larger sections, the axis of the specimen should be located midway between the center and surface of the piece.



NOTE. If desired, the length of the reduced section may be increased to accommodate an extensometer.

Fig. 1 Examples of small specimens proportional to standard ½-in. diam specimen (ASTM E8–46)

In testing bars and shapes less than ½ in. thick, a specimen is frequently used that has the dimensions of the standard tension test specimen for sheet, with a reduced section ½ in. wide and 2¼ in. long. (*See* Fig. 2 of the article on page 87.) For testing plate thinner than ½ in., a specimen of this type is used. For plate ½ in. thick or more, the standard tension specimen ½ in. in diam is used. When plate no more than 1½ in. thick is to be tested, the axis of the specimen should be midway between the two surfaces of the plate, but for thicker plate the axis should be midway between center and surface.

Tension tests are usually made to determine yield strength, tensile strength and elongation. The yield strength for most nonferrous materials is specified as the stress corresponding to an offset of 0.002 in. per in. The yield strength is readily determined by a testing machine that is equipped with an autographic extensometer, which draws a load-strain curve as the test is being made. Yield strength is sometimes specified and determined as the stress correponding to a definite amount of extension under load; in this case the yield strength can be determined either with an autographic extensometer or merely an indicating extensometer. It is recommended that all tension tests be made in accordance with ASTM Standard Methods of Tension Testing of Metallic Materials.

Bend Tests. Bend test specimens from rods, bars or shapes are frequently of full cross section. When machined specimens are used, they are ordinarily either ¾ in. in diam or of rectangular cross section, having a width of approximately 1 in. or at least six times the thickness. The edges of such specimens may be rounded slightly before testing. For material no more than 1½ in. in diam or thickness, the bend test specimens are generally machined from the center of the section. For testing material of greater diameter or thickness, specimens are usually machined from the material midway between the center and the outside of the section. The bend test consists of bending the specimen, usually 180 deg, around a mandrel of specified diameter or radius. To pass the test satisfactorily the specimen must withstand the required bend, without evidence of fracture on the outside.

Hardness Tests. Brinell hardness tests of nonferrous materials consist of applying to a specimen a load of 500 kg through a ball 10 mm in diam for at least 30 sec, and determining the Brinell hardness by measuring the diameter of the impression in the specimen. For testing very small specimens or very thin specimens, it is sometimes necessary to make Brinell hardness tests with a ball of smaller diameter. For such tests, the ratio of the applied load (in kilograms) to the square of the ball diameter (in millimeters) should be five. Considerable care is required to make accurate Brinell hardness tests. To make sure that the results will be reliable such tests should be performed in strict accordance with the ASTM Standard Method of Test for Brinell Hardness of Metallic Materials.

Rockwell hardness tests are sometimes required for nonferrous materials. Rockwell hardness scales are numerous and involve different penetrators, major loads and dial figures. No attempt is made here to list all these combinations, since they can all be found in the article on page 93 of this Handbook and in the ASTM Standard Methods.

Mechanical Testing of Tubular Products

By A. W. SIMPSON*

TENSION, compression, hardness, impact, creep, fatigue, and other standard mechanical tests are made on specimens machined from tubular products. Modification of the standard specimens may be required on account of the curvature and the limited wall of the tube or pipe. In addition, special mechanical tests are applied, depending on the intended use and the kind or grade of metal.

Tension Tests. The evaluation of the mechanical properties of tubular products is usually obtained from a tension test of a longitudinal strip. The standard turned tension test specimen, 0.505-in. diam, is rarely used, since it can be obtained only from heavy-wall pipe. With the strip specimen, accurate measurements of the reduction of area after rupture are unobtainable, and the ductility is judged by the measurement of the elongation in a given gage length, usually 2 in. The elongation is not constant for all sectional areas but it increases as the sectional area of the test specimen increases. Consequently, when heavy-wall pipe is being tested, a change to the standard turned tension test specimen with an area of 0.2 sq in. results in a lower elongation than that which will be obtained with a strip tension test from pipe of the same weight. Subsize turned tension test specimens are frequently machined from pipe with walls between ¼ and ½ in. thick. The elongation values are then adjusted by the rule that the gage length shall be four times the diameter of the specimen. The over-all length of the subsize specimen is the same as for the standard specimen, 0.505 in. in diam, if it is desired to attach an extensometer with a 2-in. span. For nonferrous metals, the specimen blanks from light-wall tubes are machined to a rectangular section; from

* Supervising Engineer, Research Laboratory, National Tube Company, Pittsburgh.

Prepared for the Subcommittee on Mechanical Testing.

tubes that have a very light wall, blanks may be hammered flat on a hardwood block with a rawhide mallet.

Tension tests are frequently made requiring the full section of the pipe. For such a test, a short length of pipe is fitted with a hardened steel plug in each end and is pulled in the tension-testing machine by suitable gripping jaws, shown in Fig. 6 of the article on page 88.

Flattening Tests. This kind of test is made on short sections or crop ends of pipe by compressing them between parallel plates. The closeness of approach of the parallel plates depends on the grade of material and the dimensions of the pipe. In general, flattening tests are not feasible on pipe with diameter to thickness ratios lower than 10. No break or crack in the wall of the pipe should occur within the limits of approach of the parallel plates. Certain nonferrous tubes are subjected to a flattening and doubling-over test with the doubled-over bend at right angles to the longitudinal axis of the pipe.

Bend Tests. Bend tests are made on suitable lengths of pipe, usually in the smaller sizes, for nonferrous metals and the milder grades of steel. The test is made cold around a cylindrical mandrel several times the diameter of the pipe. The mandrel is provided with a groove to fit the outside diameter of the specimen. No cracks should be developed and no welds should be opened in testing.

Drift Gaging. Drift tests of pipe are made to verify the roundness of the pipe and to test for a minimum inside diameter. This is accomplished by passing a cylindrical mandrel or a ball of specified dimensions through the pipe without sticking.

Expansion Tests. Expansion tests of tubes are made in order to determine the tightness of a longitudinal weld and the soundness of the metal or its freedom from flaws and surface defects. This is accomplished by forcing a tapered pin of specified dimensions a prescribed distance into the end of the tube, thereby expanding it. Failure may occur by splitting at the weld or in the tube wall.

Crushing Tests. These tests are made on mild steel grades and on some grades and sizes of nonferrous tubular products to disclose the general ductility of the metal and to develop surface flaws. A short length of tube is loaded axially in compression until it is reduced a specified amount in length. The metal should not break or crack.

Crushing tests are satisfactory only for a limited range of sizes of tubular products. Difficulties in obtaining good test behavior are encountered when testing tubular products that have large ratios of outside diameter to wall thickness, as well as when testing those that have small ratios. In the first instance trouble comes from the difficulty in keeping crushing specimens truly circular and loading them uniformly. At the other end of the range, with sizes that have a small bore and a heavy wall, the specimens possess so much inherent stability that they will not crush in a manner similar to that of the intermediate size of tubular specimens.

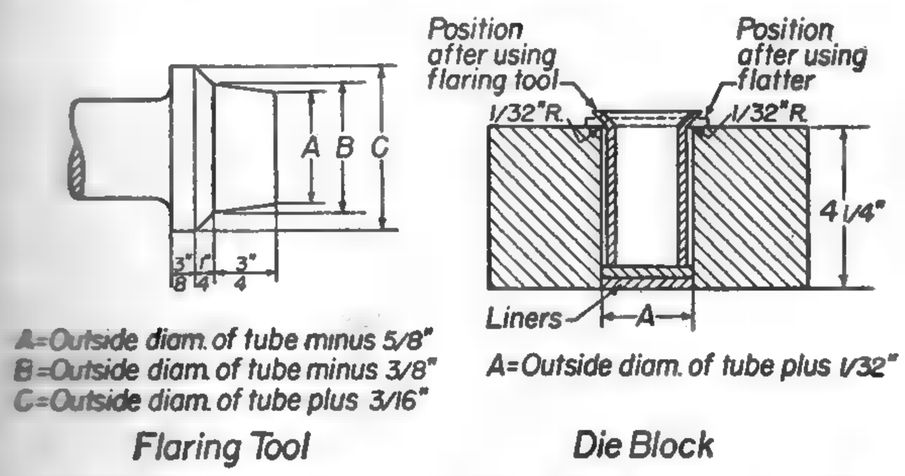


Fig. 1 Flaring tool and die block for flange test (ASTM)

Flange Tests. Flange tests are made on short test sections cut from tubes of nonferrous metals or of mild steel in order to show the ability of the tubes to withstand a flanging operation. The flange is made on one end of the specimen by using a flaring tool and a die block of specified dimensions (*see* Fig. 1). The flange is turned over at right angles to the body of the tube and should not show a crack or flaw in the metal. The outside diameter of the flange varies with the kind of metal.

Pressure Tests. Pressure tests involve the use both of pneumatic pressures and of hydrostatic pressures to determine whether a vessel is leakproof for gases as well as for liquids. Hydrostatic pressure is most frequently employed to determine the resistance of the material against internal or external pressures. The test may continue to destruction or it may be simply a proof test for inspection purposes. The proof test consists of the imposition of a momentary pressure of specified magnitude in order to determine the soundness of welds and the tightness of joints. The time of holding the hydrostatic pressure on the test piece varies. For the routine commercial testing of pipe, the duration of the test will not exceed 5 sec, but for special pressure vessels the test may last for hours. The pressure is limited to a value not greater than that prescribed by Barlow's formula,

$$P = \frac{2St}{D},$$

where P = the pressure, in psi
S = the maximum allowable fiber stress, in psi
t = the thickness of the metal, in inches
D = the outside diameter, in inches

Bursting tests are made on pipe, tubes and cylindrical pressure vessels, by using a suitable hydraulic pump to increase the pressure gradually to the maximum. With preliminary measurements of the average outside diameter and wall thickness, the maximum fiber stress at bursting can be calculated by Barlow's formula, already given.

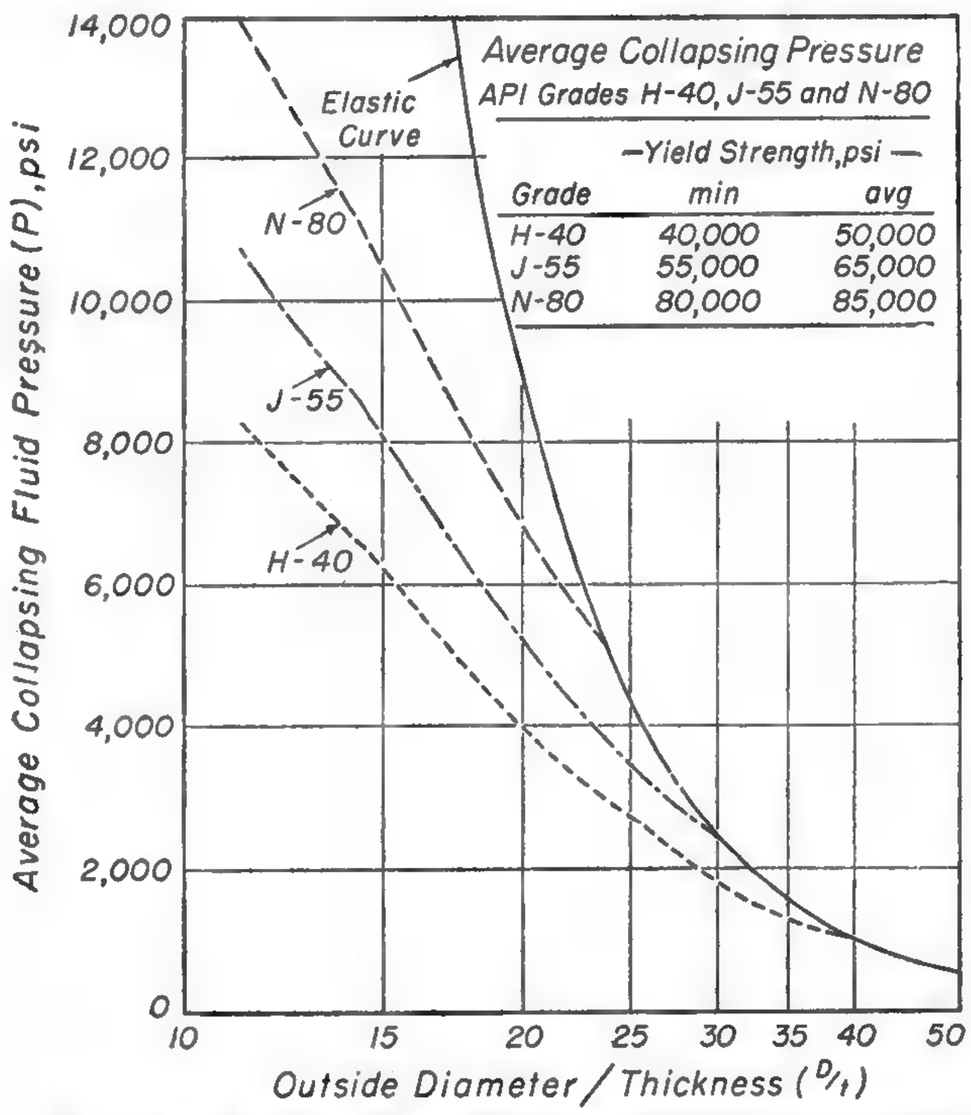

Fig. 2 Effect of D/t ratio on the average collapsing fluid pressures for certain grades of steel

At times, inspection tests for tubular products call for the measurement of the permanent set of the material after applying a stated maximum internal pressure. High-pressure gas cylinders are tested while immersed in a jacket containing a known volume of water. When the maximum pressure is applied within the cylinder, the volume expansion of the cylinder is measured by the displacement of water from the jacket. After the pressure has been relieved, the permanent set of the cylinder is indicated by the change in the volume of water in the jacket. The permanent set may be not more than ▪ or 10% of the total expansion while under the maximum pressure. The exact figure depends on the specification.

The need for subjecting the pipe to external fluid pressure is less frequently encountered. For certain uses, however, tests under external pressures are important. For the setting of casing in oil wells, the resistance of the material to external fluid pressure must be known in order to determine the safe setting depth. The tests to discover this point are called collapse tests. The collapse test is made on either an open-end specimen or a closed-end specimen placed in a heavy cylindrical jacket capable of withstanding high internal hydrostatic pressures. The open-end specimen projects through the jacket heads, which are provided with packing glands to hold the pressure. The closed-end specimen is used as a capsule short enough to fit inside the jacket, which is then provided with solid heads. The ends of the closed-end specimen are sealed by mechanical means or by welding circular plates over each end. For either the open-end or the closed-end test the hydraulic pressure is applied gradually, with a hydraulic pump, at a rate that will permit reading the maximum pressure on an indicating gage when the specimen collapses. Either a mercury column or a Bourdon-tube gage may be used. To obtain reliable results equipment must be available for calibrating the pressure gage at frequent intervals. The length of the collapse-test specimen should be at least ten to twelve times the outside diameter in order to eliminate the end effect on the collapse value. Original measurements of the wall thickness are made at both ends of the specimen to obtain the maximum, the minimum, and the average wall. Original measurements of the outside diameter are also made at intervals along the length in order to obtain the maximum, the minimum, and the average outside diameter. The ratio D/t is determined by using the measurements of the average outside diameter nearest the collapse lobe and the average wall thickness at both ends of the specimen. Collapse for failures that are plastic depends principally on the D/t ratio of the pipe and on its yield strength. This is illustrated by the curves of Fig. ▮ which, with the formulas that follow, apply to steel pipe.

For values of D/t of approximately 14 and up to and including the point of intersection of each curve for plastic failure with the elastic curve, the collapse value,

$$P = YS\left(\frac{2.503}{D/t} - 0.0460\right)$$

where P = the collapse value, in psi and YS = the average longitudinal tensile yield strength, in psi.

For values of D/t less than 14 approximately

$$P = \frac{2\ YS}{(D/t)^2}\left(\frac{D}{t} - 1\right)$$

For failures that are elastic

$$P = \frac{62.6 \times (10)^6}{\frac{D}{t}\left(\frac{D}{t} - 1\right)^2}$$

This formula, which applies to steel pipe, is a practical modification of the more general theoretically determined elastic curve equation,

$$P = \frac{2\ Et^3}{(1 - r^2)\ (D_1)^3}$$

where E is the modulus of elasticity and
r = Poisson's ratio
D_1 = the diameter at the midpoint of the wall = $D - t$.

Mechanical Testing of Wire

By H. C. Boynton* and H. J. Godfrey*

A description of the mechanical testing of wire must necessarily be general because of the many shapes of wire—round, flat and irregular—and the many kinds of metals and alloys, including iron, steel, copper, brass, bronze and aluminum, that are used in producing wire with or without protective coatings. Information regarding the mechanical testing of any particular material should be obtained from a specification or other authoritative sources.

Since there may be some question concerning the distinction between flat wire and strip, the following definition* is given:

"Dimensionally, flat wire is a product having a width greater than its thickness; the maximum width is ½ in. and the cross-sectional area does not exceed 0.050 sq in. Steel products which exceed those dimensional limits are classed as cold rolled strip, cold finished bars or shaped wire. A product with a raw slit edge is classed as cold rolled strip."

Similar nonferrous products are made in considerably larger sizes.

A number of tests are used to determine the strength and ductility of wire. The processing of certain types of wire is such that the finished material is definitely anisotropic, requiring various types of tests to determine its physical characteristics completely.

The mechanical tests usually employed are the following: (1) tension, including measurements of elongation and reduction of area, (2) torsion, (3) bend, (4) wrap, (5) fatigue, (6) hardness.

* John A. Roebling's Sons Company, Trenton, N. J.
Prepared for the Subcommittee on Mechanical Testing.

* Steel Products Manual on Flat Steel Wire, Section 17, AISI, February 1942.

Sampling. Specimens for testing may be obtained by cutting from the ends of the coils immediately after processing or before fabrication into the desired product, or at both times. Since these coils contain many thousands of feet, sometimes miles, of wire in the fine sizes, the desired samples are cut to meet the customer's specifications.

Tension Tests. These are usually made in a hydraulic or screw type of testing machine equipped with special hardened steel jaws, which ordinarily have serrated tooth grips. For the testing of fine round wire or thin flat wire, grips of the drum or snubbing type are necessary to prevent jaw breaks.

The speed of testing has been found to influence the tensile strength of wire. For example, with hard drawn copper a maximum speed of 3 in. per min is suggested by ASTM Specification B 1-40 when a specimen 60 in. in gage length is used.

The elastic properties, such as proportional limit and yield strength, are sometimes required, particularly on tempered and hard drawn spring wire. This information is obtained either by extensometer readings or autographic recording devices. The proportional limit of a cold drawn wire is rather difficult to obtain and depends largely on the accuracy of the extensometer.

Elongation Tests. The test for elongation is made at the same time as the test for tensile strength. Two methods are used: (1) The gage length (usually either 10 in. or, for wire ⅛ in. in diam and larger, four times the diameter) may be marked on the sample before testing, and the actual or "recovered" elongation may be measured directly on the test specimen after fracture. Or (2) an extensometer or strain gage may be clamped on the specimen in the tensile machine and the total elongation may be observed visually at the time of the fracture. Method 2

will yield figures somewhat higher (about 1% on hard drawn wire) than those obtained by "recovered" elongation measurement.

In the testing of hard drawn copper the elongation is measured on both 10-in. and 60-in. gage lengths, depending on the size of the wire. The elongation in 60 in. is measured between the jaws of the testing machine. The zero reading is taken with a 10% load on the wire and the final reading is taken at the time of fracture.

Reduction of Area. This test is made on the tensile test piece. The original diameter is obtained by a micrometer reading to 0.001 in. for large wire and 0.0001 in. for fine wire. After fracture the reduced diameter is measured with a pointed micrometer.

Torsion Test. A torsion test on round wire is made by clamping a sample between two jaws, usually 8 in. apart, one fixed and the other free to rotate. The specimen is kept straight by a weight attached to the fixed jaw. The movable jaw is rotated by power or by hand at a constant speed and the number of twists necessary to fracture the wire is recorded by a counter.

The number of twists for any given type of wire is not comparable unless computed on the basis of a gage length of 100 wire diam. An additional torsion test sometimes used for oil-tempered spring wire is called "reversed torsion". A specified number of forward and reverse twists is required for a given size and grade of wire and the fracture should be a square break normal to the axis without splits or cracks.

Bend Tests. These tests are made on round wire by clamping the wire between jaws of exact radii, ordinarily a function of the diameter of the wire. The upper part of the wire is free to move as it is being bent alternately right and left through an angle of 180 deg. The minimum number of bends to fracture the wire is specified. The figures obtained from the bend test generally correlate well with the figures for reduction of area; that is, high bends accompany a high reduction of area.

Bend tests are also made on flat steel wire, usually on material containing less than 0.25% C. The severity of the bend test depends on the classification of the material as listed in the AISI Manual 17.

Another form of bend test for very fine round wire is the kink test. For this test a loop is made in the wire and then tension is applied by hand, causing the wire to kink. Some specifications require that the wire should not fracture when kinked; others require that the kink should be opened a desired amount without fracturing.

Wrap Tests. Wrapping may be done manually or by a special machine. Some users specify that wire must be capable of winding on its own diameter or a larger one. The wrap test is employed for testing the ductility of the metal and users may demand winding "on or off" certain size mandrels without fracture. When wrap tests are made for determining the adherence of a coating, a larger size mandrel is specified than for testing the ductility of the metal alone. (ASTM Specification A 122-41). Wrap tests are regularly specified for bare or zinc-coated iron and steel wire and for bronze wire.

Fatigue Tests. These tests are not a part of conventional specifications but are sometimes made when it is desired to know something about the life of the wire under alternate bending stresses. Fatigue tests on round wire are usually made on a "rotating-strut" machine. Flat wire may be tested on machines of the repeated-flexure type. It is important to make fatigue tests on wire without machining the surface, because the surface condition is of prime importance. The rotating-strut machine was developed for round wire in order to have the fatigue fractures take place away from the gripping points. The bending stresses are zero at the gripping points and maximum at midlength of the specimen.

Hardness Tests. The Rockwell hardness test, although sometimes made on round wire, is generally used for flat wire. For thin-gage flat wire the Rockwell Superficial hardness tester must be employed. If wire is so thin that the impression made by the ball or diamond cone shows through on the underside of the strip, the test is of little value. In such an instance the tension test is substituted. The hardness test procedure for flat steel wire as suggested by the AISI is as follows:

Carbon Content, per cent	Treatment	Thickness, in.	Test Procedure
0.25 max	All tempers	0.040 and heavier	Rockwell B
0.25 max	All tempers	Less than 0.040 to 0.010 incl	Rockwell 30-T
0.25 max	All tempers	Less than 0.010	Tension Test
More than 0.25	Annealed or hard rolled	0.040 and heavier	Rockwell B
More than 0.25	Annealed or hard rolled	Less than 0.040 to 0.010 incl	Rockwell 30-T
More than 0.25	Annealed or hard rolled	Less than 0.010	Tension Test
More than 0.25	Tempered	0.025 and heavier	Rockwell C
More than 0.25	Tempered	Less than 0.025 to 0.015 incl	Rockwell 30-N
More than 0.25	Tempered	Less than 0.015 to 0.005 incl	Rockwell 15-N

Hardness tests, if specified for round wire, are made either directly on the round surface or on a flat surface prepared by filing or grinding. If tests are made directly on the round surface a correction factor must be used.

Mechanical Testing of Forgings

By A. O. Schaefer*

THE tension test is the mechanical test most frequently applied to forgings, although hardness tests and bend tests are often used and a number of standard specifications require these tests. In the United States, notched-bar impact tests are seldom applied to forgings except to those used in aircraft and ordnance.

Tension Tests. The standard machined tension test specimen, 0.505-in. diam and 2-in. gage length, is most frequently used, although smaller specimens of the same proportions (0.357-in. diam, 0.252-in. diam, and even 0.125-in. diam) are used when the size of the forging or the location of the test specimen does not permit taking a test specimen of the standard size.

Tension tests from forgings are generally taken from extensions or prolongations when the size of the forging permits. Tension tests from smaller forgings and from closed-die forgings may be taken from one or more forgings in a melt or heat treatment group by cutting up a representative forging or forgings.

It is desirable to take tension tests from locations that are representative of the entire forging. For this reason, it is usually required by forging specifications that the prolongations or extensions provided for tests be of the same size as the forgings they represent. Test specimens are usually taken at sufficient depth from the surface to be fairly indicative of the condition of the forging. It is usually specified, for solid forgings, that they be taken at half-radius; and for hollow or bored forgings, that they be taken at mid-wall thickness. When forgings are heat treated by a process including a liquid quench, test specimens must be taken at sufficient depth to avoid end effect, or allowance for it will have to be made in design calculations. Test pieces from forgings that are cut up for testing purposes are usually taken from either the center of the section, or from the most highly stressed location.

Some forging specifications permit taking representative tension test specimens from bars or billets that have received approximately the same amount of forging work as the pieces they represent, and that have been treated together with them or in the same way. Such tests are usually considered an indication of the quality of the steel from which the forgings are made. They indicate that it

* Executive Metallurgical Engineer, The Midvale Co., Philadelphia.
Prepared for the Subcommittee on Mechanical Testing.

is possible to obtain in the forgings themselves properties of the order revealed in the tests, rather than that such properties are to be found in the forgings.

It is to be expected that a difference will be found in the results of virtually all the common mechanical tests, between specimens taken parallel or perpendicular to the direction of the hot mechanical working. The forging manufacturer usually applies forging work in such a way as to leave flow lines in the optimum direction. Therefore it is frequently stated that test specimens should be taken in the direction in which the forging had greatest distortion. This means longitudinal or axial test specimens for shafts and similar forgings, and tangential or transverse test specimens for rings or upset disk forgings. There are notable exceptions to this rule, including ordnance forgings, pressure vessels, and other forgings subject to stress in service in a direction perpendicular to the direction in which the forging is most extended in manufacture. Specifications for such products generally recognize that the ductility to be expected in transverse tests is less than that to be expected in longitudinal tests.

The number of tension test specimens necessary to represent a forging or forgings can be determined only after due consideration of a number of factors. It is impossible to state a comprehensive set of rules to cover all possibilities. In general, it might be said that fewer tests are necessary for untreated or annealed carbon steel forgings than for heat treated alloy steel forgings. Size is an important factor. For representative tests which are frequently applied, small forgings may be grouped as those from a single melt, those heat treated in one charge, and so on. Forgings heat treated in continuous furnaces are often tested by taking specimens at intervals from the product of the furnace.

Large forgings and those subject to severe stresses in service are usually tested individually. As the size and weight of forgings increase, it may be necessary to test forgings in more than one location. Thus ship shafting more than 7000 lb in weight is tested on both ends. Turbine or generator rotors subject to high rotative stresses are tested at a number of locations, including tangential or radial specimens from the bodies and tangential or longitudinal specimens from the shaft ends. Forged pipe and pressure vessels may be tested either longitudinally or transversely and pinion forgings are tested transversely from locations representing the condition of the teeth.

Bend Tests. Bend tests in some form are often required for forgings, particularly those for marine propulsion units. Usually not more than one bend test per forging is specified, regardless of the number of tension tests, and this one is taken from the end of the forging representing the top end of the ingot. Bend tests are also required for pressure vessels, such as boiler drums. Forged pipe is tested by cold bending a piece or by a flattening test made on a section of the pipe. Both of these tests approximate in value the conventional bend test made on a machined bar. It is usually required that a bend test specimen be bent cold 180 deg around a pin of stated diameter, although the angle of the bend may be decreased in tests applied to harder forgings.

Hardness Tests. Hardness testing ranks next in importance for its application to the testing of forgings. Hardness testing may be applied to every forging of a group from which only representative tension test specimens have been taken. In this instance the test is made to give an indication of the uniformity of the group. In general, hardness testing is specified for forgings when no tension tests are to be made. In such forgings, the results of the hardness test indicate the strength of the material.

The Brinell machine is standard equipment for the hardness testing of forgings. It is highly desirable, and usually required for important forgings, that the Brinell hardness-testing equipment be standard, that is, imposing a load of 3000 kg on a 10-mm diam ball. Other devices may be utilized for the Brinell hardness testing of forgings when such standard equipment is not available. One of the testing aids most commonly used is the Brinell meter, which consists of a standard Brinell ball held in a fixture that exposes one side of the ball to the surface of the forging to be tested, and the other to a bar of known Brinell hardness. One blow of a sledge leaves an impression both in the forging and in the standard specimen. The unknown hardness of the forging is determined from the known hardness of the standard specimen by multiplying by the inverse ratio of the squares of the diameters of the impressions. Another type of equipment strikes the ball by means of a calibrated coiled spring.

More accurate readings are obtained by small portable hydraulic machines adjusted to give a true 3000-kg load, or standard Brinell machines may be mounted on rigid supports in such a way that large forgings may be placed under them. Smaller forgings may be tested on standard machines.

The scleroscope hardness is used for forgings that are practically finished and consequently should not be marked on the surface by Brinell or Rockwell hardness testing.

Hardness readings should be taken after removal of sufficient metal from the surface to avoid effects of decarburization. When the hardness of the forging is critical, it is advisable for producer and consumer to agree in advance on the exact location of the test.

Notched-Bar Impact Tests. It is not usual to specify that notched-bar impact specimens be taken from forgings, except from those subject to similar stress conditions in service, or from those in which the impact test is utilized as an indication of the effectiveness of the quenching treatment. Bars should be taken from locations selected on the same basis as those for tension tests. In general more impact test specimens are required, and the results are averaged to allow for the variations in results.

Other Tests. Compression tests, torsion tests, fatigue tests and creep tests are seldom applied to forgings except for research purposes. In addition to the conventional tests already enumerated several others have been applied to certain products. Railroad axles are sometimes tested by allowing a weight to fall on them from a specified height, measuring their deflection and examining them for cracks. Pressure vessels, pipe, headers, and so on are usually tested hydrostatically at 1½ to 2 times the working pressure.

Mechanical Testing of Castings

By A. Allen Bates*

TENSION and hardness tests are the two tests most commonly applied to castings as well as to wrought products. The methods of making these tests are the same for both classes of products. The standard machined specimen, 0.505-in. diam and 2-in. gage length, is generally used for tension tests of castings; the values usually recorded are those for tensile strength, yield point, percentage elongation in 2 in., and reduction of area.

The great variety of sizes and shapes among castings requires that particular thought be given to the method of locating test specimens in relation to the castings. Occasionally it is desirable that test specimens be cut from actual specimen castings at sections determined jointly by the customer and the foundry; for example, at sections of maximum service stress.

More frequently, test coupons are cast as protuberant bosses on the body of the casting. These coupons may be detached by flame cutting or sawing, without injury to casting or to coupon if reasonable care is taken in the operation. When the casting is to be heat treated, it is customary to make not more than a partial detaching cut before treatment.

A third and common method is to cast test coupon blocks outside the casting but attached to it. In this

* Vice President, Portland Cement Association, Chicago.
Prepared for the Subcommittee on Mechanical Testing.

method, as in the previous one, care must be taken, first, to insure the soundness of the coupons by designing, locating and gating them properly and, second, to prevent bleeding of the casting or other harmful effects.

A fourth and frequent practice is to cast corresponding test blocks and castings simultaneously but separately. This method is often preferred because it introduces no problem in the successful pouring of a sound casting. When this unattached type of specimen is used—or the second and third (attached) types mentioned above—the tests should be regarded more as a measure of the metallurgical characteristics of the metal than as determinations of the actual mechanical properties of the castings.

The number of tests required for reasonable representation of the castings must be a matter of agreement between customer and foundry. Experience is needed to determine this number judiciously, because of wide variations, depending on the nature of the casting, the kind of service that it must perform, and other factors.

Bend Tests. Bend tests are sometimes required, especially when the castings are designed for applications in which pronounced vibratory or shock stresses will be encountered or fabrication by welding is involved, or both. The bend test is usually performed on a machined bar that has a rectangular cross section, 1 in. by ½ in., and slightly rounded corners. The specimen is generally required to bend cold around a pin 1 in. in diam to some agreed angle, as 120 or 90 deg, without cracking on the outside of the bent section.

Hardness Tests. Because of its speed and simplicity, the hardness test is by far the most frequently used of all mechanical tests for castings. The Brinell hardness test is the one most commonly used for castings as well as for wrought products. It is carried out in the various ways described in the section on testing of forgings, page 135. Rockwell and scleroscope tests are usually made only in special instances; for example, when the relatively large Brinell impression is undesirable or when the castings are of such size as to make them particularly suited to test by Rockwell or scleroscope machine.

The hardness test is sometimes applied to all the castings of a given group for the purpose of assuring uniformity. This testing is frequently done by the foundry for its own information and protection. Conversion relationships among Brinell, Rockwell and scleroscope hardness test values are only approximate at best and should not be used for comparison of castings that differ greatly in chemical composition or heat treatment.

Transverse or Flexure Tests. A rather special test known as the "transverse" or "flexure" test is commonly applied to cast iron to determine a "modulus of rupture" or "modulus of shear". The test, commonly performed in a tension-testing machine, consists in loading transversely a round test bar that is supported at both ends. Test bars are machined or otherwise prepared for testing, depending on stipulations in individual orders or contracts.

The diameters used are commonly 0.875, 1.20 and 2.00 in. with corresponding lengths of 15, 21, and 27 in. The distance between supports would be respectively 12, 18 and 24 in. Load to rupture and deflection at rupture are measured and applied to the following formulas. Standard specifications do not include the minimum values to be obtained, but leave this decision for agreement between purchaser and consumer.

$$\textit{Modulus of Rupture} = \frac{2.546\ LS}{D^3}$$

where L = span length or distance between supports, in inches

S = breaking load, in pounds

D = diameter of test bar, in inches

$$\text{Modulus of Elasticity, psi} = \frac{\text{Load in pounds} \times 1194}{\text{Deflection, in inches}}$$

Typical details of this test are given in ASTM Specification A 48-46.

Other Tests. Hydrostatic pressure tests are applied to castings for special uses involving high temperature, high pressure, or both; for example, certain valves, fittings, flanges and such. Other tests—creep, endurance and the like—are used for special investigations or development.

Mechanical Testing of Weld Metal and Welded Joints

BY THE SUBCOMMITTEE ON WELDING AND CUTTING*

MANY products and structures, such as pressure vessels, ships, tanks, buildings and machinery, fabricated by fusion welding, are made under some form of specification that requires inspection by the purchaser. In certain welding applications the inspection must conform to a particular code of construction requirements, and tests are specified to govern the qualification of the welding operator or the quality of the welding performed.

Strength and ductility are the mechanical properties most frequently measured in order to determine the quality of weld metal and welded joints. The tests that are used for evaluating these and certain other mechanical properties, will be described in this article. For a brief discussion of the inspection of welds by nondestructive methods, the reader may refer to the article on page 71 of this Handbook.

Tension Test. The specimen for a tension test of a welded joint is usually taken transversely, with the weld in the center of the specimen, as directed in the ASTM standard for flat-plate tensile specimens (Fig. 1). The weld reinforcement may be removed or not, depending on the information sought.

It is customary to obtain only the tensile strength and the location and type of failure from a joint type of tensile specimen. Values for yield point and ductility

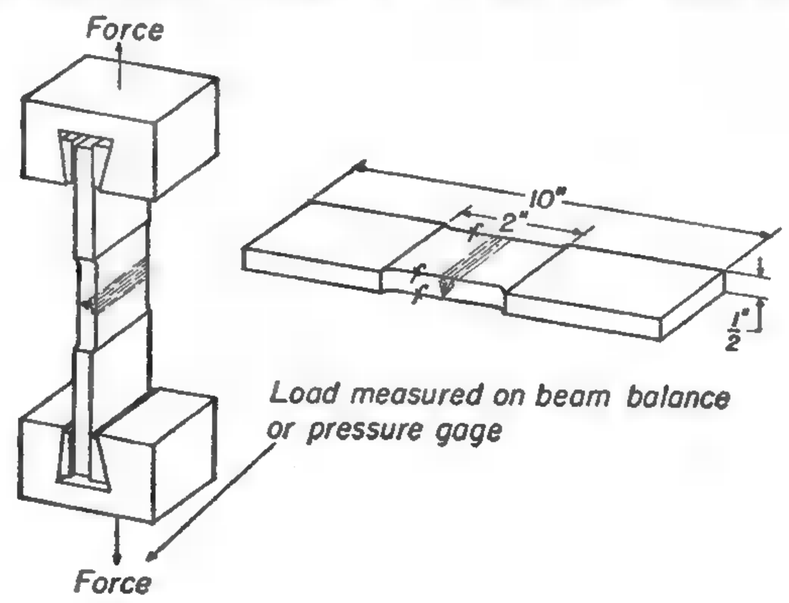

Fig. 1 A tensile specimen for testing welds

are sometimes obtained but usually they have little significance because of the nonhomogeneity of the reduced section of the specimen, which is composed of both base metal and weld metal. For high-strength welds that are stronger than the plate, the yield point will be that of

* The members of this subcommittee are C. W. Obert, *Chairman* (The Linde Air Products Company), C. L. Altenburger (Great Lakes Steel Corporation), Roger W. Clark (General Electric Company), Chas. H. Jennings (Westinghouse Electric Corporation), H. L. Maxwell (E. I. du Pont de Nemours & Company), H. R. Morrison (The Linde Air Products Company) and E. H. Roper (Air Reduction Sales Co.).

Some of the information contained here has been abstracted from an article prepared for the Subcommittee on Mechanical Testing by A. J. Raymo, Works Manufacturing Engineer, The Baldwin Locomotive Works, Philadelphia.

the base metal and the elongation will be confined only to the plate. For welds that are weak in comparison with the plate, the yield point will be that of the weld metal and the elongation will be principally in the weld. The ductility of the weld metal in a joint is evaluated best by means of the free-bend test.

In order to obtain the tensile strength, yield point, elongation, and reduction of area of the weld metal, specimens entirely of weld metal are taken longitudinally

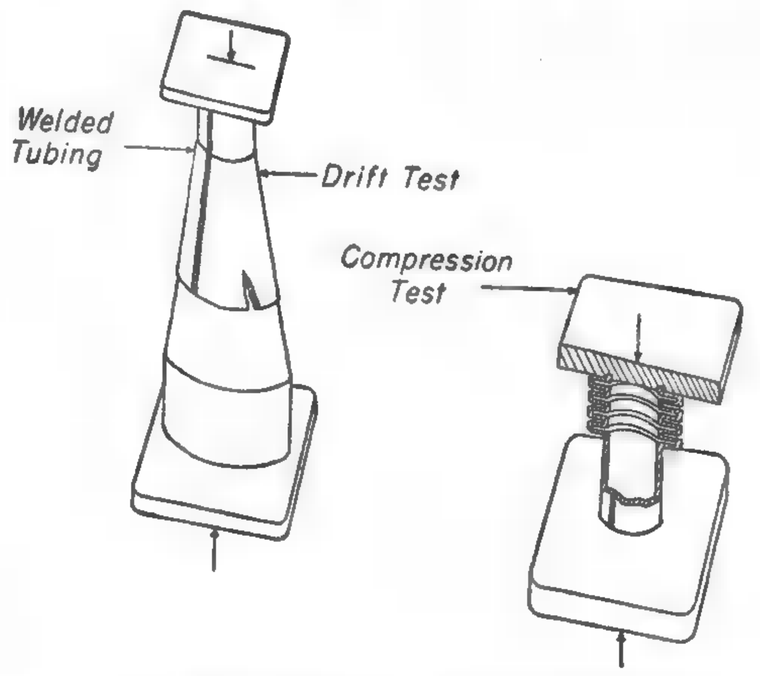

Fig. 2 Drift and compression tests for welded tubing

from the weld. A specimen 0.505 in. in diam can be taken from welds made in plate 5/8 in. thick or more. Specimens proportionately smaller can be taken from welds in thinner plate; for instance, a specimen 3/8 in. in diam with 1.5-in. gage length may be taken from a 1/2-in. test plate. The tension test specimen that is all weld metal gives reliable data concerning the mechanical properties of the weld metal, and is required by the ASME Boiler Construction Code and by the AWS specifications for filler metal.

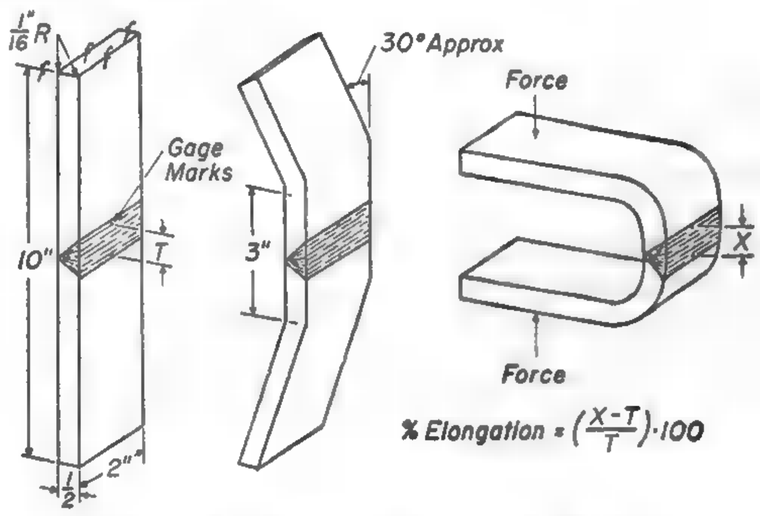

Fig. 3 A bend test for testing welds

For evaluation of fillet welds, a tension test is used to determine the tensile strength, and a guided bend test is used to determine the soundness, fusion and ductility. The tension test is commonly applied to a specimen formed by fillet welding two splice bars to opposite sides of two butted test bars; the fillet welds are made either longitudinally or transversely along the edges of the splice bars. In either design, the resulting failure of the fillet weld is a shear failure and the stress is recorded in pounds per square inch of weld throat or in pounds per linear inch of weld, which serves as a ready means of comparison for any average size of fillet.

Drift Test. From thin-wall welded tubing, it is impossible to obtain the regulation tension test specimens, and a drift test (Fig. 2) has been devised to determine the strength of the weld. This simple test consists in forcing a tapered, hardened steel drift into the end of the tube that has been welded longitudinally. The drift may be driven by a hammer, or forced in with a press; pressing is the more desirable method because it eliminates shock. The end of the tube is gradually expanded until it splits, usually outside the welded area, showing the weld to be stronger than the base metal and to have adequate toughness and ductility. The distance to which the drift is forced into the tube, may be taken as a measure of the ductility of the welded tube. Since this test stretches the welded joint, the action is quite similar to that of the tension test.

Crush Test for Flanging Qualities. A short length of welded tubing, when placed axially in a compression machine and loaded, will collapse like a bellows and, in doing so, will be subjected to shear, tensile and bending stresses. This qualitative test for ductility affords a good evaluation of the flanging qualities of the welded tube. Of course, a simple flanging operation is an adequate test of the ability of the welded tube to withstand flanging operations, but flanging is less severe than the crush test.

Hydrostatic Tests. The hydrostatic test may be used as a destructive or a nondestructive test. The destructive hydrostatic test, an extension of the tension test, is applied in some instances to pressure vessels and closed containers in order to determine the ultimate strength of them, as well as to ascertain the character of the failure. However, this form of test can be applied only in connection with design studies and research and is not necessarily a test of the weld joint, since the vessel may rupture at a place apart from the weld. A test of this type is a test of the entire structure and will reveal the weakest section, whether weld or base metal.

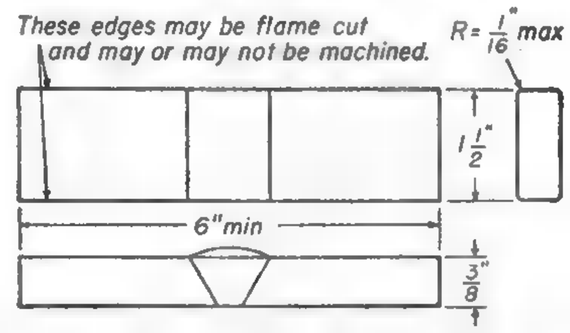

Fig. 4 A specimen for face-bend and root-bend test (AWS)

Weld reinforcement and backing strip, if any, should be removed flush with the surface of the specimen. If a recessed strip is used, this surface of the specimen may be machined to a depth not greater than the depth of the recess in order to remove the strip; however, in such instances, the thickness of the finished specimen should be that indicated above.

The nondestructive hydrostatic test is essentially a proof test, made to determine whether or not the vessel or container being tested, contains leaks, and whether it will withstand working pressures. This type of test may be made with a variety of mediums, such as water, oil, or air, and the pressures applied will depend on the mediums used and the individual container that is being tested. In general, the test pressures that are used range from 1¼ to 2 times the working pressure of the design.

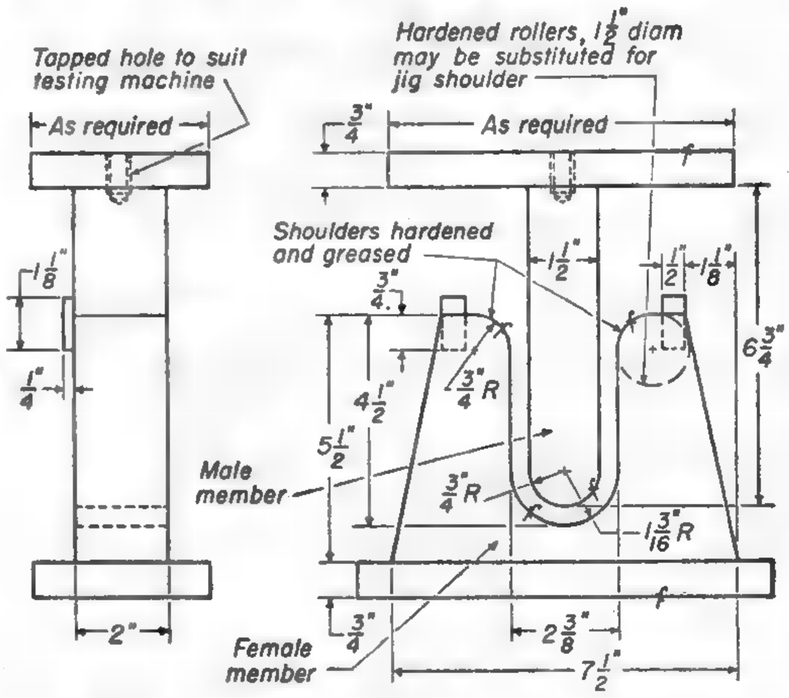

Fig. 5 A test jig for making a guided bend test (AWS)

Tension-Impact Tests. The tension-impact test has been developed in order to permit evaluation of the effect of rate of straining. The advantage of such a test is that all zones of a welded joint can be tested in impact. The test results are expressed in foot-pounds of energy required to break the specimen, rather than in pounds per square inch. For further discussion of the tension-impact test the reader may refer to page 114 of this Handbook.

Shear Tests. Shear tests of fillet welds can be conducted about as easily as tension tests. The shearing strength of a joint can be evaluated conveniently in terms of pounds per linear inch of failure in the weld. This value is computed by dividing the maximum force by the sum of the lengths of the welds that ruptured.

Spot welds are sometimes tested by means of a lap shear test. The specimen for this test is prepared by lapping two strips of metal and joining them by means of a single spot weld. The specimen is then pulled to failure on a standard testing machine. Failure may occur either by shear of the weld metal or by tearing of the parent metal. Shear strength is usually expressed in pounds per spot weld.

Bend Tests. Since the tension test, using flat specimens, gives no quantitative measurement of the ductility of the welded joint, the free-bend test has been devised to furnish this much-needed information. Free-bend tests yield quantitative data independent of the thickness of the specimen, provided the width is at least three times the thickness. However, the ASME Boiler Construction Code calls for a width one and one-half times the thickness.

Figure 3 shows the design of the free-bend specimen and the method of preparation. After the initial bends have been made, the specimen is placed as a strut in a vise or press and is bent until failure occurs on the outside bent surface between the gage marks, or until the specimen is bent double. Corner cracks are not considered failures. Any failure on the surface is not considered such until its greater dimension is 1/16 in. or more. The elongation of the outside fibers is measured directly with a flexible scale, or it can be calculated from the curvature by the formula $100t/2R$ where t is the thickness and R the radius to the neutral plane. The ductility can also be measured by means of a bend extensometer; however, direct measurement is more satisfactory. For specimens ½ in. or more in thickness, a heavy press or tension-testing machine is desirable.

The guided bend test is for determining the soundness of welds and is ordinarily used to check the ability of an operator to make satisfactory welds. Fillet-welded or butt-welded joints are made in plates, from which are machined two specimens 1½ in. wide. (Fig. 4). These specimens are bent 180 deg in a special bending fixture (Fig. 5) with the root or face of the weld in tension. This test is usually evaluated on a "go or no go" basis; bending through a certain angle (usually 180 deg) without failure is accepted as an indication that a satisfactory weld has been made. In certain instances, plates thicker than 3/8 in. are used and specimens 3/8 in. wide are cut from them and tested in side bending.

Root-break and side-bend tests are new forms of the bend test that have been introduced to reveal lack of soundness in welded joints, but as yet they have not met with general acceptance. The root-break test is applied by bending the specimen backward, so as to stretch the bottom of the V of a single V-weld; this test is particularly effective in revealing lack of penetration and soundness at the bottom of the V. The side-bend test is applied by bending a thin specimen, taken transversely across the welded joint, so that the length of the weld is perpendicular to the plane of the specimen. This test is said to be particularly effective in revealing lack of side-wall fusion in the V or groove.

Specific Gravity. This test is made to determine whether the weld metal is free from fine porosity. The specimen of weld metal is usually ⅝ in. in diam by 2 in. long. The weight and volume of the specimen are determined carefully; the weight in grams divided by the volume in cubic centimeters gives the specific gravity. For ferrous weld metal of highest quality, a specific gravity of 7.80 or greater is required.

Nick-Break Test. This test consists in rupturing, with a sudden blow, a specimen notched in the edge of the weld. The nick-break test is a homogeneity test indicating the soundness of the weld by showing on the fractured surface (1) whether complete penetration has been obtained, (2) the presence of oxide or slag inclusions, and (3) the degree of porosity, which should not exceed six gas pockets or holes per square inch of fractured surface. The maximum dimensions of any defect should not exceed 1/16 in.

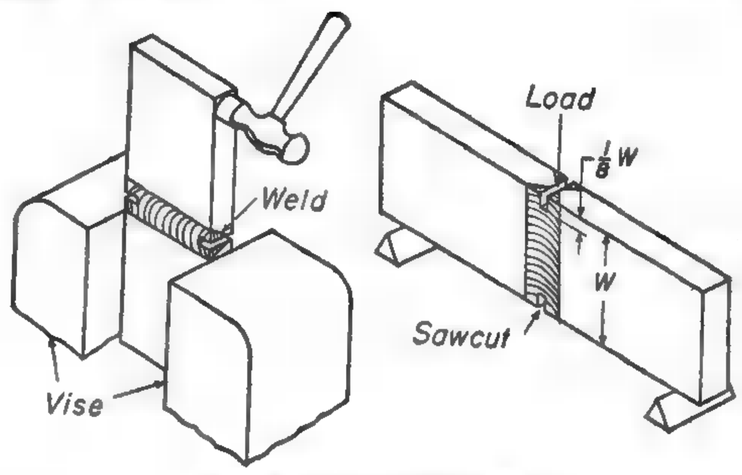

Fig. 6 A nick-break test

The materials required for making the nick-break test are a vise or anvil, in or against which the specimen is clamped; a heavy hammer for applying the blow; and a specimen 1½ T wide plus ½ in., slotted at the edges by a hacksaw to a depth not greater than ¼ in. No machining is required on the specimen. With material ½ in. thick or more, the specimen may be laid on supports about 6 in. apart, and may be fractured by a power hammer or by a falling weight of sufficient intensity to cause sudden fracture. Examination of the fractured surface will reveal the presence of porosity, oxide, or lack of fusion.

Although the nick-break test is extremely simple, it is severe and weld metal and welding must be of good quality to pass. This is one of the tests that has long been used for the qualification of processes and welders in the ASME Unfired Pressure Vessel Code for paragraph-U69 quality vessels. The specimen is shown in Fig. 6.

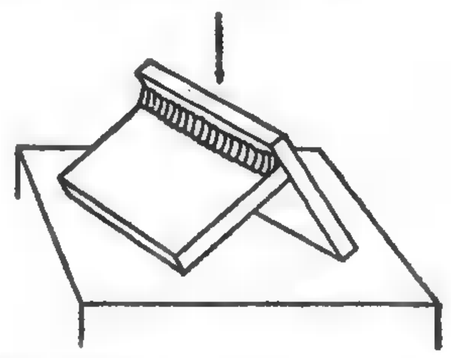

Fig. 7 A test specimen for fillet welds

For fillet welds, a test equivalent to the nick-break test is applied to a so-called "fillet-weld break specimen" (Fig. 7). This specimen is formed by fillet welding one flat plate or bar at right angles to another, in such a manner that by application of pressure or a blow to one edge of the specimen, the fillet weld can be opened at its root. The resulting fracture in the weld reveals any lack of penetration or lack of soundness.

Impact Tests. The Izod and the Charpy impact tests are generally used. These tests are carried out by fracturing a notched specimen with a swinging pendulum and measuring the energy absorbed in breaking the test specimen. The tests are described on page 112 of this Handbook.

In testing the impact strength of welds, it is customary to make at least three specimens, placing the notch at the bottom of the weld in one, at the side in another, and at the top in the third, and taking the average of the three results as the impact value in foot-pounds.

Hardness Tests. The hardness test is used considerably in the laboratory but has not been used in the field to any great extent for testing welds, except for determining the hardness of built-up rail ends.

Inspecting and Testing of Bolts, Screws, Nuts, Studs and Pins

BY THE SUBCOMMITTEE ON BOLTS*

THIS article presents the requirements and procedures involved in inspecting and testing bolts, screws, nuts, studs and pins.

Sampling. When a shipment comprises a number of kegs or boxes, it is suggested that one or more samples should be taken from each container in order to test the average quality of the shipment as nearly as possible.

Mechanical Inspection. The physical dimensions are determined by suitable rules, gages, micrometers and special instruments. Thread dimensions and tolerances for the several classes of threaded products are specified in the standards of the American Standards Association.

Hardness Tests. The Brinell hardness test is generally used when the size, shape and character of the part permit. For routine testing in the shop, the Brinell hardness determination on headed parts should be made near the center on the upper surface of the head. For purposes of arbitration and for approximating as nearly as possible the tensile strength of the bolt, the Brinell impression should be made on a transverse section of the threaded part of the piece, at a point ⅛ diam from the center.

The Rockwell C scale is used on hard surfaces of sufficient thickness. The Rockwell A scale may be used on some thinner parts where the C load breaks through. The Rockwell B scale is used on soft surfaces where the size, shape or application of materials will not permit the use of the Brinell tester.

Although its use is not standardized, the file often serves as a guide in estimating the hardness and uniformity of surface hardened parts, especially where resistance to abrasion is of major importance.

Tests for Tensile Strength. The tensile strength of bolts should be measured in a tension-testing machine with the load applied between the head of the bolt and a nut or threaded fixture, with enough thread engagement to assure that the full strength of the bolt is measured. The nut or fixture should be assembled on the bolt so as to have at least three bolt threads exposed between the bearing faces of the nut and the bolt head. Results from tests in which failure occurs by thread stripping are worthless.

When large bolts from ⅞ to 1⅜ in. in diam are to be tested, if the tensile equipment is not adequate for testing full-sized bolts, the shanks of the bolts should be turned down to a suitable gage size concentric with the bolt axis. The head and threaded sections should be left intact. For still larger bolts, a standard tension test specimen should be machined from the bolt shank, but its axis should be taken midway between center and surface of the bolt.

An excellent method for writing specifications is to state the minimum load in pounds for the yield strength or tensile strength that a given specific part should sustain. When the strength per square inch is required, it should be calculated by dividing the actual load by the area computed from the average of the root and pitch diameters.

When bolts are too short for tension testing the Brinell or Rockwell hardness is used as an indication of strength.

The tensile strength of unthreaded sections is calculated on the minimum cross-sectional area. In the testing of a threaded section, if the part breaks outside the threaded length, the area of the section that breaks should be used for the calculation.

A threaded section may be considered as a cylinder strengthened by one or more spiral ridges which are the threads of the screw. This strengthening effect of the threads is usually greater on the yield strength than on the tensile strength. Since a straight piece turned from a threaded part may give a result somewhat different from that of the threaded part itself, the actual piece should be tested whenever possible.

Tests for Yield Strength. The yield strength is determined in the tension-testing machine as the load is being applied for the determination of the full tensile strength of the piece. The yield strength is indicated by the "drop of the beam" on low-carbon ferrous materials having a yield point. On stronger material, since yield strength corresponds to the beginning of permanent plastic flow, it can be measured by dividers, extensometers, autographic attachments, beam hesitation or pointer hesitation.

Elongation and Reduction of Area. Since a bolt normally breaks in the threaded section in a tension test, and since the plastic flow of the material is greatly hampered by the notch and strengthening effect of the threads, determinations of elongation and reduction of area are not commonly made.

Head Test. To determine whether there is proper union between the head and shank, samples may be tested by placing the bolt sideways on a block of steel, with the head just over and against the square edge. The head is then hammered to determine whether the steel deforms plastically or ruptures without plastic flow.

Bend Test. Although it is not standardized, the bend test is used on the shanks of bolts as an aid in judging toughness and ductility. The bend test is made in the tension-testing machine with a specially designed fixture holding adjustable rolls to accommodate the bending bolt as it is forced down by the mandrel, which has a rounded end with the same radius as the bolt radius. A screw press is used for case-hardened parts that should deform plastically to some extent before complete rupture of the core. The bend test does not apply to threaded sections because the notch effect of threads produces low, erratic results.

Shank Fracture Test. The shanks of the threaded products may be fractured to show visible defects such as piped steel, seams, or coarse grain structure. Usually these defects can be seen by the naked eye or through a hand lens.

Shear Test. Shear tests are made best in a special shear block with holes in the block and in the plunger to hold the specimen rigidly in alignment. The holes must be closely fitting and the block and plunger made of hardened steel or with hardened steel inserts. The block is used in the tensile machine and the results are expressed in pounds load or pounds per square inch of sheared section.

Thread Stripping Test. The strip test for threads is applied to nuts and made in tension on a tension-testing machine. The sample nut is assembled on a hardened threaded mandrel and the load is applied until the threads in the nut are stripped. The test result is not significant if the threads of the mandrel are damaged. To convert the load to tensile stress in the mandrel the mean area of the threaded section should be used.

Inspection of Protective and Decorative Coatings. A protective coating may or may not be decorative. A decorative coating, however, must always be protective.

The decorative quality of coatings is usually determined by visual examination. The protective quality of coatings may be subjected to tests on the unthreaded portions of a part and on such surfaces as may be considered significant.

Outdoor Exposure. An outdoor exposure test, although quite reliable, usually involves too much time.

Salt Spray Test. The salt spray test is in general use for checking the corrosion resistance of coatings. The test should be conducted in a closed cabinet in which a solution of salt (NaCl), 20% by wt, is atomized continuously so as to give a visible fog in all parts of the cabinet. Pieces under test should be suspended or supported in such a manner that the solution will not be retained in pockets. The temperature should be 92 to 97 F. The pieces should be free from protective films other than the coating in question, and should be exposed until corrosion appears on the underlying metal. The solution should be changed frequently to avoid concentration by evaporation or contamination with zinc or iron chlorides. For details see ASTM Method B 117–44T.

Measuring the Thickness of Coating. To determine whether the coating is thick enough to give satisfactory protection, the thickness may be measured under a microscope, by micrometer, or by chemical determination.

Radiography of Metals

BY KENT R. VAN HORN*

X-RAYS, a form of radiant energy or electromagnetic waves, were first detected by Roentgen in 1895, and are frequently called "Roentgen rays" in honor of the discoverer. X-rays are similar to light and other radiation of the electromagnetic spectrum in that they travel in straight lines, traverse space without transference of matter, affect a photographic film, and are not influenced by either electric or magnetic fields. The various electromagnetic vibrations differ essentially in wave length; the gamma rays emitted during the disintegration of radioactive elements are the shortest,* then the X-rays, followed by the ultraviolet, the visible, infrared, radio and other forms. The shorter wave lengths are less absorbed by matter and are consequently more penetrating. Thus, gamma rays and X-rays penetrate material that is opaque to visible light.

Light is transmitted through different types of glass with varying degrees of absorption. Similarly, all materials do not possess the same degree of X-ray transparency. The absorption coefficient of X-rays is roughly proportional to the density of the absorbing medium. More precisely, the absorption coefficient increases with the atomic number of the absorbing atoms, the number of atoms per unit volume and the X-ray wave length. Consequently, a sound section of steel will absorb more radiation than a similar section of aluminum. It is possible, therefore, to locate regions differing appreciably from the surrounding material in density. These relations are the basis of the science of radiography, which may be defined as the nondestructive testing of matter by utilizing radiant energy (either X-rays or gamma rays). The experimental procedure consists of passing radiation through the specimen and detecting or measuring by some means the various intensities of the emergent beam. The present article is confined to X-ray radiography. However, much of the discussion of general technique and interpretation also applies to the gamma ray.

* Chief, Cleveland Research Division, Aluminum Research Laboratories, Aluminum Company of America

* The cosmic rays have a shorter wave length than the gamma rays but their nature is controversial.

Generation of X-Rays, and Apparatus. X-rays are produced when matter is bombarded by a rapidly moving stream of negatively charged particles (electrons); that is, when the electrons are suddenly stopped by matter, a part of the kinetic energy is converted to energy of radiation (X-rays). The essential conditions[1] for the generation of X-rays are: (1) a source of electrons (cathode rays) proceeding toward the target; (2) a target (anode) located in the path of the cathode rays; (3) a difference in potential between the cathode and the target, by means of which the requisite velocity is given to the electrons during their passage across the intervening space, so that when the target is bombarded, the necessary X-rays will be propagated.

The first two requirements are incorporated in the X-ray tube, which may be of two types. The first is a gas (ion) tube, where the source of electrons is a residual gas that is ionized; the second (electron) type is a highly evacuated glass bulb, cylinder or doughnut containing either one or, in special tubes, two tungsten wire filaments, which emit the cathode rays, and either a button, solid or hollow target. The tubes constructed for higher voltage (1 to 8 million volts) consist of many sections so that the velocity of the electrons can be accelerated in stages before striking the target. Radiographic tubes may or may not be self-rectifying.

The third condition, a difference in potential, is obtained by storage batteries, several types of transformers, electrostatic generators and magnetic induction generators. The high-tension a-c closed-core transformer is used for industrial installations from 45,000 to 500,000 volts. The electrons are accelerated in the 1 to 2 million-volt units by low-frequency resonance transformers.[2] Similar voltages can also be obtained by electrostatic generators (Van de Graff)[3] where the charges are transferred on a moving insulated belt to a high-voltage collector. The potential thus accumulated is applied to the tube terminal. The magnetic induction accelerator[4] (Betatron) offers the most promise for producing high-energy X-rays, from 2 to 100 million volts. This accelerator consists of an electromagnet and a doughnut-shaped vacuum tube. The electrons shot into the vacuum tube are continually accelerated in a circular

path until the desired velocity is attained, at which time the orbit is magnetically expanded and the electrons strike the target.

Accessory equipment for the transformer type of power that is used so extensively in industry today consists of: (1) an autotransformer for controlling the input to the high-tension transformer; (2) a means of current rectification, generally valve tubes; many of the recent installations are equipped with self-rectifying X-ray tubes that have cooled targets; (3) a device for regulating tube current; (4) separate transformers for supplying the filament current of the X-ray and valve tubes; additional windings on the high-tension transformer or insulated storage batteries are also satisfactory as a filament supply; (5) instruments for measuring voltage, such as a calibrated primary transformer voltmeter, electrostatic voltmeter, sphere gap, or spectrometer.

Radiographic units may be of a permanent type where the location of the apparatus is fixed, or of a portable type that may be moved throughout a plant quite easily.

Protection.* X-rays and rays from radioactive substances are potentially dangerous to all exposed persons, so that adequate safeguards must be employed. Overexposure of local areas of the body may result in the production of skin burns and ulcers, which may develop into cancers after a period of several years. Overexposure of the entire body may lead to the production of severe anemia or even leukemia; also the genetic cells may be injured and sterility can occur.

A potential health hazard exists in any area where the daily amount of radiation measured in air exceeds 0.1 roentgen.* An intensity of 0.1 roentgen per day, or 3 roentgens per month is allowable; however, that amount is accepted as the tolerance limit for an individual. Since X-rays and radiation from radium cannot be perceived by ordinary sensory means, it is the responsibility of the management to protect the personnel adequately.

Necessary safeguards consist essentially of shielding all X-ray sources so that no radiation hazard exists, or of barring all persons from areas in which such a hazard is present. Radiation barriers are to be preferred whenever practicable. In considering the use of shielding, it must be emphasized that shielding of the direct beam alone is not sufficient because of dangerous secondary or scattered radiation from objects in the path of the direct beam.

Detailed safety and health recommendations for the industrial use of X-rays and radium are embodied in the new safety code,[5] and should be followed constantly. Particular attention must be directed to the proper use of interlocking controls and switches that will interrupt the high-voltage supply to X-ray tubes if persons attempt to enter dangerous areas; to the proper use and frequent checking of shielding materials to eliminate possible hazards; and to proper identification and handling of radium.

All persons casually exposed to X-rays must be protected, but the health of the personnel working with these rays should receive special attention. Before employment, all such workers should have a blood count and a complete physical examination, with particular emphasis on their medical or exposure histories. These workers should be re-examined annually, and blood counts should be made at regular intervals (60 to 90 days).

Methods of Detecting X-Rays. X-rays are detected by their effects on matter; these effects may be visible and either temporary or permanent. Thus X-rays are detected by a photographic emulsion, a fluorescent screen, ionizable gas and electron multiplier tubes. Inasmuch as the photographic emulsion is generally used for industrial radiography, the other methods will be mentioned briefly.

Vapors and gases such as sulfur dioxide, ethyl bromide, and methyl iodide are readily dissociated by X-rays but difficulties are encountered in measuring the ionization without secondary effects. Tedious manipulation is required, and further, the average intensity over an entire region is measured, not the variations from point to point. Thus, an ionization chamber would be unsuitable for revealing small defects in large castings.

The visible fluorescence excited by X-rays on screens of calcium tungstate, zinc sulfite or barium platinocyanide is utilized for the inspection of metals of low density, but only to a limited extent. On fluorescent screens variations in brilliancy (glow) correspond to different degrees of transparency of the exposed object, so that the dense structures causing less glow appear darker, which is the reverse of the effect on photographic film. The fluoroscope offers the advantages of speed and economy but unfortunately does not integrate X-ray energy as a film emulsion does; therefore much larger quantities of radiation are required to penetrate the same specimen. Furthermore, the record is temporary and the sensitivity is inferior, ranging from 1/5 to 1/15 that of a film.

The electron multiplier tube (Geiger-Mueller counter)[6] in the past has been considered unreliable because of variations in response and life. However, recent developments indicate that this is a stable, long-lived and sensitive means of recording X-ray energy quantitatively. It is being used currently on diffraction apparatus for the precise measurement of X-ray intensities and undoubtedly will find future application in the radiography of metals.

An X-ray paper is marketed that costs about one-half as much as a film and differs in several significant characteristics. The contrast of the paper is 40% less than that of the film, and the range of useful densities (latitude) is more limited, because of the reflection of some light from the surface. However, X-ray paper may be satisfactory for certain uses; for example, in the examination of a large number of similar parts where previous tests with films have indicated that objectionable defects would be adequately disclosed.

X-rays and gamma rays, similar to light, produce on a photographic emulsion a latent image which is permanent and reproducible.[7] Dupletized films designed especially for X-ray service consist of two thick sensitive layers, separated by a cellulose acetate base. Since 1939, special films have been manufactured for industrial radiography. Some of these films are for "direct" exposure to X–radiation and others are of the "screen" type; that is, they are used with intensifying screens. The image registered on the negative depends on the variations in absorption of X-rays by the object and on the characteristics of the emulsion.

The important qualities of films are contrast, latitude and speed. Industrial X-ray films available have various speeds. In general, the speed is a function of the grain size—the coarser the grain, the faster the film; fine-grained films, although slower, give better registry of details. Radiographic sensitivity is greatest with high-contrast emulsions. However, with maximum differentiation of detail (contrast), the range of useful film intensities (latitude) is diminished. In other words, a high-contrast emulsion will reveal minute defects in a certain section but will not record clearly, during the same exposure, images of regions appreciably thinner or thicker. Sufficient latitude will allow for unavoidable variations in exposure and development as well as for reasonable differences in thickness. Generally, emulsions that offer a compromise of contrast and latitude are desirable, although for some conditions requiring extraordinary sensitivity, high contrast alone may be specified. Preferred film sizes for the radiography of castings are 14 by 17 in., 11 by 14 in., 8 by 10 in., and 5 by 7 in., while the narrower sizes for welds are 4 by 10 in., 3½ by 17 in., and 7 by 17 in.

X-ray films are developed and fixed by the tank method in solutions designed to give extreme contrast and negligible chemical fog. Films can be processed manually or, when the production is large, by a machine.

Accessory Equipment. No attempt will be made to describe the many radiographic accessories. However, a few of the important features that appreciably affect the applications or limitations of radiography will be mentioned.

A decided reduction of exposure time can be obtained by employing intensifying screens. A screen consists of an intensifying compound—usually calcium tungstate, infrequently zinc silicate or zinc sulfite—mixed with a cellulose binder and coated on a cardboard support. When calcium

* Condensed from a contribution by Phillip Drinker, Harvard University School of Public Health, Cambridge, Mass.

* The roentgen is that quantity of X-rays or gamma radiation having associated corpuscular emission (secondary beta radiation) producing in 1 cu cm of air, ions carrying one electrostatic unit of electricity of either sign.

tungstate or similar material is exposed to X-rays or gamma rays, visible and blue light is emitted to which a film emulsion is highly sensitive, thereby accelerating the exposure effect. Two screens are used ordinarily, one in front and the other behind the film, although superior definition but less speed is procured with only one screen. The particle size of the calcium tungstate is important, since coarse grains increase the speed, while fine grains are more conducive to sharpness (definition). Zinc sulfite has recently attracted attention because the speed in exposures below 100-kv peak exceeds that of calcium tungstate.

Metal foils—particularly lead, but sometimes copper or aluminum—slightly decrease the exposure period in certain voltage ranges and improve the quality of the negative. A lead-foil filter (about 0.005 in. thick) placed on each side of the film will reduce film fogging by absorbing some of the secondary radiation.

For interpretation, negatives should be viewed near a source of diffuse illumination that will reveal detail in areas of both average and extreme blackening without glare. The color of the light is of no optical consequence although bluish-white is preferred. Mazda, fluorescent and photoflood lamps are the common sources of illumination. Photoflood lamps require adequate cooling by fans or water cells so that the film will not be overheated.

Film darkening is usually expressed in H and D units (standard density scale of Hurtel and Driffield). This is defined as the reciprocal of the transparency of the film (blackening = log 1/T; that is, a film that reduces the transmitted light to 1/10 of its original brightness has an H and D value of 1.0). Film blackening can be precisely measured by a microphotometer. A density difference of 0.1 is considered the standard minimum value of detection. Detail is perceptible, with adequate illumination, as high as 4.0. Film densities of 2.0 to 2.5 are common for good practice and serve as a relative standard for comparing technique. Formerly, 0.7 was preferred and some still adhere to this value. It is desirable to use a darkening value in the range where the characteristic curve of the film is a straight line. However, with the new fine-grain high-contrast films (with continuously increasing slope of the characteristic film curve), the contrast increases with the degree of blackening, and therefore greater film densities are now being specified.

Sensitivity of Radiography and General Technique. The minimum perceptible variation in density (sensitivity) within a specimen is a measure of the over-all accuracy of the radiographic method. The sensitivity may be expressed as the smallest thickness of discontinuity in inches that is revealed on the radiograph, or as the percentage of the total thickness examined which is represented by the smallest discontinuity detectable. Of the factors that affect sensitivity, some may be controlled, but others are permanent limitations imposed by the apparatus.

The type of target in the X-ray tube, the material supporting the target, the size of the focal spot, and the method of rectification cannot be altered.[8] The higher the atomic number of the target metal, the more penetrating (shorter) the wave length of the X-rays, although this is accompanied by decreased contrast. The focus of the X-ray tube is not a point source but occupies a fixed area; consequently, the smaller the focal area, the better the definition. Rectification units of the same peak kilovolt capacity have dissimilar distributions of wave length (mean voltages), thereby generating different proportions of long and short wave lengths.

Among the important controllable factors that affect sensitivity is the quality of the radiant energy. The radiation emitted from the tubes having tungsten targets varies over a considerable range of wave lengths and is related to the voltage applied to the tube. As the potential increases, the wave length of maximum intensity decreases with a corresponding reduction in contrast and sensitivity. Consequently, it is desirable to employ the lowest potential that will penetrate a certain thickness in a reasonable period of exposure.*

* Exposure charts are available for various thicknesses of metals under different conditions.[9] However, these data will not apply to all situations because of the difficulty in reproducing radiation with a constant potential and variations in films or screens.

The sensitivity is reduced by the fogging effect produced by scattered (secondary) radiation from the specimen and surrounding objects. Secondary radiation consists of primary X-rays that are scattered through wide angles with no change in wave length and X-rays of longer wave length, characteristic of the absorbing substance, generated by ejected electrons. The quantity of secondary radiation increases with the applied voltage[10] and the number of atoms encountered (thickness of the material). Fortunately secondary radiation may be greatly reduced by the use of diaphragms, or lead or copper screens. The recently available multimillion-volt apparatus makes it possible to obtain more penetrating (less absorbed) radiation, thereby reducing the secondary effects compared with those from lower-voltage X-radiation.

Additional undesirable radiation causing fogging, but primary in nature, is that proceeding directly from the X-ray tube to the film, without passing through the object. This can be eliminated by shielding technique, using lead shot, lead sheet, or immersing in suitable solutions.

The sensitivity of radiography is influenced also by the focus of the X-ray tube in its geometrical relation to the film and to the location, size and orientation of discontinuities. Although the focal area is fixed, definition can be improved by increasing the distance from tube to film. This expedient is limited because of the corresponding increase necessary in exposure time, since the intensity of X-rays or gamma rays, similar to that of light, decreases inversely as the square of the distance from the source of emission. As the source approaches the film, the exposure angle is enlarged, which induces a nonuniformity of film density. It is, therefore, desirable to use the longest tube-to-film distance consistent with a reasonable exposure period.

Discontinuities may occur in any part of the specimen and may be oriented at any angle to the incident X-rays. As the distance is increased from dicontinuity to film, or the diameter of the discontinuity is decreased, the actual sensitivity is proportionately diminished. Consequently, if imperfections are more likely to exist in a certain section of a casting, this section should be placed adjacent to the film during examination. A longitudinal cavity or crack may necessitate several exposures at different angles so that the void presenting too small a variation in thickness for detection in one direction may be revealed in another where the path of the X-rays coincides approximately with the longitudinal axis of the discontinuity.

The important factors influencing the sensitivity of radiography have been briefly described and the desired practice has been indicated. Various governmental agencies have adopted specifications to insure that a satisfactory technique is employed. Penetrameters made of an alloy of the same density as that to be inspected, and containing synthetic voids or defects, are exposed with the specimen according to certain specifications.

When influential factors are carefully controlled, voids 0.5 to 1.0% of the thickness of an aluminum alloy or steel will be revealed on the radiograph. However, a sensitivity of 2% is relatively easy to obtain and is sufficient to meet the requirements of the various specifications for castings and welds. The significance of these values is that variations of composition or thickness less than the percentage of sensitivity will probably escape detection. Radiography should not be applied in these instances.

Interpretation of Radiographs. A radiograph is a shadow picture of material more or less transparent to radiation. The X-rays darken the film so that regions of lower density, which readily permit penetration, appear dark on the negative in comparison with areas of higher density, which absorb more of the radiation. Thus, a cavity in metals is recorded as a darker area, whereas copper segregation in an aluminum alloy registers as a lighter area.

The general appearance of the familiar discontinuities encountered in castings or welds will be described because of the extensive applications of radiography in these fields. In castings, certain sections that are thinner because of the design, and intentional cavities, such as cored holes, are regions of low density and are revealed as darkened areas. Specimens containing variations in thickness caused by the unintentional absence of metal are also

more transparent, resulting in darkening of the film. Excess metal and inclusions more dense than the base metal appear as light regions. The common casting discontinuities may be recognized on the negative by the following characteristics:*

1 Surface roughness appears as irregular white or dark areas with a smooth contour. The coloration depends on whether the surface protrudes or is depressed. The surface irregularities of the actual casting must be compared carefully with the radiograph and identified before an attempt is made to interpret the internal discontinuities.

2 Gas cavities, blowholes and minute gas porosity appear as well defined, spherical or rounded darkened areas. Hydrogen or other gas porosity in aluminum alloys is represented by round, dark spots and is generally distributed through the section or entire casting. In coarse-grained aluminum alloy castings these voids tend to be curved or elongated.

3 Inclusions such as foreign material, slag, oxide or sand, appear as regular or irregular areas. The areas may vary in intensity and are either lighter or darker than the background, depending on the relative densities.

4 Segregation may be well defined or may appear as mottled areas, either regular or irregular in shape and lighter or darker than the background.

5 Shrinkage cavities and shrinkage porosity (pipe or sponge) are represented by filamentary or dendritic dark regions of irregular dimensions and indistinct outline. These voids are localized. Shrinkage porosity is lacy or honeycombed and not a continuous cavity.

6 Microshrinkage in magnesium alloys appears on a radiograph as dark, feathery streaks or irregular dark patches caused by shrinkage in the grain boundaries.

7 Misruns appear as very prominent darkened areas of variable dimensions with definite smooth outlines where the metal failed to fill the section.

8 Cold shuts are represented by dark lines or bands with variable lengths and definite smooth outlines that tend to be curved (meniscoid). Cold shuts occur where the metal has come together but has failed to unite and the contact surfaces are oxidized.

9 Hot cracks are represented by darkened lines of variable width and often possess numerous branches that follow the outlines of the dendrite. A cold crack, originating from residual or external stresses, is a straight dark line usually continuous throughout its length.

The origin and identification of flaws in steel welds have been studied exhaustively.[11] The discontinuities in order of prevalence of occurrence are: (1) slag inclusions, (2) porosity, (3) cracks, (4) incomplete fusion between the weld and base metal or between two layers of weld metal. All these imperfections are less dense than steel itself and are recorded as darkened regions on the radiograph. With the exception of incomplete fusion, which is represented by a dark line of variable width parallel to the scarf, the discontinuities in steel when recorded on a radiograph, resemble similar discontinuities in sand castings.

The significance of imperfections in steel welds in boilers, pressure vessels and such, has received much attention, and general agreement has been reached on the correlation between their radiographic appearance and the effects on the strength of welds. Standard films illustrating the size, shape and location of permissible or rejectable flaws in steel welds have been prepared by the ASME-API, U. S. Navy and U. S. Army Ordnance,[12] and are used extensively in industry.

Standards for acceptance cannot be so easily formulated for castings, and are expensive and time-consuming to develop. Thus films representing permissible or rejectable discontinuities have been obtained after laborious testing of castings under conditions approximating actual service. The established standards apply specifically to castings of the design tested and not to other types of castings. Nevertheless, progress has been made in establishing standard films for some castings by this procedure. Also, certain types of discontinuities are undesirable in any types of casting. Accordingly, the U. S. Navy[13] has developed acceptance standards for steel castings, and the Army Air Corps, for structural aircraft castings of aluminum and magnesium.[14] The standards are more or less generalized and the appearance of the discontinuities on the radiographs of castings is related to tests approximating service conditions.

Radiographic Applications. In the metal industries, radiography has been used primarily for the inspection of castings and welded products. The examination of wrought metal, such as forged, rolled or drawn sections, is very limited because of the uniformly dense structure and the unlikely existence of flaws large enough to be detected by the radiographic method. Therefore, the commercial value of radiography depends on the nature of the material to be tested.[15] The most extensive applications[16] of radiography to steel, aluminum and magnesium are:

1 For welds.
- (*a*) An aid in the development of welding procedures,
- (*b*) Routine inspection of pressure vessels, boilers and such, according to specification,
- (*c*) Intermittent checking of the quality of less critical products,
- (*d*) Determining the quality of repaired areas.

2 For castings.
- (*a*) An aid in the development of casting technique,
- (*b*) Routine inspection of critical castings,
- (*c*) Percentage or spot examination of less critical castings,
- (*d*) Determining the quality of areas salvaged by welding,
- (*e*) Locating core wires, chaplets and the like in complex castings.

3 For forgings.
- (*a*) An aid in the development of forging practices,
- (*b*) Routine inspection of critical parts. Used only to a limited extent for forgings, because of the very infrequent occurrence of discontinuities of a size detectable by radiography.

4 For assemblies.
- (*a*) Determining location and dimensions of internal components,
- (*b*) Inspecting quality of soldered or brazed joints,
- (*c*) Locating foreign materials, drills and such in complicated assemblies.

5 For plastic and other nonmetallic parts.
- (*a*) In the development of operating procedures.
- (*b*) Routine inspection.

Special Applications. *Fluoroscopy.* Fluoroscopy consists in observing the emergent radiation from an object on a fluorescent screen rather than on a photographic film. This method is used for both routine or percentage inspection and for development of operating technique for aluminum and magnesium castings (up to 1 or 1.5 in. thick) and for plastic parts. Recently, greater screen brightness has been obtained by improvement in fluoroscopic screens, and technique permitting short focal distance. Rotation of the part[17] during exposure makes possible the detection of discontinuities, in certain castings, not revealed by the more sensitive method using X-ray film. The best sensitivity obtainable for an aluminum alloy is 4%. Equipment can be safe, shockproof and highly mechanized by a conveyer system.

Photofluoroscopy. Apparatus is available for photographing on high-contrast film a larger image appearing on a fluoroscopic screen. The film can be enlarged or projected on a screen, thereby improving the sensitivity. This process provides a permanent record and reduces film costs. The sensitivity is intermediate between that of the film and of the fluoroscopic screen; that is, under good conditions in thin sections of an aluminum alloy, 0.5% for film, 3% for photofluoroscopy and 4% for fluoroscopy. Photofluoroscopy is used for routine or percentage inspection of light metal sand and die castings or nonmetallic parts.

Spot Weld Radiography. During the war it was desirable to develop apparatus especially for the examination of numerous spot welds in thin aircraft sheets of the strong aluminum alloys. Low-voltage (20 to 45 kv) apparatus, beryllium-window X-ray tubes and close-fitting tube heads gave good sensitivity in a one-second exposure.[18] An X-ray

* No attempt has been made to present definitions from a particular organization, technical group or governmental agency. It is hoped that the descriptions are sufficiently general to apply to all metal castings.

tube on a long flexible cable, operated by remote control, made possible the production examination of numerous spot welds. Radiographs indicate reliably the strength and quality of spot welds in the aluminum alloys (24S-T4 and 75S-T6) and therefore have been used for both control and development of welding procedures.

Ultra High-Speed Radiography. The trend in industrial radiography has been toward the penetration of greater thicknesses of steel in shorter times. This progress in reducing exposure time is carried to the extreme in ultra high-speed radiography.

A cold-cathode tube has been developed that will pass very high currents, 2000 to 3000 amp, in one millionth of a second.[19] With intensifying screens, thicknesses up to 1 in. of steel can be examined. It is possible to reveal bullets passing through armor plate, jacket failure inside a gun, the explosion of a shell or the internal deformation of a golf ball on impact with the club.

Microradiography. In microradiography thin sections of metal (0.005 in. or less) are exposed at low voltages with a film that can be magnified. The sensitivity is obtained by regulating the voltage in the low range where high contrast is obtainable (8 to 40 kv) or by selecting an X-ray tube with target material appropriate for the alloy to be examined.[20] By variation of target material, chemical constituents can be identified because of the variations in absorption characteristics. Special fine-grained film emulsions make it possible to obtain magnifications of $\times 50$ to 200, thereby recording more detail than in standard radiography. Microradiography has two fields of application: (1) to show minute voids in metals, such as the appearance of fine shrinkage or gas cavities, and (2) to reveal the distribution and appearance of the constituents in alloys. Microradiography has the advantage of distinguishing the structure below the surface without depending on the etching behavior or the hardness of the microconstituents. However, the magnification is much less than that obtainable by metallography.

Gamma Ray Radiography. Gamma rays are also used for radiography. The source may be radium, radon or mesothorium, all of which emit radiation of considerably more penetrating wave length (less contrast) than that of X-rays. Gamma radiation differs from X-rays in several other important qualities. The wave lengths of gamma rays are characteristic of the source and cannot be regulated for contrast or variable thickness. An advantage of the gamma radiation which improves the sensitivity is the small absorption and low scattering power, resulting in appreciably less fogging than that produced by low-voltage X-rays. The net effect of the two compensating factors, lack of scattering and low contrast, is that the sensitivity of the gamma ray is inferior to that of the X-ray for most applications. The sensitivity of gamma ray radiography is between 2 and 5%.

Other important considerations which limit the use of gamma rays in radiography are the expense and time required for testing. Because the rental or purchase of only a small quantity of radium is feasible, exposures of the order of 10 to 16 hr would be required for penetrating steel sections ½ to 6 in. thick. Gamma rays are not directional but are emanated spherically, permitting many specimens to be distributed suitably about the source and examined simultaneously. Even so, the number of exposures during a specific time is relatively small compared with the large number that could be obtained by the X-ray method in the same period.

The gamma radiation is attractive for applications where absence of apparatus and ease of arranging exposures are desired. The technique has been developed and the details are described.[21, 22, 23]

Magnetic Particle Inspection

By R. R. Moore*

MAGNETIC particle inspection is a nondestructive method of detecting the presence of cracks, laps, bursts, tears, splits, seams, inclusions, segregations, laminations, shrinks, cold shuts, porosity, lack of fusion and similar discontinuities in ferromagnetic materials, such as iron and steel. This method will detect discontinuities that are open to the surface, but too fine to be seen with the naked eye. Magnetic particle inspection will readily detect discontinuities that lie slightly below the surface and, with special technique, will detect discontinuities that are more deeply seated. The location of the discontinuity is indicated and the approximate size and shape are outlined. The method is applicable to billet bars, tubes, forgings, comparatively thick sheet, and bodies that are irregular in shape, such as machine parts and structural members. It is not applicable to nonmagnetic materials.

*Chief Metallurgist, Naval Aircraft Factory, U. S. Naval Base Station, Philadelphia

Procedure. The work piece to be inspected is magnetized and then covered with fine magnetic particles, or the magnetization and application of the particles may occur simultaneously. The magnetic particles may be held in suspension in a liquid that is flushed over the piece, the piece may be immersed in the suspension, or the particles, in the form of dry powder, may be dusted over the surface of the object. The presence of a discontinuity is disclosed by the formation and adherence of a particle pattern on the surface of the work piece over the discontinuity. This pattern, known as an "indication", assumes the approximate shape of the surface projection

of the discontinuity. A magnetic particle indication of a seam in a connecting rod is shown in Fig. 1 and that of a crack in a crankshaft is shown in Fig. 2.

Development of Indications. The magnetic particles display a preference for adhering only at the particular locations of discontinuities, because the lower magnetic permeability across discontinuities, compared with that of the iron or steel body in which they are located, causes the magnetic field to pass around them, in following the path of least reluctance, as shown in Fig. 3 and 4. When a discontinuity is open to the surface, the magnetic field

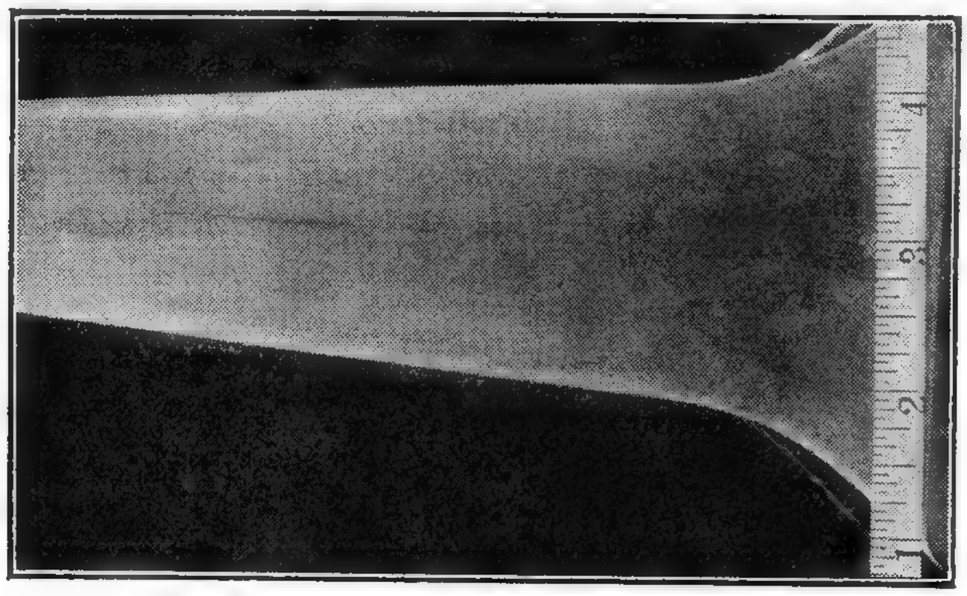

Fig. 1 Magnetic particle indication of a seam

leaks out to the surface and forms local magnetic poles that attract the magnetic particles, thus forming an indication of the approximate shape and size of the discontinuity. When fine discontinuities do not extend to the surface, some flux may still be deflected to the surface, but the leakage is much less and fewer particles are attracted; consequently a weaker indication is obtained. If the discontinuity is too far below the surface, the flux may find a path around the discontinuity without leaking out, and therefore no indication will be obtained. Blowholes and other large discontinuities located below the surface, may give quite large and prominent indications, because of interrupting a larger portion of the magnetic field.

Direction of Magnetic Field. To be detected by this method, a discontinuity must interrupt or distort the magnetic field sufficiently to cause external leakage. Fine, elongated discontinuities, such as inclusions, seams and some cracks, require that the magnetic field be transverse to the long axis of the discontinuity. If the magnetic field is parallel to the long axis, no indication will be obtained, because the thin slice of the magnetic field that is interrupted does not have sufficient magnetizing force to attract the magnetic particles in appreciable quantity. Although indications are obtained when the flux direction is at an angle of less than 90 deg to the discontinuity, the strength of the indication decreases as the angle becomes smaller, as illustrated in Fig. 5.

Because fine discontinuities may exist at any angle of orientation in a metal object, it is necessary to perform magnetic particle inspection by magnetizing in two directions so that the magnetic field of one direction is at 90 deg to that of the other. Small parts are commonly magnetized parallel to the major axis and also at 90 deg to it. Blowholes are more nearly equiaxial and therefore usually require magnetization in only one direction for their detection. Because of their larger size, blowholes generally cause greater distortion of the magnetic field, and are detected at greater depths below the surface than are fine discontinuities. Blowholes have been detected as far as 1 in. below the surface by careful regulation of magnetizing current and indicating medium.

Magnetizing Methods. The magnetic field may be produced in a direction parallel to the long axis of the work piece by placing the piece in a solenoid excited by electric current, so that the long axis of the piece is parallel to the axis of the solenoid. The metal part then becomes the core of an electromagnet and is magnetized by induction from the magnetic field created in the solenoid. Very long articles are magnetized in steps, by moving the solenoid or coil along the length, as shown in Fig. 6. This is referred to as longitudinal magnetization and is used to detect transverse discontinuities in parts of this type. If the work piece is very short, it can be magnetized parallel to any axis by being placed in an appropriate position in the solenoid. Magnetization of this type is hardly "longitudinal" and may be called "bipolar" more appropriately because an external pole is formed at each end of the axis along which it is magnetized. Longitudinal or bipolar magnetization can also be produced by making the work piece a link in a magnetic circuit or by placing it in a magnetic field created by a strong permanent magnet or electromagnet. To magnetize shafts, drums, girders and many other parts too large to be placed in a fixed or permanent solenoid, a flexible electrical cable (about No. 2/0 or 4/0) may be coiled around the part and then a current may be passed through the cable so that it acts temporarily as a solenoid.

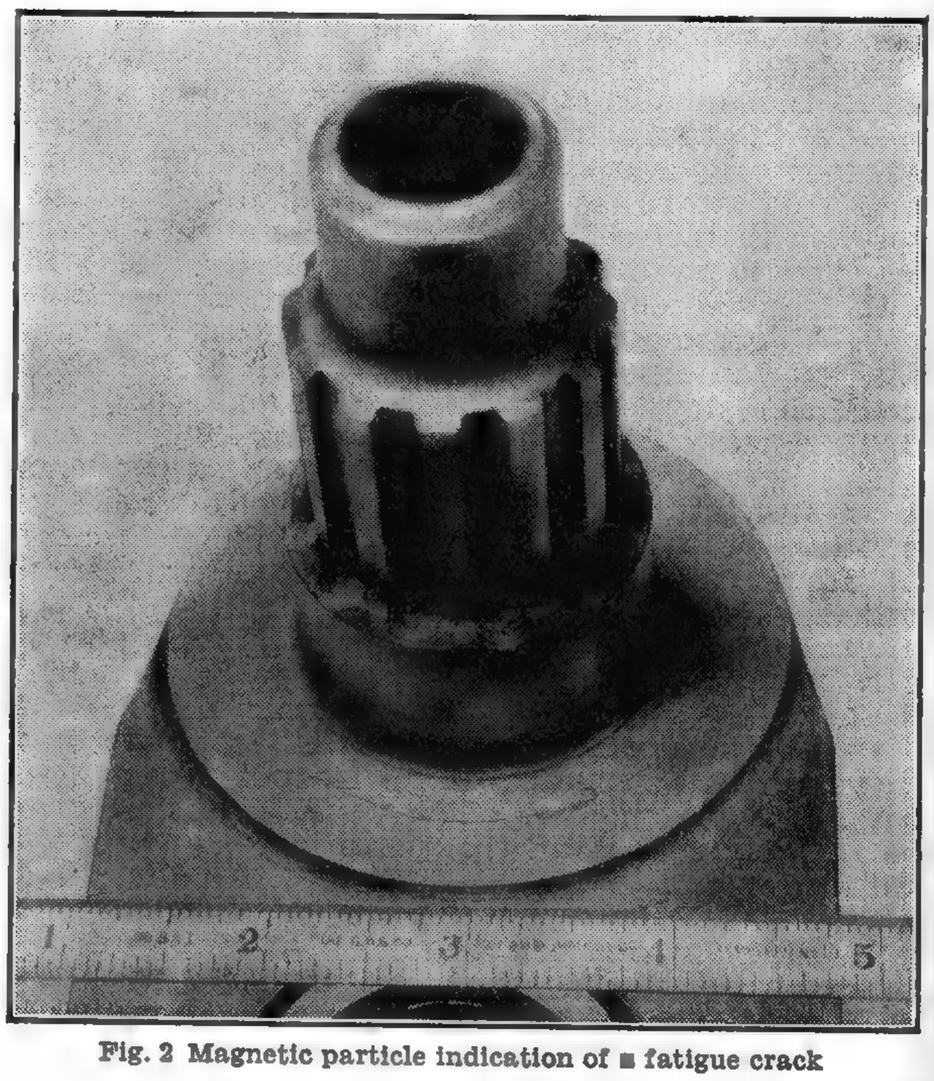

Fig. 2 Magnetic particle indication of a fatigue crack

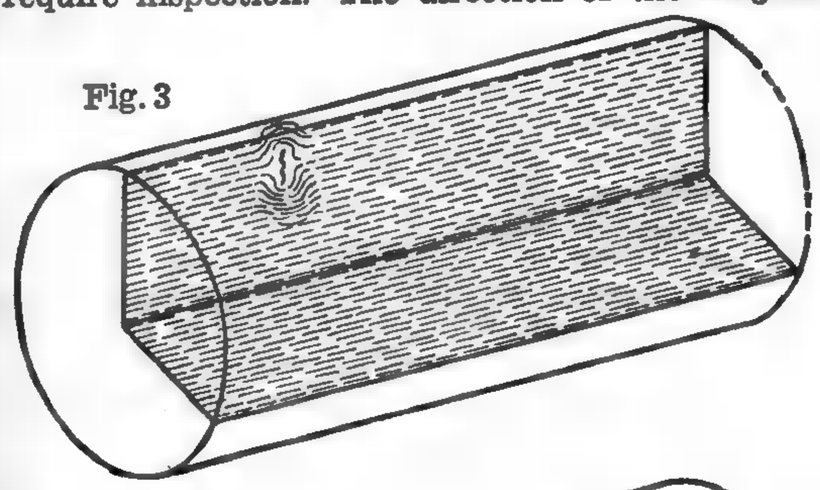
The strength of the magnetic field induced in a part by the solenoid method, depends on the magnetizing force, which is the product when the current is multiplied by the number of turns of the cable or wire. For a given magnetizing force, the induced field depends on the size and shape of the part, and on the magnetic properties of the iron or steel involved.

A magnetic field transverse to the long axis of the work piece is readily produced by passing the magnetizing current through the piece along this axis, as shown in Fig. 7, which illustrates circular magnetization of a crankshaft. The article is magnetized by induction from the magnetic field that is formed in and around any conductor carrying an electric current. The magnetic field is represented by a series of concentric circles centered on the axis of the conductor, as shown in Fig. 4, and often is referred to as "circular magnetization". The magnetic field, though circular in form, is transverse to the axis of the article, and therefore can be used to detect discontinuities that lie approximately in the direction of the axis. To obtain circular magnetization, hollow parts, such as cylinders and piston pins, should be mounted on a conductor bar located on the axis of the part. Then the magnetizing current should be passed through the bar. This procedure is preferable in order to obtain magnetization of the inner surface, because a current through a hollow part does not magnetize the surface of the bore. The strength of the magnetic field induced in a part by passing an electric

current through it, or through a conductor located on its axis, depends on the strength of the current as well as on other factors. The magnetic field induced by a given strength of current depends on the size and shape of the part and on the magnetic properties of the particular iron or steel involved.

The procedure is somewhat different for large castings, forgings or weldments; such large parts cannot be handled in the same type of equipment as that found efficient for small parts. On large pieces, it is common practice to use clamps, leeches or prod-contacts attached to flexible electrical cables, an arrangement that enables the operator to pass the magnetizing current through local areas that require inspection. The direction of the magnetizing

Fig. 3



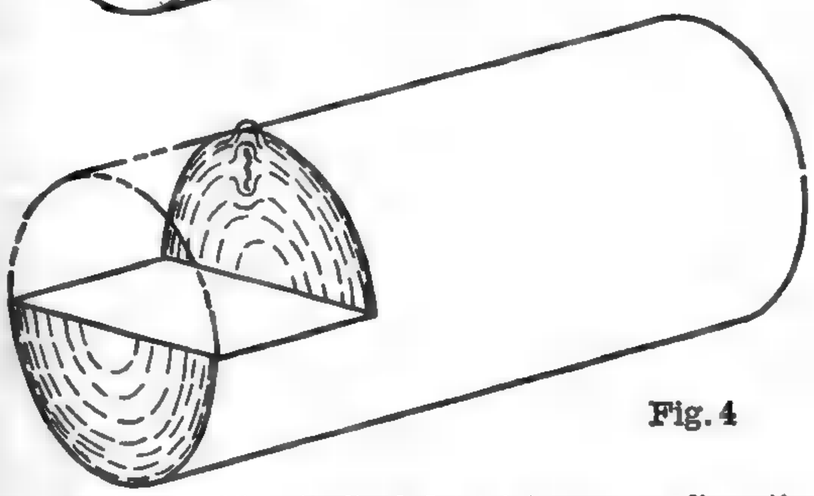


Fig. 4

Fig. 3 Distortion of longitudinal flux at transverse discontinuity
Fig. 4 Distortion of circular flux at longitudinal discontinuity

current is controlled by changing the location of the contacts, and the magnetizing field can be produced in almost any direction desired. In the prod method, the field is usually limited to about 12 in. in length and several inches in width for each passage of current, but by successive contacts, considerable area can be covered. Thus, magnetization can be produced in all directions by the circular method.

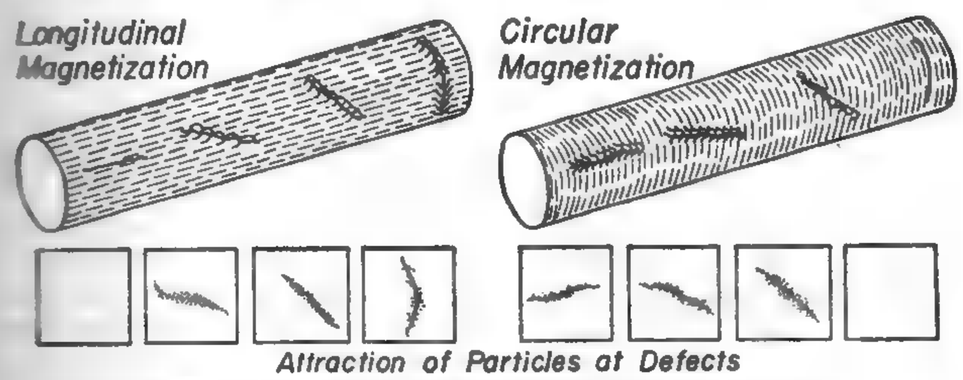

Fig. 5 Effect of direction of flux on strength of magnetic particle indication

Two variations in methods of applying the magnetizing current, relate to its timing with respect to the application of the indicating medium. In the *continuous* method, the indicating medium is applied to the work piece while the magnetizing current is acting. Under these conditions, the strength of the magnetic field induced in the work piece to attract the magnetic particles, is a direct function of the magnetizing current and the permeability of the iron or steel constituting the part. In the *residual* method, the indicating medium is applied after the magnetizing current has been cut off. Therefore, the useful magnetic field is determined by the residual magnetism remaining in the work (always less than that obtained by the continuous method) and depends on the retentivity of the metal, which varies with composition and hardness. Consequently, the residual method is less sensitive than the continuous method, when a particular part is magnetized by means of a given current.

Types of Magnetizing Current. Direct current, alternating current and rectified alternating current are all used for magnetizing. Direct current is more sensitive than alternating current for detecting discontinuities that are not open to the surface. Alternating current will detect discontinuities open to the surface and is used when the detection of this type of discontinuity is of exclusive interest. When alternating current is rectified, it provides a pulsating, surging force that increases the penetration of the magnetic field. In the magnetization of parts that are large in cross section, it has been shown that full-wave three-phase rectified current has greater penetrating effect than direct current from batteries. It is considered that half-wave single-phase rectified current has a penetrating effect at least as great as direct current from batteries. For special problems, permanent magnets of the alnico type have been used on welds and at locations where irregularities make more usual methods difficult.

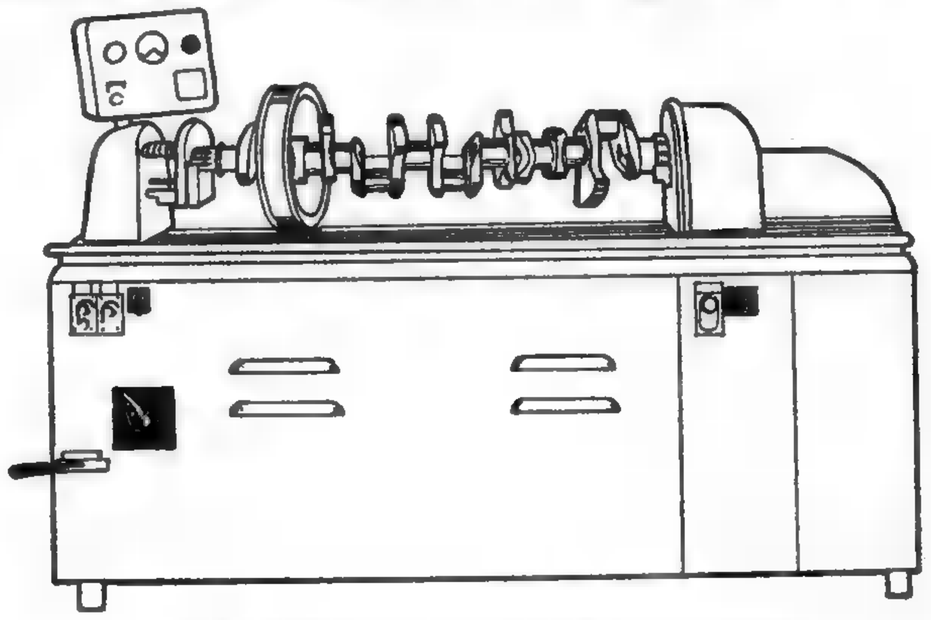

Fig. 6 Magnetizing a crankshaft longitudinally

Strength of Magnetizing Current. The sensitivity of magnetic particle inspection is affected by many factors, including strength of the indicating suspension, time in contact with the suspension, time allowed for indications to form, number of turns in the solenoid, time subject to the magnetizing current, and strength of the magnetizing

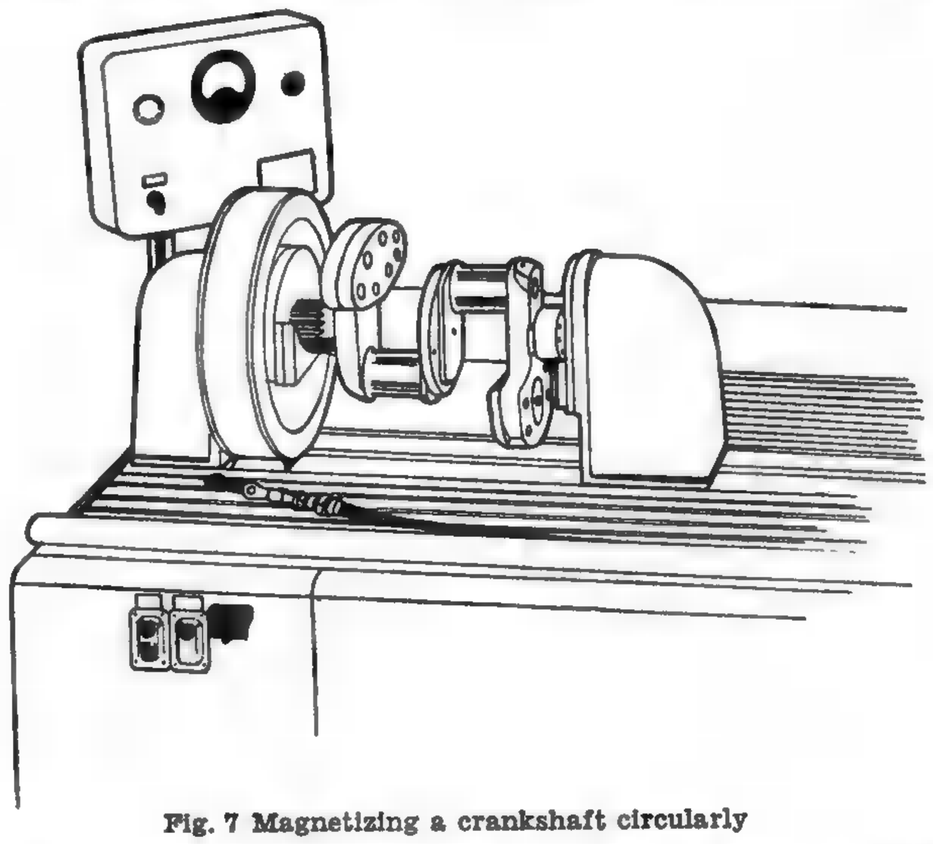

Fig. 7 Magnetizing a crankshaft circularly

current. The strength of the current can be adapted to provide a convenient, flexible control of sensitivity when other factors are kept constant. Therefore, most commercial magnetizing units are equipped with convenient means for adjusting the magnetizing current. The re-

quired current strength varies for different purposes. Usually a greater current strength is required for detecting discontinuities below the surface than for detecting those at the surface, and cracks open to the surface require less current strength than most other types of discontinuities. Cracks open to the surface can be detected with 500 to 800-amp residual circular magnetization in a 1-in. diam bar. If the inspector is interested only in cracks that are much deeper and wider than the smallest crack revealed by 800 amp, then a lower current strength should be used; but if he is interested in finer cracks or inclusions below the surface, a higher current strength should be used. Excessively high magnetizing currents should be avoided, because they cause the magnetic field to leave the metal at locations other than the ones desired. Where this occurs, the indicating powders will stand up in "whiskers", confusing the inspector.

Indicating Methods. One of the most widely used methods of indicating discontinuities is the wet method, in which the indicating medium is a liquid bath, consisting of a suspension of magnetic particles in a light petroleum distillate or a light oil. The liquid vehicle should have a flash point of not less than 140 F and a maximum kinematic viscosity of 3 centistokes at 100 F. The suspension is hosed over the part, or the part is immersed in the suspension, which serves to distribute the magnetic particles uniformly over the metal. The magnetic particles, treated to increase their dispersion and their ability to remain suspended in the liquid, are usually supplied in the form of a paste to be mixed in the liquid vehicle. The pastes are available in black and red colors and give indications of the same colors. The red paste improves visibility on dark surfaces. The usual concentration of solid particles in the suspension is about 1 oz per gal of liquid.

In the dry method, the indicating medium is a fine magnetic powder that is dusted uniformly over the work material by means of a cloth dusting bag, an atomizer or a special spray gun made for this purpose. The magnetic particles are available in black, red, and gray, and give indications in corresponding colors.

A third method often used is the fluorescent wet method, in which the magnetic particles are treated with fluorescent materials, causing them to glow or fluoresce under the action of part of a particular wave-length range of ultraviolet light called "black light". This is often referred to as "fluorescent magnetic particle inspection" and is performed in a manner similar to the wet method, except that the examination for indications is carried out under special lamps that emit "black light". This method is particularly valuable in locating discontinuities in corners, keyways, splines, deep holes and similar locations where illumination is poor. Also, the abrupt changes in cross section that are present in keyways, splines, shoulders, threads and such, cause the formation of nonrelevant or false indications heavy enough to mask the indications of true discontinuities. These heavy indications are developed by leakage from the magnetic field, under high magnetizing currents used to detect fine discontinuities. Fine discontinuities will develop more readily discernible indications when formed from fluorescent magnetic particles than when formed from nonfluorescent magnetic particles. Therefore, in such instances, the magnetizing current should be reduced below the point where nonrelevant indications form, and the fluorescent magnetic particles should be used for bringing out the fine discontinuities. The method is also of value when the color of the nonfluorescent magnetic particles available does not give satisfactory contrast against the surface of the parts being inspected. It is important for the oil vehicle to be nonfluorescent, because otherwise it will give off a confusing background glow, making the detection of indications difficult.

Effect of Protective Coatings. Primers, paints, enamels and similar nonmetallic coatings, as well as coatings of cadmium, copper, tin and zinc do not interfere with the satisfactory performance of magnetic particle inspection, unless the coatings are unusually heavy, or the discontinuities to be detected are unusually small. Chromium and nickel plating will not generally interfere with the formation of indications of cracks open to the surface of the base metal, but will prevent the formation of indications of fine discontinuities, such as inclusions. Because it is more strongly magnetic, nickel plating is more effective than chromium plating in preventing the formation of indications.

Interpretation of Indications. The principle features that distinguish among indications of different types of discontinuities, are shape, sharpness of outline, width, and the height to which the indication has piled up, known as "build-up". The particular value of these features is in distinguishing among different types of discontinuities, rather than in determining the significance of them.

Cracks open to the surface are distinguished by a well-defined sharp pattern, with a definite build-up produced by low magnetizing field strengths in residual.

Seams give indications that are straight, sharp, fine, and often intermittent, showing weaker build-up, and requiring higher magnetizing currents than cracks.

Indications of inclusions below the surface are broader and more fuzzy in outline than cracks or seams. They show minimum build-up, requiring high magnetizing field strength, and often require the use of the continuous method to develop indications.

False Indications. Interpretation of magnetic particle indications is often confused by particle patterns that simulate the appearance of indications of discontinuities when no discontinuities exist. When an internal keyway or spline is cut in a thin-wall shaft, or when a hole is drilled near a surface or edge, the magnetic field changes direction suddenly, in order to pass around the air gap formed by the opening. This causes magnetic field leakage that attracts the magnetic particles to form false indications on the surface behind the gap. When two materials with widely different magnetic properties are joined to form a composite part, an indication develops at the junction and is difficult to distinguish from that of a crack. This occurs when a low-alloy steel or carbon steel is resistance welded to an austenitic steel, and also when weld metal is deposited that has widely different magnetic properties from the base metal. If the structure of the steel contains a large proportion of retained austenite and is scratched or otherwise marked severely enough to cause local transformation, the transformation products display much greater susceptibility to magnetization than does the surrounding matrix. Consequently indications are developed that do not represent discontinuities. When a magnetized steel part is struck by another part, or another piece is dragged over it under pressure, leakages occur in the magnetic field at these places that have been cold worked, and cause indications to appear although no discontinuity exists. These conditions may occur while the parts are being handled or transported during inspection.

Demagnetization. Engine and machine parts that have been strongly magnetized to perform the inspection are usually put through a demagnetizing operation. Otherwise, during service operation, these parts will attract filings, grindings and chips that have not been cleaned out, and steel particles resulting from operational wear, with the result that these particles will cause scoring or galling of bearings and other wearing parts. In aircraft construction, steel parts in the proximity of the airplane compass must be demagnetized to eliminate any effect on the compass.

Demagnetization is usually accomplished by subjecting the work piece to a magnetizing force that is continually reversing in direction and gradually decreasing in strength, so that the hysteresis loop is reduced to virtually nothing. A simple and effective method of accomplishing this is to insert the piece in the field of an alternating current solenoid and gradually to withdraw it from the field. Complicated structures too large to be inserted in a solenoid can be demagnetized, one member at a time, by passing an alternating current through a member and gradually decreasing the strength of the current by means of a current controller. When large masses of iron or steel are involved, alternating current does not have sufficient penetration to demagnetize the piece thoroughly, so it becomes necessary to pass direct current through the metal and gradually to reduce the current to zero while it is undergoing cyclic reversals. Of course, total demagnetization can be accom-

plished by heating the work piece above the transformation temperature range, but this is rarely, if ever, feasible.

Equipment. Equipment for performing magnetic particle inspection is available in numerous types and arrangements. Some units serve only as a source of magnetizing current and are portable, while other units develop the magnetizing current, support the work pieces, contain the indicating medium and provide means for applying it to the work pieces.

Equipment of the latter type, suitable for relatively small parts for aircraft, automotive equipment and small machinery, is shown in Fig. 7, which illustrates a crankshaft supported between the electrical contact heads in position for passing the magnetizing current through the shaft, to produce circular magnetization. The heads are often equipped with different types of fixtures to support the various shapes of work pieces that may require testing. One of the heads is stationary; the other is free to slide in longitudinal guides to accommodate articles of different lengths. The source of the magnetizing current may be batteries, rectifiers, or transformers, located in the cabinet below the grill. The current is thrown on by a pushbutton, generally located on the front of the cabinet, and is cut off automatically after about ½ sec. The desired strength of the magnetizing current is set by using an autotransformer or other suitable means, before throwing on the magnetizing current. The amount of current passing through the part being inspected is indicated on an ammeter, on the instrument panel shown at left rear.

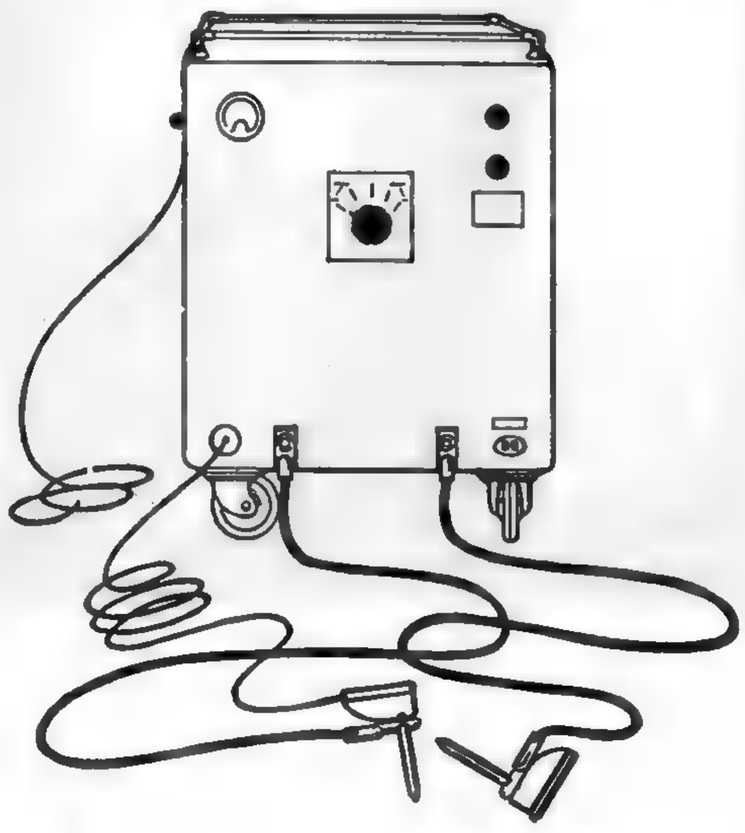

Fig. 8 Portable general-purpose equipment for magnetic particle inspection

The liquid indicating medium is contained in a collecting trough in the cabinet, and is circulated through a hose by means of a pump. The medium is directed over the surface of the work piece by a nozzle on the end of the hose shown lying on the grill in the foreground. The medium drains from the part and falls through the wooden grill into the collecting trough.

When it is desired to produce longitudinal magnetization, the work piece is supported in the coil, as illustrated in Fig. 6, and the magnetizing current is made to pass through the coil. Small parts that do not require the heads for support are simply held or laid in the coil.

The type of equipment described is suitable for general production inspection of the class of parts indicated. Other types of equipment, in which the magnetizing coil is arranged in a vertical position and contains the indicating bath, have been found of particular value for testing cylindrical and other special pieces. When production is intensive, and requires the inspection of thousands of pieces per day, as in the manufacture of bolts, studs, small projectiles, AP shot and such, automatic equipment is preferable. In such equipment, the parts are carried through the magnetizing coil on a conveyer belt, and the indicating medium is applied automatically.

Portable equipment that can be moved near the work pieces, is required for the inspection of large parts, such as railroad axles, crankpins, side rods, wheels, or large structural members, drums, or tanks. Equipment of this type ordinarily serves only as a source of magnetizing current, and carries rectifiers, transformers, or sometimes batteries for this purpose, as well as suitable current controls and meters. Flexible electrical cables carry the magnetizing current to the metal being tested, and are used to produce the magnetizing field by wrapping around the part (solenoid), or through and around drums and tanks; or the ends of the cable may contact the work material by means of prods, clamps, magnetic leeches or other devices, so that the magnetizing current can be passed through.

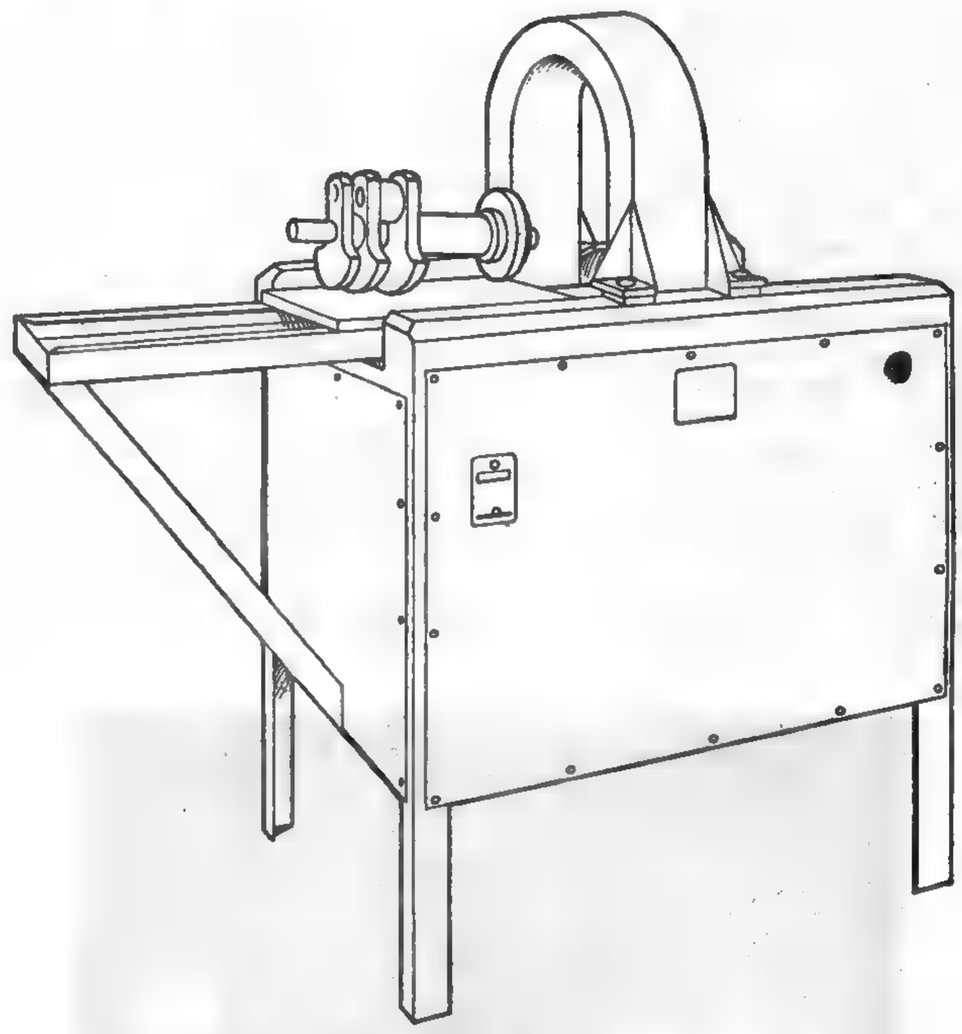

Fig. 9 Narrow-coil demagnetizer with carrier

Large welds are inspected with similar equipment, or the welding machine may be used as a source of magnetizing current. For weld inspection, the ends of the electrical cable are often fitted with prods, which are copper rods mounted in suitably insulated handles. They are used to contact the weld in order to pass the magnetizing current through it, producing circular magnetization. Equipment of this type is shown in Fig. 8.

Demagnetization of small parts is usually carried out by means of an a-c solenoid of suitable size. Figure 9 shows one type of construction. The truck and rails for carrying the part are convenient, although the part could be held in the hand as it is moved in and out of the solenoid. For large work pieces, many of the commercial magnetizing units are equipped to pass an alternating current through a piece and then gradually to reduce the current. This device serves to subject the piece to a reversing and gradually diminishing magnetic field. Other types of equipment, particularly suitable for heavy pieces, provide a reversing direct current that can be reduced gradually.

Fluorescent Penetrant Inspection

By C. E. Betz* and Greer Ellis*

FLUORESCENT penetrant inspection* is a sensitive, nondestructive way of detecting minute discontinuities open to the surface, such as cracks, shrinkage and pores. The procedure consists of applying fluorescent liquid penetrant, which enters into discontinuities; removing excess penetrant remaining on the surface; and viewing, by fluorescence under near-ultraviolet radiation or black light, minute amounts seeping back out from discontinuities. Penetrant is often aided in re-emerging from discontinuities, by the application of a thin, powdery film of developer material, which acts as a blotter. Indications are brilliant under intense near-ultraviolet light. Lines indicate cracks and similar discontinuities; dots indicate pores. The spread of an indication away from a discontinuity gives a rough evaluation of the size of the discontinuity beneath the surface. Of necessity, inspection is confined to surfaces. Since discontinuities open to the surface are almost always more detrimental to the strength of parts than similar discontinuities not open to the surface, inspection is automatically limited to the most vulnerable regions.

Penetrant Materials. Materials most commonly used are oil-base, water-emulsifiable penetrant, which washes cleanly off surfaces of all types by a forced spray of water; and dry powder developer, dusted on parts after excess penetrant has been removed and the parts have been dried. Other penetrant materials include water-soluble, solvent-base penetrant, particularly useful on ceramics, and oil-base penetrant without emulsifier, the excess of which is removed by solvent action. Another type of developer is a colloidal suspension of powdery materials applied after the removal of excess penetrant and then dried in a film on the part, preferably by heat.

Fig. 1 Indication by fluorescent penetrant of a tight-lipped shrinkage in an aluminum permanent mold casting.

Methods of Inspection. In practice, small parts to be tested are usually briefly immersed in the penetrant and are allowed to drain for a period ranging from a few seconds to about 30 min before the removal of excess penetrant. The duration of this time for draining or penetration depends on the materials being inspected and on the character of the discontinuities being sought; tight fine discontinuities require more time for penetration than coarse open ones. Large objects may be painted or sprayed with penetrant. Local inspection (as of welds) may be made by applying penetrant with a brush to the areas in question.

When the best type of penetrants yet developed are used, no advantage is gained by heating parts or penetrant. The more penetrating components of the penetrant are volatilized with the increase in temperature, so the net gain in sensitivity is negligible.

After the draining, excess penetrant is removed from the surface by washing with water or using a solvent, depending on the type of penetrant employed. At this time and until final inspection is made, care must be taken to keep the cleansed surface uncontaminated by penetrant from the hands of the operator or any other source, in order to avoid confusing, irrelevant fluorescence, resulting from such contamination. Before inspection, parts should be cleaned of any fluorescent matter that might hold or absorb penetrant and result in pseudo indications.

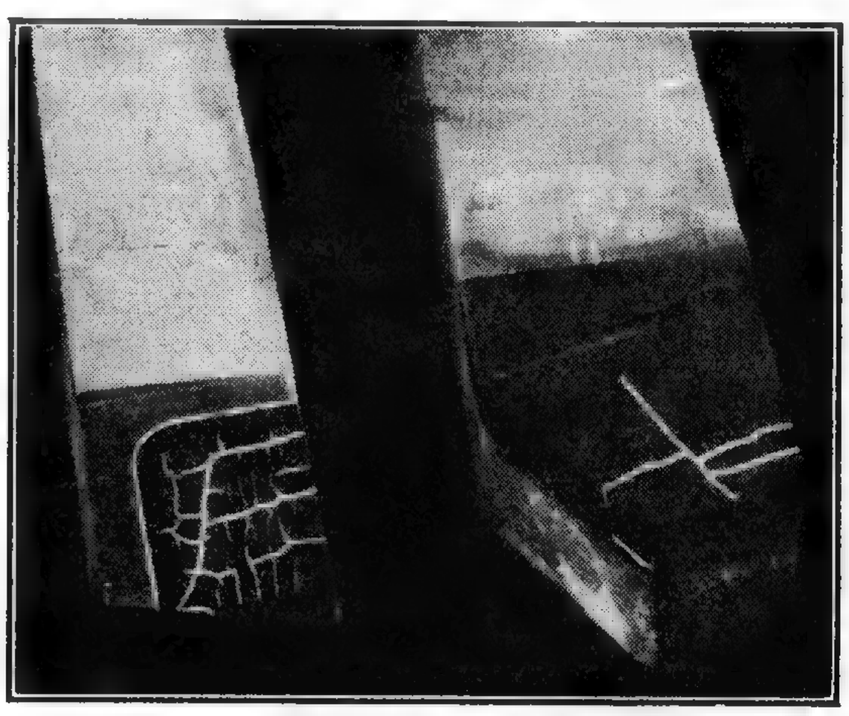

Fig. 2 Carbide-tipped tools with cracks identified positively under black light. Visual inspection, under high-power magnification, fails to disclose many such cracks and confuses scratches with cracks.

If developer of the colloidal suspension type is used, it may be applied to a water-washed wet surface before drying. If dry powder developer is used, parts washed in water are dried immediately after washing. Drying is accomplished preferably by heating, though wiping with a cloth is also satisfactory when dry developer is to be used. For some applications, where the discontinuities sought are rather large and wide open, no developer may be required. Developing time may be from a few seconds to several minutes, depending on the types of discontinuities.

Inspection under black light is carried out preferably with some exclusion of white or visible light. The more minute the discontinuities sought, the more darkness is required. In some applications it is desirable to conduct the inspection in almost complete darkness.

Sensitivity. When the best materials and equipment are being used on *clean* discontinuities open to the surface, the sensitivity of fluorescent penetrant inspection is comparable to that of magnetic particle inspection by the wet method. (*See* page 145.) Unlike magnetic particle inspection, however, fluorescent penetrant inspection is of no value in finding discontinuities that have no connection or opening to the surface. Since cleanliness of discontinuities determines the ease with which the penetrant can enter, it is essential that fluorescent penetrant inspection be used at a point in the manufacturing cycle when discontinuities would be expected to be clean. Otherwise ■ cleaning step must precede the inspection. For example, aluminum cast-

* Magnaflux Corporation, Chicago
* U. S. P. 2,259,400

ings merely cleaned of sand are found to respond very satisfactorily; whereas forgings, which may have die lubricant forced into discontinuities such as laps, may not give proper indications unless a previous cleaning or machining operation removes the included dirt or creates a void beside it.

Applications. Fluorescent penetrant inspection may be applied in locating cracks and shrinkage in castings made of aluminum, magnesium, brass, iron and other metals; cracks in the initial fabrication and regrinding of cemented carbide tools; cracks and pits in welded pressure vessels with nonmagnetic lining, during both fabrication and overhaul periods; cracks in steam and gas turbine blading, new and used; fatigue cracks in nonmagnetic parts of internal combustion engines; cracks in insulators for ceramic spark plugs during several stages in the fabrication of plugs; and seams in tungsten leads for vacuum tubes.

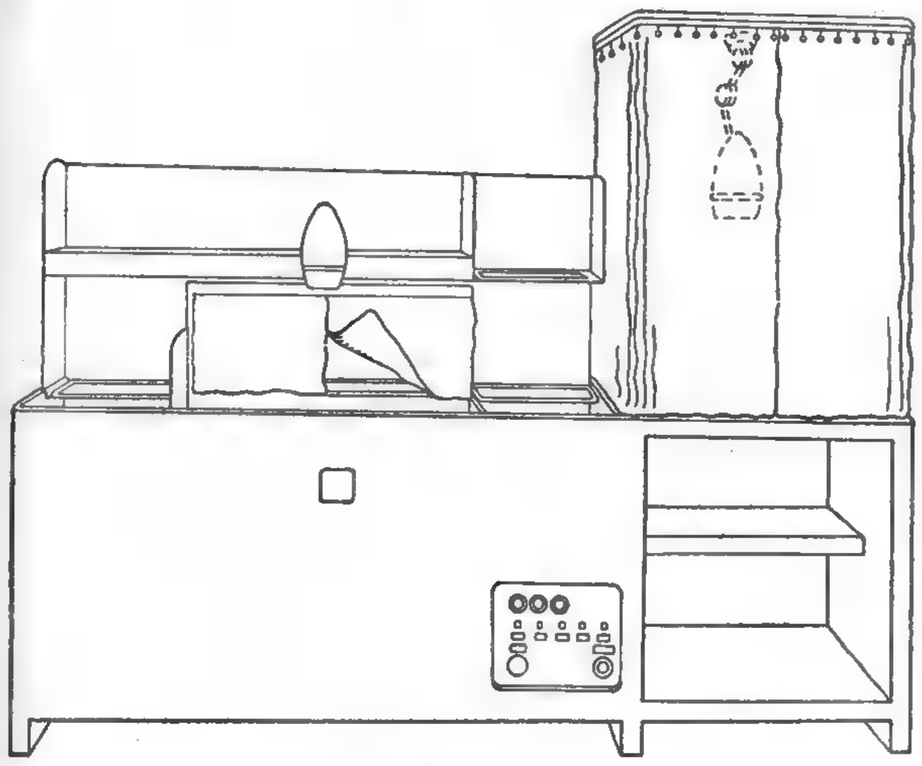

Fig. 3 Complete unit for inspection with fluorescent penetrant, to be used in laboratory work or in production inspection of small parts in moderate quantities. Penetrant dip station at left, drain above, water rinse in center, wet developer in tank at right, drier in rear, and inspection under black light in hood.

Fluorescent penetrant inspection is applicable to castings, particularly as a means to improve quality. For example, shrinkage, especially when it lies in a plane, is a serious defect difficult to locate visually, but immediately apparent when fluorescent penetrant is viewed under black light (*see* Fig. 1). Control of shrinkage is best started during setup experiments. Control should be continued during production, since an unobserved shift of any critical variable may start trouble without being noticed unless regular checks are made. Although light metals constitute the natural field for fluorescent penetrant inspection, simplicity of procedure has made this method useful for testing other materials, such as malleable iron.

Manufacturers and users of carbide-tipped tools have found an important application for fluorescent penetrant inspection, because carbides can be cracked without giving indication of the damage until the tools have failed in service. Although cracks occur most frequently during the grinding operations, their real origin is often traced to high residual stresses imposed by improper mounting. Figure 2 shows typical indications of grinding cracks.

Education of workmen is an important factor in eliminating trouble. One of the best systems is to have the workmen inspect their own work by the fluorescent penetrant method at locations convenient to them. Less time is required for this type of inspection than for a thorough visual examination, and results are much more positive. As an operator corrects his technique, he can taper off the amount of inspection and yet maintain the quality of his work.

Inspection of parts in service, such as pressure vessels and steam turbines, is relatively easy, because the only power needed is a 110-v a-c lighting circuit. Wet rags can be used for washing if water under pressure is not available. Penetrant is applied by spray or brush. Suitable portable sources of black light, such as pistol-grip lights, are powerful enough to allow inspection in daylight, if the operator simply uses his hand and body to shield the area being viewed. Smaller parts from service, such as those from aircraft engines, are inspected for fatigue cracks in permanent equipment.

Expensive parts can often be salvaged by grinding out discontinuities until no further indications appear. Much of the grinding can be done directly under black light, which causes the initial charge of penetrant in a discontinuity to continue glowing while new portions of the discontinuity are uncovered. A final retest through the penetrant cycle is customarily made to assure complete removal of the discontinuity.

The most fruitful use of any method for detecting defects comes during initial experiments, while setting up production procedures. If defects are observed, changes can be made until all troubles are remedied. The next most fruitful use is in continual sampling inspection to make certain that the quality is maintained during production runs. When defects do appear, it is important to be able to check back to the cause quickly and to correct it before much material of low quality is produced. During the emergency period of running down and remedying trouble, it is best to inspect all doubtful material 100%. Fluorescent penetrant inspection, within its scope, lends itself well to all these needs for inspection.

Inspection by Magnetic Analysis Using Measurements of Wave Form Distortion

By T. Zuschlag*

THE demand for better quality steel has stimulated the development of testing procedures that permit more efficient inspection at lower cost. This is particularly true of modern inspection by magnetic analysis to check ferromagnetic articles for uniformity and to detect flaws in steel bars and tubes.

Principles of Operation. Magnetic analysis, in its present state of development, relies on the fact that two specimens of identical composition, dimensions and physical properties possess the same magnetic characteristics and that this relationship makes it possible to ascertain the value of nonmagnetic conditions and properties by means of magnetic measurements. Alternating magnetic fields are utilized as sources of energy; corresponding sections of ferromagnetic materials are exposed to these fields and are systematically tested for changes in magnetic properties by comparative methods of measurement based on continuous procedures for wave analysis. The investigations are carried out with reference to electric standards of comparison that are representative either of a similar section of a standard specimen or of a different section of the same test specimen.

The essential requirement for this type of inspection is the existence of consistent correlations between the conditions of primary interest and the magnetic effects on which the inspection is based. To exploit such correlations successfully, the following circumstances are necessary:

1 The specific condition under examination must affect the magnetic characteristics of the material to be inspected.
2 The change in the magnetic characteristics must distort the alternating magnetic field that is used to investigate the material.
3 The resultant distortion of the alternating magnetic field or of any voltage induced by the field must be measurable and interpretable as an indicator of the condition that caused the deviation in the magnetic characteristics.

* Chief Engineer, Magnetic Analysis Corporation, Long Island City, N. Y.

A complete discussion of the first stipulation is found in Spooner, "Properties and Testing of Magnetic Materials", McGraw-Hill Book Co., 1927. The second stipulation is explained extensively in most textbooks on electrical engineering. No comparable references, however, are available for the third stipulation, since it relates to developments not yet adequately described in current technical literature.

Range of Application. Magnetic analysis is the nondestructive inspection by magnetic measurements of ferromagnetic articles for variations in nonmagnetic properties and conditions. This definition covers the testing of uniformly cross-sectioned material such as bars and tubes, as well as that of objects irregularly shaped but of like dimensions, such as small forgings, castings, machined parts and various other items.

The most important problem of inspection by magnetic analysis relates to the magnetic effect of the mechanical stresses normally present in ferromagnetic materials. These stresses change with the type of stress-forming operation and with the grade, heat, shape and dimensions of the material; and they are closely related to such factors as brittleness, case depth and machinability, as well as to the presence of defective sections in otherwise sound specimens. Representing the factual link between variations in mechanical conditions and magnetic characteristics, this relationship is the core of many magnetic test problems, since the efficiency of inspection by magnetic analysis depends largely on the level and the uniformity of the prevailing stress pattern. Thus, a magnetic inspection of annealed material, low in stress, is less efficient than a comparable inspection of material in a stressed state and, in fact, is limited to indicating the uniformity of such physical, chemical or mechanical factors as affect the magnetic characteristics directly. Test results of greater sensitivity are obtained for stressed material, because the inspection is normally concerned with conditions that change the prevailing stress distribution, thus affecting the magnetic characteristics both directly and indirectly. This is true of bars and tubes straightened by machine, and particularly of heat treated material. Cold drawn, stress relieved, hot rolled, and annealed stock, in that order, are less highly stressed and thus less sensitive to investigation of the following conditions and properties: uniformity of grade, heat, heat treatment, processing, cold working, hardness, structure, decarburization, case depth, stress distribution, and such flaws as cracks, seams, slivers, cupping, as well as defective welds in tubing.

The penetration of alternating magnetic fields into ferromagnetic materials is limited even for 60-cycle investigations. This fact makes testing by magnetic analysis a surface inspection method and, in general, prohibits the possibility of locating internal defects such as subsurface cracks and pipes, unless these flaws are linked to variations in the stress pattern at the surface. Similarly, the depth of flaws that can be located by these measurements is primarily a function of the magnitude of the disturbance in the normal distribution of surface stress caused by the defect, and the depth of perceptible flaws varies with the grade, size, shape and processing of the specimen. For cold drawn bars straightened by machine, the minimum depth of intermittent defects that can be detected by these methods is about 0.015 in. per in. diam for round bars and 0.012 in. per in. for hexagonal bars of comparable size.

Commercial inspections that can be carried out by methods of magnetic analysis vary with the type of materials, as indicated in Table I.

Table I. Types of Inspection by Magnetic Analysis

Type of Inspection	Material
Uniformity and *identification* of properties and conditions affecting magnetic characteristics directly	All shapes of ferromagnetic articles of like dimension and in annealed state
directly and indirectly	in stressed state
Detection of flaws	Machined — straightened bars of all shapes, including:
cracks	hot rolled, ground
seams	hot rolled, heat treated
slivers	cold drawn
cuppings	cold drawn, stress relieved
	cold drawn, heat treated
	Seamless tubes
	stress relieved
Welds	Electrically welded tubing
open and weak welds	Butt-welded tubing
burned areas	

Measurement of Distortion of Wave Form. During recent years the number of applications for magnetic analysis tests has been potentially increased by the introduction of investigation methods that possess greater sensitivity, selectivity and resolving power than many of the older test procedures formerly used for purposes of magnetic inspection. As employed in a majority of equipments for production testing, modern inspection by magnetic analysis relies primarily on measurements of wave form distortion to solve test problems.

The basis of these measurements relates to the fact that the wave form of any voltage induced by an alternating magnetic field is distorted by the introduction of ferromagnetic material into the field and that the type and strength of the distortion is characteristic of the inserted material. When different materials are exposed to the same alternating magnetic field, the resultant wave forms differ in many respects, including the properties and conditions mentioned. Although it is not generally possible to correlate a particular wave form with a specific property or condition, many chemical, physical, metallurgical or mechanical variations affect only limited sections of the basic wave cycle and therefore may be investigated by measurements that are restricted to the same, if relatively short, portions of successive wave cycles.

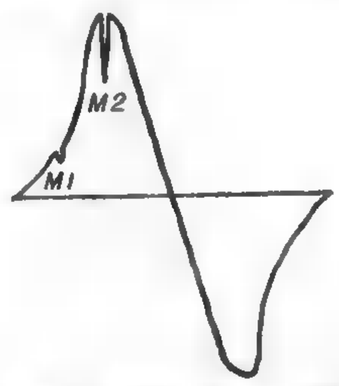

Fig. 1 Typical wave form of secondary voltage, showing superimposed electronic markers.

The utilization of these phenomena for test purposes requires inspection methods that are capable of a "point analysis" of the induced voltage wave. Although various types of laboratory methods suitable for such measurements have been known for some time, it was not until electronic circuits were developed for investigating cyclic distortions that these modern "point" methods proved their utility for commercial testing. (T. Zuschlag, Inspection by Magnetic Analysis, ASTM Bulletin, Aug 1939)

In their present form, electronic point methods are capable of measuring instantaneous amplitude at arbitrarily selected points of any induced voltage wave, by means of circuits with "gated" vacuum tubes. Adaptable for operation at any frequency, these methods are employed preferably for investigations at 60 cycles. The principle of these measurements can be visualized with the help of a cathode-ray oscilloscope pattern, as indicated in Fig. 1. Illustrating a single cycle of alternation, a typically distorted 60-cycle wave of induced or secondary voltage is shown as being inspected at two different phase locations identified by the electronic markers M1 and M2. The positions of the markers represent the locations where the measurements of instantaneous amplitude are carried out: these locations can be shifted to any portion of the voltage wave. When comparative measurements are employed even very slight variations from predetermined or standard voltage values are accurately determined by vacuum-tube voltmeters. This direct method of investigating wave amplitude is known as the "electronic standard method of point investigation" and is used primarily for separation of grades and problems of quality control involving bar and tube inspections.

A modification of this method is employed in connection

with the "mechanical standard" or "two-coil" method of magnetic comparison. Properly used, this arrangement permits the solving of test problems that would normally yield only to interpretation by the oscillograph. However, the most important application of electronic point inspection is for detecting flaws in bar stock and tubing. The method used for this purpose provides for the comparison of a section of the test specimen with another section of the same specimen spaced at some distance. The differential wave resulting from this comparison approximates a straight line with two 180-deg phase-displaced peaks that frequently show violent but meaningless fluctuations because of changes in the stress distribution of the material. The presence of minor flaws, such as shallow seams, does not affect this pattern greatly, even though it may change the shape of the peaks or result in the appearance of a slight additional distortion. Because the magnitude of this additional distortion is often smaller than that of the normal peaks, it would be difficult to detect such variations by means of standard methods of measurement. However, by using point inspection, it is quite feasible to avoid the regions of meaningless peak fluctuations and to investigate only such sections of the differential wave as contain pertinent or significant test information. The "null method" of point inspection is best suited to indicate the start and the end of intermittent defects and is used primarily for purposes of flaw detection.

Commercial Installations. Commercial equipment for magnetic analysis provides for the complete inspection of ferromagnetic articles, except for short sections at the ends. Practical speeds for inspection of bars and tubes range from 100 to 150 ft per min, depending on the diameter and shape of the material, the handling facilities, the standard of inspection and the ability of the operator. Under average conditions it is possible to test about 20 tons of 1-in. rounds in a single 8-hr shift.

Installations for production tests by magnetic analysis are either of the bar-and-tube tester type or of the comparator type. A typical installation for testing bars and tubes comprises a test-coil assembly, a combination indicator and control cabinet and auxiliary arrangements for operating and feeding. The material to be tested is passed through exchangeable secondaries capable of handling stock from ¼ in. to 3¼ in. in diam. The effect of the material on the primary energizing field is analyzed by several electronic point methods operating simultaneously, and the results of this analysis are individually presented for inspection by separate meters or high-speed indicators equipped with neon lights.

Comparator installations employ the mechanical standard method of magnetic comparison and consist of a two-coil assembly and a smaller combination indicator and control cabinet. The differential output wave of the two-coil units can be viewed directly by means of a cathode-ray oscilloscope or can be point analyzed and the result observed by means of a meter and a neon-light indicator.

Installed by a majority of leading steel companies and, during the war, by many plants manufacturing airplane engines, equipments for inspection have checked a large amount of material for flaws and for separation of grades by magnetic analysis, as well as for production and quality specifications. These results were obtained with equipment not incorporating the latest improvements in measuring distortion of wave form; therefore, it is reasonable to believe that the development of these methods will mean further advances in testing by magnetic instruments.

Nondestructive Inspection by Comparisons of High-Frequency Core Losses

By P. E. Cavanagh*

THE theoretical, experimental and practical establishment of useful correlations between the magnetic and electrical properties and the physical properties of metals has demonstrated the possibilities of developing nondestructive methods of comparing physical properties of metals. In particular, the agreement recently reached between fundamental magnetic theory and experimental results has allowed a theoretical explanation of many phenomena which formerly raised doubts as to the validity of using magnetic determinations in this manner.

Principles of Operation. If a metal sample is placed in the field of a test coil that is part of the tuned circuit of an oscillator, energy losses will occur in the metal sample, which will decrease the energy output of the oscillator. Both magnetic and eddy current losses will make up the total core losses in the coil. This principle offers a possible tool, with certain very definite limitations, for quick comparisons of physical properties of metals.

If such an oscillator is to provide useful information, it must be extremely sensitive and yet sufficiently stable for practical purposes. These objectives can best be realized in a frequency range from about 1,000 to 200,000 cycles per second. One commercially available instrument consists of a carefully constructed two-stage oscillator (Fig. 1). The test coil, which is part of the tuned circuit, is bifilarly wound to obtain maximum mutual inductance between the two sections of the oscillator, and to provide self-shielding from outside interference. This coil controls the operating frequency of the oscillator.

The oscillator is essentially a multivibrator. A sensitivity control governs the amount of regenerative feedback and allows adjustment of the initial energy output of the oscillator to any desired level. Core losses, occurring in the field of the test coil, decrease the output of the oscillator. The operating frequency remains constant within narrow limits. In order to stabilize the oscillator when it is operating near zero output, it is modulated by a much lower frequency, usually 330 cycles. The oscillator output is viewed on the screen of a cathode-ray tube. Descriptions of this instrument and its uses may be found in current technical literature.[1,2]

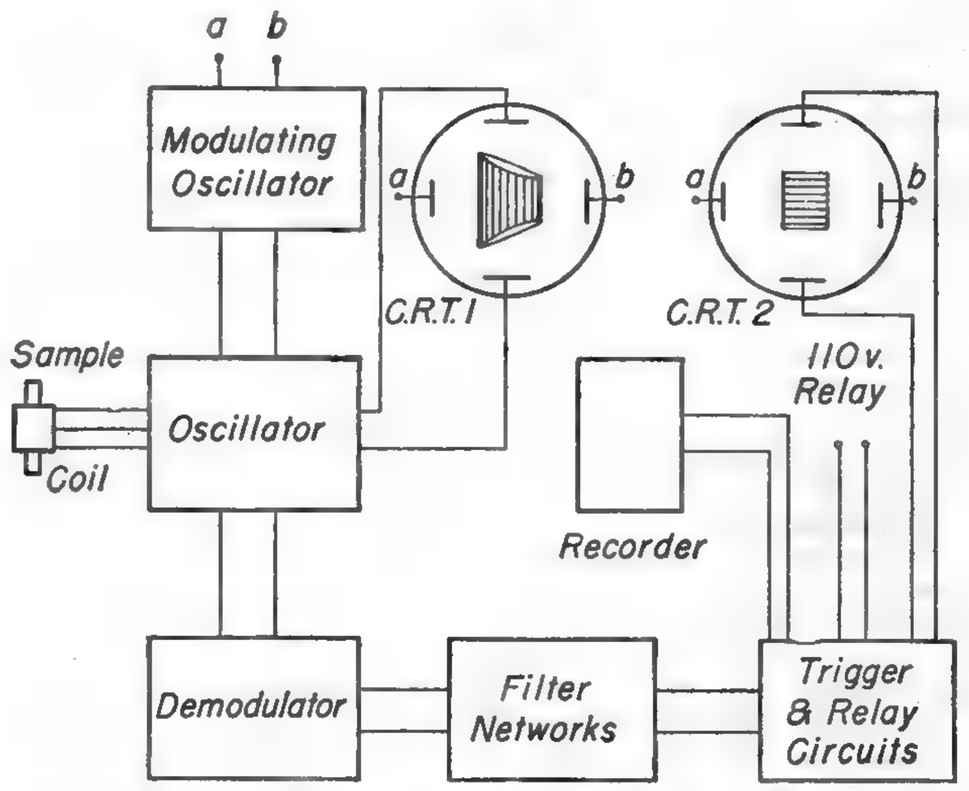

Fig. 1 Cyclograph block diagram

Many magnetic testing instruments in use today provide practical means for inspecting metals for one or more physical properties. The most serious limitation of magnetic testing is the fact that it is sometimes possible, on such an instrument, to obtain the same indication for two widely different pieces of metal. This is to be expected in a few instances, since an increase in one magnetic property may sometimes be exactly balanced by a decrease in

* President, Cyclograph Services, Ltd., Toronto, Canada; Senior Research Fellow, Ontario Research Foundation, Toronto

others. A further complication is that small variations in unimportant physical properties may be accompanied by large changes in magnetic properties.

A major advantage gained by the use of high frequencies is the ease of performing multiple tests at several frequencies. Since it is obviously unreasonable to expect a single test always to evaluate a large number of variables correctly, multiple tests are required for reliable results when this type of testing instrument is used on production lots where many extraneous variables may affect the test.

Various physical properties affect the magnetic and electrical properties to different degrees. Since the proportions of magnetic and electrical losses which make up the total core losses vary with frequency, correlation can be obtained with different sets of physical properties by testing at different frequencies (Fig. 2).

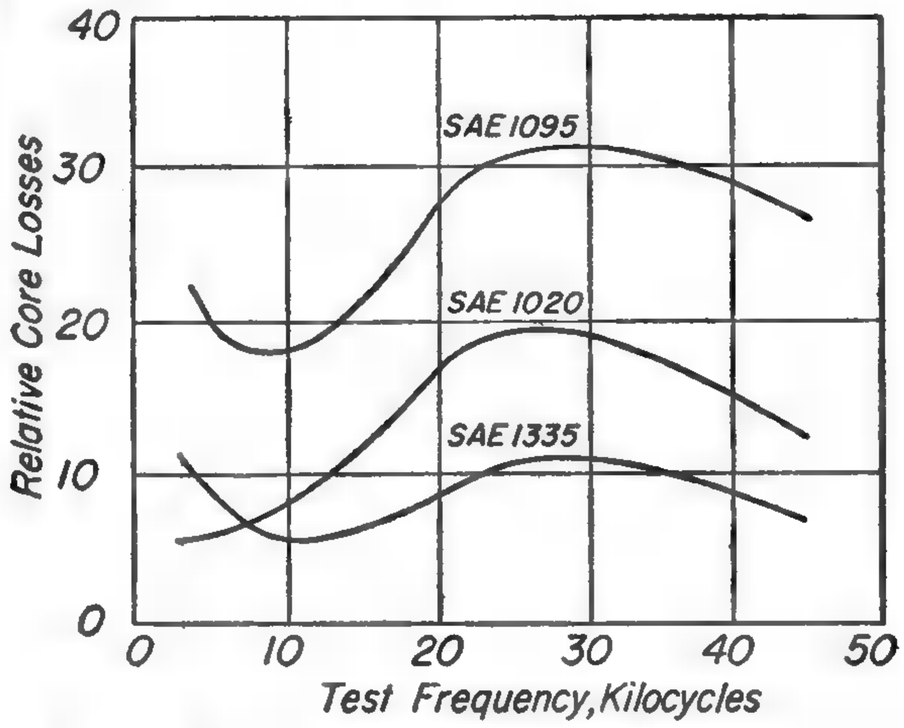

Fig. 2 Changes in relative core losses with test frequency. Excluding other factors 25 kc would be optimum test frequency; 7 kc would be entirely useless for separating these three steels.

Choice of Test Frequencies. In the lower range of test frequencies, from 1,000 to 10,000 cycles, the test flux penetrates a metal sample to a considerable distance and an average evaluation of the properties of the piece is obtained. At higher frequencies or with very large diameters, the test flux is confined to the material near the surface of the metal piece. This allows examination of the surface layers independent of the properties of the core material beneath the surface.

By use of auxiliary circuits, the output of the oscillator may be made to operate automatic rejection relays, which will throw out material not within specified limits. The rate of automatic inspection may be as high as five pieces per second for small metal parts.

Cracks and flaws do not affect the output of the instrument to any significant degree, except in certain instances. The test coil is designed to minimize the effect of discontinuities so that their presence does not influence the comparison of physical properties. Variations of approximately 10% in mass do not interfere with the results of the test.

Practical Uses. High-frequency core losses may be said to compare only two characteristics of metals. If the structure or stresses in a sample are different from those of a standard, this fact will be indicated by a change in the total core losses. The magnitude of change that is detectable depends on the sensitivity of the instrument used.

It follows that where this method is used to distinguish between metals that differ in chemical composition, the difference in composition, in order to be detectable, must produce some significant change in physical properties or structure. In general, a sufficiently sensitive instrument will readily distinguish among the commonly used grades of SAE and tool steels. On the other hand, the instrument would not be expected to distinguish between steels differing only by a small amount of sulfur. Furthermore, any change in composition is most easily detected in the stage of heat treating at which it produces the greatest difference in physical properties or structure. The same rules hold for ferrous and nonferrous metals.

Since a change in structure is usually accompanied by a difference in penetration hardness, it is sometimes possible to use high-frequency methods for acceptance tests of metal parts within certain limits of hardness. The test gives an over-all average for the metal within the test coil, so that good correlation with Rockwell hardness will be obtained only when the structure is extremely uniform or when Rockwell hardness measurements are integrated throughout the volume that is being inspected.

In order to obtain practical correlation with penetration hardness, extraneous variables must be reasonably constant. It is possible to conduct preliminary tests at a suitable test frequency; thus groups of pieces sufficiently alike in extraneous variables may be segregated from production so that inspection for hardness can be carried out successfully on each group at another test frequency. If too many extraneous variables are present, this procedure becomes too complicated to be practical and the instrument does not provide a suitable method for inspecting production.

These same comments apply to inspection of malleable castings for detection of an underannealed condition, and to all tests that have as their objective the selection of a certain desired structure which may be within certain limits of machinability, hardness or composition.

Inspection of Surface Layers. The use of tests at higher frequencies provides practical methods for comparing case depths and plating thicknesses. The test frequency is chosen so that the flux is confined to the area of the case or plating. Changes in case depth or plating thickness will affect the total core losses.

It is usually essential that preliminary tests be made on case-hardened parts to insure that all parts, in a group being compared for case depth, are sufficiently alike in extraneous variables to allow evaluation of case depth.

Since the relationship between case depth and core losses depends primarily on flux penetration, it will hold over only a certain range of case depth. In practice, this means that the high-frequency method of comparing case depths may be successful in grading parts within the range from 0.010 to 0.040 in., but that it will not segregate successfully parts with a greater case-depth range of 0.10 to 0.90 in.

The accuracy attained in comparing plating thicknesses is generally about 10% of the total plating thickness. A variation of 10% can be detected regardless of the total plating thickness, as long as the test frequency is properly chosen to penetrate just beyond the junction of plating metal and base material.

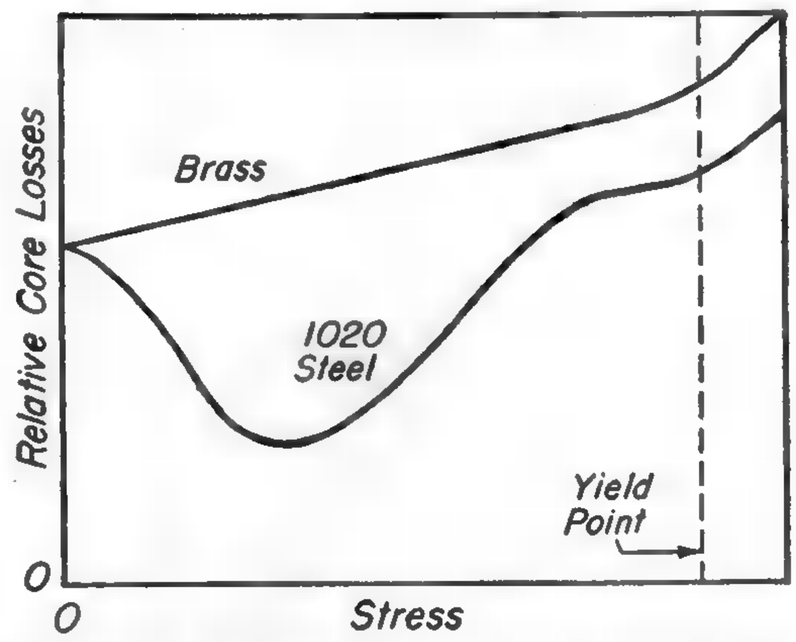

Fig. 3 Change in core losses in magnetic and nonmagnetic metals as tensional stress is increased. Tests on standard ½-in. diam tensile specimens mounted in tension test machine. Instrument reading decreases as core losses increase.

Stress Comparisons. Any distortion of the crystal structure in metal will produce some effect on the magnetic properties of a ferromagnetic material. Whether this change is measurable or not is a practical problem. The theoretical relationships between different types of stresses and magnetic properties have been established by several investigators.[3,4,5] Stresses in a nonmagnetic material will change the electrical resistivity. The manner in which total high-frequency core losses vary with stress is shown in Fig. 3. In this field of application, high-frequency core

losses may be used to compare stresses set up during quenching or cold working. Abnormally high residual stresses, which may cause cracking or premature failure, can be detected.

There are some interesting applications of this method for the detection of the beginning of plastic deformation. Practical use has been made of the fact that there will be a different relationship between an increase in applied stress and the resulting increase in core losses before and after a metal part has undergone plastic deformation.

Detection of Cracks and Flaws. As stated previously, circuits similar to that of Fig. 1 are not appreciably affected by cracks and flaws except in certain cases. If a radial crack extends completely through a ring-shaped sample, it can be detected easily by such an instrument.

Special testing arrangements have been used to locate cracks by designing eccentric test coils in which the sample is rotated. As a crack is brought into the field of the test coil, a sudden change in eddy-current losses will cause a large change in instrument reading. Several instruments use variations of this principle. In some instances, the sample may be rotated in a constant magnetic field. A small stationary pickup coil is placed beside the rotating sample and generates a surge of current each time a crack or flaw passes by. Tuned auxiliary circuits are used to emphasize this signal and give an indication of the presence of a crack or flaw.

Several types of radio-frequency crack detectors are also in use. These instruments depend on the large change in eddy-current losses caused by surface cracks in metal samples inserted in the test coil. The most successful type uses this change in core losses to change the frequency of one oscillator, which is then compared or "beat" against the standard oscillator.[6]

The only advantage of these methods is in the rapid inspection of great numbers of small parts. The results obtained are no better than those obtained by magnetic particle inspection or by low-frequency instruments for detecting cracks.

Applications. Practical uses of high-frequency test instruments are being made in many fields. The practical range of sample sizes is from a minimum of about $\frac{1}{16}$-in. diam to a maximum of 2 to 3 ft in some special instances. The portion of the samples within the field of the test coil must have the same dimensions within usual manufacturing limits. Since the portion of the sample that lies outside the field of the test coil does not influence the test, a bar 2 ft long might be compared with another bar 24 ft long, provided they have the same diameter.

Where irregularly shaped castings or forgings are tested, they must all be passed through a test coil in the same orientation. Local tests can be made by designing coils that will limit the test field to some portion of the specimen in exactly the way in which special coils are used for local induction heating.

Industrial uses of this type of equipment have included the following representative operations:

1 More than a million bolts were sorted that had been fabricated from two SAE steels, 1012 and 4037, because of an accidental mix-up. The proper steel was 4037. The hardened bolts were sorted automatically into the two types present, at the rate of 2 per sec.
2 About 12,000 lb of SAE 52100 in the form of ⅝-in. bar stock was inspected to segregate fully spheroidized from partially pearlitic stock.
3 Various sizes of ball bearing races made of SAE 52100 steel were tested to detect excessive grain growth caused by overheating in forging.
4 About 90,000 small copper cylinders were sorted into satisfactory soft specimens of Rockwell 15-T 80 and lower, and hard underannealed cylinders harder than Rockwell 15-T 80.
5 Extruded cylinder-head bolts were inspected to detect those having such high stresses in the heads that they would crack when tightened in the block.

Methods of Use. In industry, there are three general ways in which this method of inspection has been used.

Salvaging. Magnetic testing can very rapidly and cheaply salvage satisfactory parts from a mixture of large quantities of good and bad pieces.

Inspection. Magnetic testing can be used to inspect production 100%. Since this is a nondestructive test, it does not harm the pieces in any way and its high speed of operation makes feasible the inspection of enormous quantities of such articles as bolts, bearings, small castings and stampings.

Process Control. The most intelligent use of such instruments is for process control. The instrument can be installed immediately after some critical operation in the manufacturing process. Satisfactory pieces will give a reading within a certain specified range. If one piece is detected that does not give the expected reading, the manufacturing process can be immediately checked. This prevents the production of large quantities of unsatisfactory pieces that later would be rejected.

Electric Inspection of Tubing and Bar Stock

By W. E. Habig*

THE objective of electric inspection of tubing and bar stock is to detect defects, such as seams, to the exclusion of all variables considered harmless. This testing is accomplished by inducing electric current to flow within the material and by measuring the degree and extent to which the current deviates from its normal path because of the presence of a defect.

The instrument to be described was designed to detect seams of various depths, without indicating variations either in chemical composition, metallurgical structure, stress concentrations or magnetic permeability.

Principle of Operation. *Excitation.* Figure 1 shows the basic principle of operation. Circumferential alternating currents are induced in the material placed within the coil, by the alternating flux within the exciter coil, which is energized by alternating current of selected frequency. These induced currents, distributed near the surface of the material, set up a magnetic field opposing the magnetic field of the exciter. The flux density at any point between the coil and the material is therefore a function of the resistance of the material and of the distance from the mean path of the current within the material.

Detection. The detection and measurement of the magnetic flux distortion are effected by means of search coils located within the magnetic flux and in close proximity to the material. The voltage induced in the search coil in an area of good material is compared with that induced in a coil in a defective area. For a searching unit it has been found most practical to use two or more coils in balanced opposition, so displaced that for the particular type of defect to be detected, one will be in a field of uniform flux while the other is adjacent to the defect. When both coils are adjacent to sound material, the voltages induced in them are equal, and since they are connected in electrical opposition, the output voltage is zero. A change of flux in one coil, because of a defect, unbalances the system, resulting in a differential output voltage, which is amplified and made to operate a signal lamp or other auxiliary equipment. The coils are so arranged that they compare the induced voltages around the bar circumferentially at numerous points and hence compare the soundness of the surface around the material rather than along it (a

* Development Engineer, Sperry Products, Inc., Hoboken, N. J.

patented arrangement). Hence, a continuous and uniform defect, such as a long seam, would be detected by this arrangement as long as its depth does not exceed that of the current penetration, whereas it would be neglected by any system that compared conditions along the material.

Elimination of Indications Caused by Stress. Indications from symmetrically displaced stress concentrations are also eliminated by the patented arrangement for locating the search coils as partially described above.

Permeability Effects. False indications from permeability variations in ferrous materials are eliminated by another arrangement for saturating the material with d-c flux.

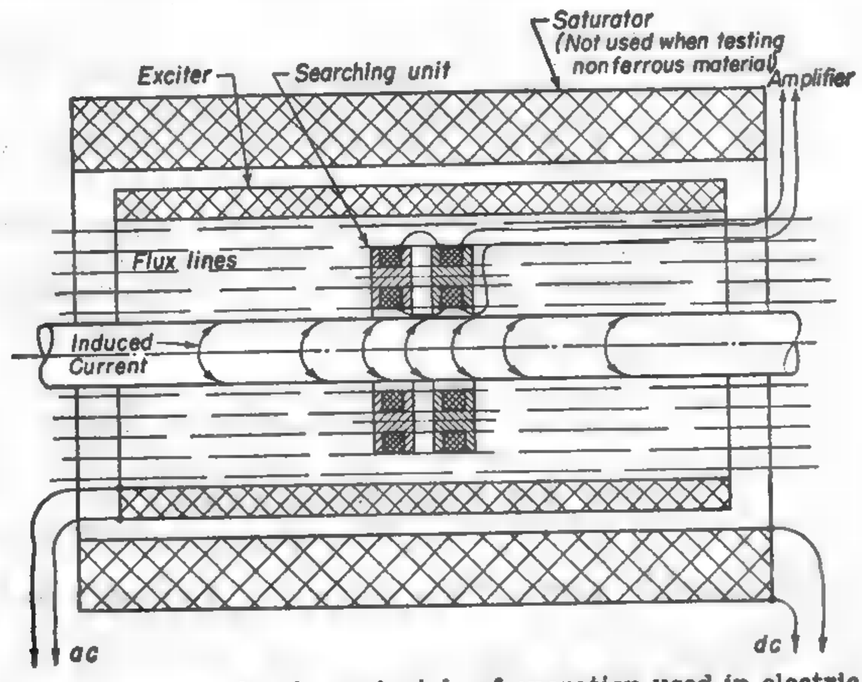

Fig. 1 Diagram showing principle of operation used in electric inspection of tubing and bar stock.

Depth of Penetration. The current induced in the material flows around it circumferentially in a thin layer near the surface, in accordance with the well-known phenomena of "skin effect". The current density varies exponentially from the surface to the center and is a function of the frequency of the exciting voltage. Since there is no clearly defined layer, the depth of penetration is considered to be the distance from the surface at which the current density drops to 37% of its value at the surface, as given by the formula:

$$D = 1400\sqrt{\frac{\rho}{\mu f}}$$

D = depth of penetration (inches)
ρ = resistivity (ohm-cm)
μ = magnetic permeability (for nonmagnetic materials = 1)
f = frequency (cycles per second)

The above formula is valid only as a first approximation, but will give reasonable results for the condition where the wall thickness is much greater than D. With d-c saturation as shown in Fig. 1, the permeability of such highly magnetic materials as magnetic steel, will be reduced to between 1 and 4. For practical purposes most magnetic materials will behave as nonmagnetic materials and the depth of current penetration can be calculated using $\mu = 1$. If the reader is interested in finding the penetration in magnetic material the permeability of which is known to be greater than 1 at saturation, he can use the data of Fig. 2 by merely dividing the result by the square root of the known permeability. It can be seen that as the resistance of the material increases, the frequency must be increased in order to maintain equivalent current density at the surface and, thereby, maximum sensitivity.

Conditions Affecting Electric Inspection. There are many conditions that cause variations in the magnetic flux around the material by currents flowing within it, namely: (*a*) defects consisting of seams, fissures or discontinuities with principal dimension perpendicular to the direction of flow of current; (*b*) stress concentrations within the material, caused by bending, cold working and similar operations; (*c*) variations in chemical composition, in successive pieces or lots; (*d*) permeability variations in ferrous materials, caused by variation in chemical composition, heat treatment or stress; (*e*) surface conditions, such as pitting, rust, checking and the like; (*f*) segregation, spheroidization, hardness and other metallurgical conditions.

All the above are measureable in the laboratory, but commercial equipment has been designed to reduce indications, from all causes except defects, to a negligible level. In order to measure any one of the conditions accurately, it is necessary either to isolate it or to eliminate all the others, employing electrical means or metallurgical treatment of the material. Seams, fissures and discontinuities,

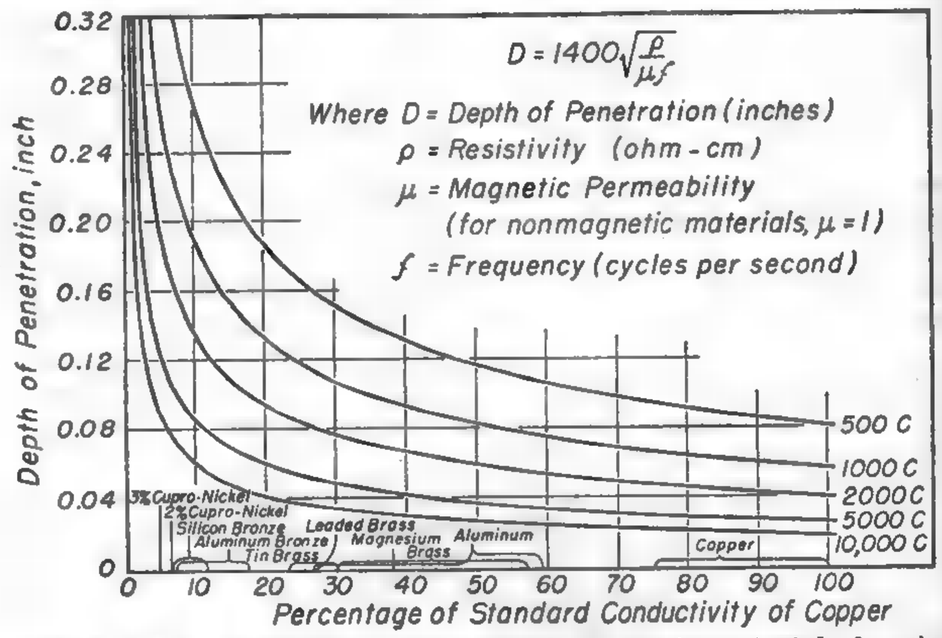

Fig. 2 Depth of penetration of induced current in material of various conductivities at 500, 1000, 2000, 5000 and 10,000-cycle exciting voltage frequencies.

as described, can readily be isolated electrically except for handling marks and dents, which are usually surrounded by nonsymmetrically displaced stress concentrations unless the material has been stress relieved after the introduction of the dents. Marks of this nature give large indications because of the extent of the stress condition. Therefore it is necessary to examine each indication, in order to insure against rejection of good material. There is naturally a limit to how near to the end of a given specimen testing can be accomplished before the end effects mark out any defect present. Experience has shown that good results can be obtained within 2½ in. of the end of a single bar or rod. With abutted ends, testing close to the junction depends on the ability of the operator to observe the flashing of the indicating light and the speed of travel of the material being tested. The junction at the ends of abutted material will cause the light to flash once. Assuming that the operator can distinguish an additional flash occurring 1/10 sec either earlier or later, testing would be continuous up to the following distances from the end of the material:

Speed, ft per min	160	120	80	40
Distance from end, in.	3.2	2.4	1.6	0.8

Size of Defect Detectable. The minimum depth of seam detachable in any given material depends on its surface condition. It has been found that several shallow seams or pits, displaced circumferentially about the material, may create signals equal to that from a single seam of greater depth. Therefore, if the material is badly pitted or checked over its entire length, the sensitivity must be reduced to the level at which signals from the pitting or checked condition are not indicated. This automatically limits the minimum depth of defect detectable in that material. In ground surface stock it is possible to detect seams of the order of 0.005 in. deep, whereas in most commercially finished stock an attempt to detect flaws less than 0.032 in. deep may result in excessive false indications caused by otherwise harmless surface conditions. Some special instances have been recorded where commercial testing has successfully revealed seams of a maximum depth from 0.010 to 0.020 in. without excessive indications. However, the smallest defect which experience has shown to be universally detectable is ⅛ in. long by 0.032 in. deep, lying within $\frac{1}{16}$ in. of the surface.

Supersonic Testing

By Floyd A. Firestone*

If a piece of metal is struck by a hammer, it will radiate certain audible notes of which the pitch and damping may be influenced by the presence of internal flaws. However, this ancient technique of hammering and listening is useful only for the determination of large flaws. A more refined technique consists in transmitting into the metal part to be inspected, sound waves with frequency so high (for example, 5,000,000 cycles per sec) and wave length so short (for example, $\frac{1}{16}$ in.) that a beam of sound waves can be sent through the piece, and will have properties similar to those of a beam of light. Large flaws will cast an acoustical shadow on the face of the piece opposite the face through which the waves entered. Small flaws can be detected by measuring the small amount of sound energy that they reflect back to the sending point. Distances to flaws, or to inaccessible faces, can be measured by measuring the time of flight of the waves, as in radar. Average grain size can be measured by measuring the attenuation or scattering of the waves. Practical equipment is now available for making such determinations in the production inspection of parts.

A supersonic wave is an elastic wave of higher than audible frequency. The properties of the wave that are useful for inspection and measurement derive not from the inaudibility but from the shortness of wave length. Air transmits only one type of sound wave (longitudinal) but a solid part will transmit three wave types if the wave length is short in comparison with the smallest dimension of the part. These types of wave are, namely: longitudinal waves, which have particle displacements in the direction of propagation (velocity in steel, 256,000 in. per sec); shear waves, which have particle displacements at right angles to the direction of propagation (velocity in steel, 128,000 in. per sec); Rayleigh waves, which travel only on the surface of the part and are somewhat similar to waves of short wave length on the surface of water, except that the particle displacement in Rayleigh waves penetrates beneath the surface for a distance approximately equal to the wave length (velocity in steel, 118,000 in. per sec).

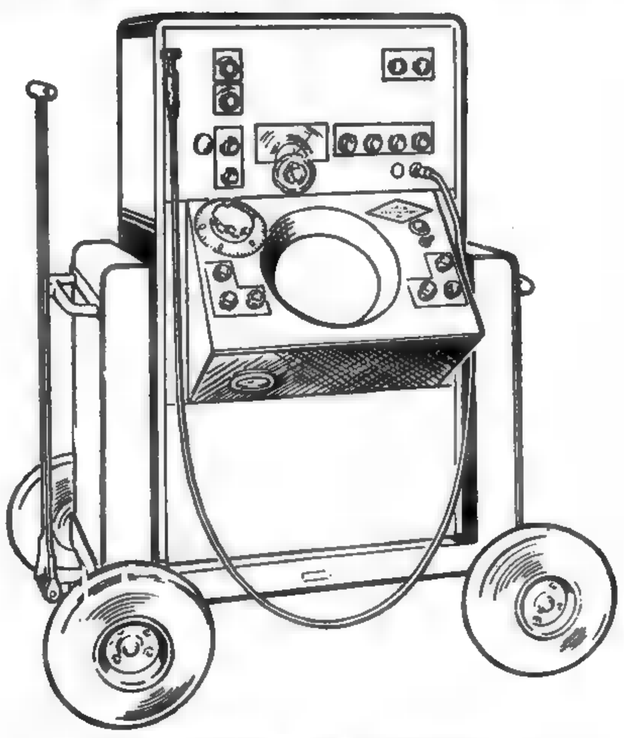

Fig. 1 Supersonic reflectoscope

If the wave length is comparable with some dimension of the part, still other wave types may be propagated, and in some instances may have useful properties. The longitudinal wave type first mentioned is the one generally used.

Supersonic waves of the desired type are radiated and detected by means of piezoelectric crystals—usually quartz of chosen cut and shape—which may be touched to the oiled surface of the part; or the sending and receiving crystals may be immersed in a tank of water, while the part to be inspected is placed in the sound beam in the water. Specific techniques are described in the references.

The simplest forms of supersonic equipment send a continuous stream of waves through the part under test. These can detect flaws large enough to cast a discernible acoustical shadow on the opposite face of the piece, or can measure accurately the thickness of sheet material by establishing resonance through it.

Another form of equipment (Fig. 1) sends into the part a wave train consisting of a few waves that are radiated in a few millionths of a second. Reflections of this train of waves from very small flaws or from the opposite side of the part are observed on a cathode-ray tube. This is the principle of the *supersonic reflectoscope*[1,2,3,8] (Fig. 2).

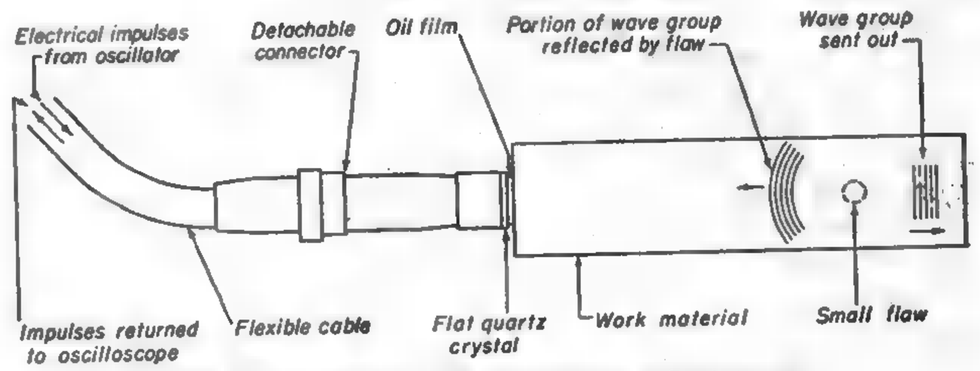

Fig. 2 Principle of the supersonic reflectoscope

Supersonic waves are interrupted wherever the solid material has a discontinuity, however thin; they are reflected from any abrupt change of density or elasticity. The velocity of propagation of the waves depends on average density and elasticity; the time of flight is proportional to the distance traversed; the attenuation of the waves (loss of amplitude with distance traveled) depends on grain size and composition. When the material has different elastic constants in different directions (that is, when it possesses elastic aeolotropy) longitudinal and Rayleigh waves have velocities of propagation that depend on the direction in which they travel through the part, while the velocity of shear waves further depends on the orientation of the plane of vibration around the direction of propagation. These are the basic physical facts utilized in supersonic determination of the condition of the interior of a metal part.

Possible Uses. *Determination and Location of Small Flaws.* When the supersonic reflectoscope is used, its crystal on the end of a flexible cable is touched to the surface of the part, and the presence and distance of the flaw from the surface are indicated at once on the screen of the cathode-ray tube. Approximately 20 ft of metal can be penetrated. Within a few inches from the contacting point, a spherical void 0.02 in. in diam can be detected, and at a distance of 10 ft, a sphere 0.2 in. in diam gives a plain indication, under average conditions. Under favorable conditions, with clean metal of small grain size, holes as small as 0.001 in. in diam have been detected, but dirty metal or unfavorable structure can yield a background of reflection that may reduce the sensitivity far below that mentioned in the previous sentence. Roughness of the surface at the contacting point also reduces the sensitivity. A rough casting should at least be touched to a grinding wheel at the contacting area; some users specify an F4 finish. Curved surfaces are contacted effectively by a crystal ground to fit the curve, although for radii greater than 3 in. a flat crystal may be used.

Determination of Large Flaws; Laminations in Rolled Plates. A beam of waves is sent into one surface of the part and is picked up on the opposite surface; a flaw large enough to occult the beam is indicated by decreased received energy. Continuous-wave equipment is simplest for this application, although the reflectoscope can also be used. Complete inspection of a rolled plate for laminations, by the aforementioned technique, requires the scanning of all parts of the plate by the supersonic beam. Another technique, which may be faster, consists in generating with the reflectoscope, near an edge of the plate,

* Consulting Physicist, Washington, D. C.; Consultant to Sperry Products, Inc., Hoboken, N. J.

a beam of Lamb or surface waves[8] that will travel across the plate and be reflected from the opposite edge or from intervening laminations; it is then necessary only to scan along a single edge in order to inspect the entire sheet.

Inspection of Bond of Plated, Welded, or Soldered Surfaces. If both opposing surfaces are accessible, the same techniques may be used as for detecting laminations (explained above). If only one face is accessible, the reflectoscope is used normally to indicate a reflection from the opposite side of the piece, but will give also an earlier reflection from any places where there is no bond. Since the stresses in the supersonic waves are only a few pounds per square inch, they will not break a weak bond. The supersonic test indicates the presence or absence of bond, but does not test strength of bond, except where regions of no bond influence the over-all strength. If the bonded piece is in the form of a plate, the sonigage[5] may detect bad bond by its influence on the resonance that may be established through the plate thickness.

Measurement of Wall Thickness Where the Opposite Side Is Inaccessible. If the thickness to be measured is ⅛ in. or more, the reflectoscope may be used to indicate thickness directly, by indicating the time of round-trip flight of the waves. The accuracy is approximately 5%, increasing with the thickness, but decreasing if the opposing faces are not parallel. The thickness of parallel sheets can be measured with an accuracy of the order of 1%, by establishing resonance through the thickness; the simplest equipment for this purpose is the sonigage[5] although the reflectoscope can also be used to establish resonance.

Inspection of Tubes. Certain types of waves can be sent around the circumference of a tube so that the whole circumference, both inside and outside, can be inspected by making contact along a single element.[8]

Measurement of Average Grain Size. Since the attenuation or scattering of supersonic waves depends on the grain size, a long series of successive reflections can be shown with the reflectoscope if the grain size is small. However, the number of reflections decreases as the grain size increases. The method may be made sensitive in any range of grain size by choice of wave length. Once the wave length is chosen, the method is calibrated experimentally against microscopic determinations of grain size; the calibration must be repeated if the shape of the piece under test is changed.[1]

Inspection of Region Near Surface Only. Since Rayleigh waves travel on and just below the surface, they may be used for inspecting this region for flaws, grain size, or elasticity. Rayleigh waves are radiated by a crystal of suitable shape attached to the reflectoscope.[8] Depth of penetration is regulated by choice of wave length. Flaws on or beneath the surface produce reflections; grain size, in the region near the surface, influences attenuation and scattering; elasticity, or possibly residual stress in the surface region, influences velocity of propagation.

Measurement of Elastic Aeolotropy. When steel sheet is rolled, the crystals receive a preferred alignment relative to the direction of rolling, which results in a considerably different shearing modulus around axes along and across the direction of rolling. The difference is approximately 8% for cold rolled and 1% for hot rolled sheet. This elastic aeolotropy results in a different velocity of propagation of shear waves through the thickness of the sheet, depending on whether the plane of vibration of the wave is along or across the sheet. A technique[8] has been worked out whereby the reflectoscope can utilize shear waves to indicate directly the percentage of elastic aeolotropy of a sheet. The special crystal is touched to the sheet and an indication of the amount of aeolotropy appears at once on the oscilloscope screen. Forgings have also been found to be aeolotropic.

Metallographic Polishing

By J. R. Vilella*

TO be of value a metallographic specimen, like any other sample, must be truly representative of the parent metal, both in chemical composition and in physical condition. If it is not, the finest polishing, etching and photomicrography are wasted effort. Ordinarily the purpose of the investigation and the shape and condition of the material suggest the position from which the specimen or specimens should be cut, but there are general rules which, if observed, help to obtain adequate specimens:

1 If the purpose of the investigation is to determine the cause of a failure, the specimen should be obtained from a position near where the failure was initiated. It is also advisable to obtain one or more specimens from a position at some distance from the failure, in order to compare the structure of sound metal with that of metal which has failed. Comparisons of this type usually yield valuable clues.
2 In rolled or forged materials, transverse and longitudinal sections should be examined. This is important whether the purpose of the examination is to study the nonmetallic inclusions or the structure. If the material has been cold reduced, specimens should be taken in the direction of working.
3 In wrought or wrought and heat treated materials, it is advisable to include in the specimen a portion of the outer skin, so that decarburization and other surface conditions may be noted.
4 If the metal is suspected of segregations, several specimens from different positions should be examined.

Cutting the Specimen. When the location most significant for examination has been selected, the specimen may be cut by a hack saw, a band saw, a cutting-off wheel, or in the sampling of hard and brittle materials, the specimen may be notched and fractured. Occasionally it is necessary to resort to flame cutting in order to obtain suitable specimens from large sections.

Regardless of the means employed, it is essential to avoid heating and dragging the metal at the cut surface. Heating hardened steel is particularly undesirable because the steel is likely to be tempered. To minimize heating during cutting, a hack saw should be used, with proper lubrication, for all specimens that can be cut by this means. Hard materials should be cut with cutting-off wheels operating under water. Dragging of the surface metal, a common defect encountered in specimens of soft materials, can be minimized by lubrication of the saw blade. The structure of a flame-cut surface is obviously not representative of the metal, and therefore not suitable for a metallographic specimen.

Specimen Size. Whenever possible, for convenience in subsequent handling, the size of the specimen should be from ⅜ to 1 in. sq (or diam) and somewhat less in thickness. Smaller specimens are not only difficult to handle but almost impossible to polish without rounding the edges excessively. Larger specimens are difficult to finish without scratching and without dislodging the nonmetallic inclusions. Specimens in which the height exceeds the linear dimensions of the face to be polished are difficult to grind with the necessary flatness. It is not always possible, however, to obtain specimens of comfortable size. Sheet metal, wire and a multitude of other small articles are too small in cross section to handle comfortably. Such specimens must be mounted either in clamps, in molding plastics or in fusible alloys.

Mounting of Specimens. The method to use depends on the purpose of the specimen, on its shape, on the maximum temperature it can stand without alteration of structure, and on the available equipment.

Steel clamps of adequate shape and dimensions are best adapted to rectangular and square specimens that have straight edges. These clamps constitute the most satisfactory means of preserving the flatness of the edges; in fact, they are almost indispensable, even when the specimens are large, if the edges are to be examined at intermediate or high magnification. In general, the degree of roundness of the edges is proportional to the difference in hardness (or abrasion resistance) between the specimen and the mounting material. For this reason, when maximum flatness is needed along the edges of hard specimens, even clamps, if made of soft metal, are not adequate. For such specimens, the clamp should be made of a material which approximates the hardness of the specimen. However, to obtain consistently satisfactory results, certain other precautions must be observed. In the first place, clamps often interfere with the etching of specimens of dissimilar composition—for example, stainless steel mounted in carbon steel clamps; secondly, their rigidity makes it difficult to obtain close contact between clamp and specimen, with the result that a trace of the etching reagent often creeps up and stains the edge it was desired to examine. A satisfactory way of overcoming these difficulties is to insert a strip of soft copper between clamp and specimen. Thus a tight contact is produced without damaging the edge in any way; and, at the same time, the interference with etching is overcome, for copper is hardly attacked by the usual etching solutions for steel.

Because of a tendency to smear and because of inability to prevent rounding of the edges, fusible alloys such as Woods metal have been largely superseded as mounting material by harder plastics, such as Bakelite, Lucite and Tenite, which have proved invaluable to those handling a large number of small specimens.[6] The chief merits of these plastics are: (1) adaptability to specimens of any shape; (2) close contact between specimen and mounting material, so that staining caused by seepage of the etching reagent is prevented; (3) relatively low molding tempera-

* Research Laboratory, United States Steel Corporation, Kearny, N. J.

ture, permitting the use of these plastics even for specimens subject to tempering; (4) inertness to the etching reagent; and (5) good, although not the best possible, preservation of the flatness of the edges.

Another practical and rapid method of mounting specimens, when optimum preservation of the flatness of the edges is not necessary, is the following: Place a brass ring of convenient size (preferably one made oval by compressing its sides) on a smooth steel plate and pour enough mercury inside the ring to form a pool ⅛ to ¼ in. deep. Turning downward the surface to be polished, push the specimen through the mercury and hold in contact with the plate. Pour molten sulfur over the mercury and specimen to fill the ring; then allow the sulfur to solidify, as it will rapidly. To recover the mercury, slide the assembly to the edge of the plate and collect the liquid in a convenient receptacle. In specimens mounted in this manner, the surface to be prepared is level with the walls of the ring but not in contact with it at any point, and also at a considerable distance from the level of the sulfur; thus the specimen can be polished without dragging the mounting material over the polished surface and without contaminating the wheels with sulfur. The low melting point of the sulfur, its rapid cooling and the fact that it never comes in contact with the immediate vicinity of the surface to be polished, minimize the danger of altering the surface structure as a result of heating.

Preliminary Facing. This may be accomplished by filing, by grinding on stones or prepared papers, or by machining. If filing is used, the best way to obtain a flat surface is to lay the file on the working bench and push the specimen against the cutting edges, preferably in one direction only, since rubbing back and forth tends to round the edges of the sample. More rapid and equally satisfactory results can be obtained with motor-driven belt surfacers. These are not restricted as files are to small specimens of soft materials, and when properely used, such surfacers produce satisfactory flatness. Grinding stones are perhaps the least satisfactory means of obtaining a flat surface; they tend to fill with metal, become dull in a comparatively short time, requiring frequent dressings, and eventually develop grooves which round the specimen. However, when a grinding stone is used by careful workers, these disadvantages can be largely overcome. Regardless of the means employed, care should be taken at this stage to keep the specimen cool and to avoid deep scratches, because a deep scratch may completely alter the structure of the underlying metal. This condition has often been observed in specimens of 18-8 stainless steel and other alloys susceptible to structural changes by slight cold working.

Grinding. Grinding consists of abrading the specimen by using a series of grits of increasing fineness, until a set of scratches is produced which are sufficiently fine to be totally eradicated in a reasonably short time by the finest polishing material available. There are several satisfactory ways of carrying out this step.

Grinding on Abrasive Papers. This method consists of abrading the specimen with papers coated with aluminum oxide (emery) or silicon carbide (Carborundum) of increasing fineness. The grades most commonly used are 100, 200, 320 and 400-mesh grit; or No. 2, 1, 0, 00 and 000. Abrading may be done either by hand or on power-driven wheels. In either method, on passing from coarser to finer paper, it is advisable to rotate the specimen 90 deg to facilitate recognizing when the coarser scratches have been entirely replaced by the finer ones.

The chief merits of this method are that the nonmetallic inclusions are not dislodged, that it is comparatively easy to master, and that the commercial papers available are well graded as to grit size and are of uniform high quality. The chief disadvantages are that in this method the structure of the surface metal is distorted, particularly when the papers are used after the grit has become dull; also there are tendencies to round the corners and edges of the specimen and to heat the specimen. However, these disadvantages can be greatly decreased by careful working.

Hand polishing is generally considered a slow and laborious process; for that reason it is seldom practiced in this country. The technique of those who still use it[1] consists of rubbing the specimen back and forth on abrasive papers stretched smoothly over a flat, hard wooden block or a metal surface. Advantages of hand polishing are that less heating and less distortion of the surface metal occur than in machine grinding.

In machine grinding, the speed of the wheels is of some importance. However, since the rate of cutting or abrasion depends on the linear velocity and not on the rpm, a higher rate of cutting is always obtained at the periphery than at the center; and likewise, the larger the disk, the faster the rate of cutting at the periphery. For these reasons, recommendations as to the best speed of grinding expressed in rpm are of little significance. High speeds are not conducive to the best results and do not appreciably expedite the process. A speed of 600 to 700 rpm for a 9-in. disk is satisfactory. With well constructed machines free from vertical vibrations, higher speeds can be used safely.

Grinding on Paraffin Wheels. Disks similar to those used for grinding with papers are covered with a layer of high-melting-point paraffin about ¼ in. thick, machined flat and having a spiral groove or a series of concentric circles 1/16 in. deep inscribed on the surface by means of a nail or some other pointed article. The function of the groove is to hold the water and abrasive on the disk. The abrasives consist of a series of emery powders, ranging in fineness from 200 to 600-mesh. These powders are suspended in a soap solution and are sprinkled over the revolving disks at frequent intervals. Natural emery is preferred.

An excellent modification of this method is to use canvas or billiard cloth previously impregnated with paraffin, instead of using a paraffined disk. The paraffin is melted in a suitable container and the cloth is immersed in it until it has absorbed all the paraffin it can hold. While the impregnated cloth is still warm and pliable, it is stretched smoothly over the disk and held in place by a ring that fits around the circumference of the wheel. Billiard cloth is preferable for the finer abrasives and 12-oz canvas for the coarser ones. At first the impregnated cloth will feel somewhat rough, but it will become smooth after grinding several specimens.

The merits of this method are: (1) satisfactory preservation of the nonmetallic inclusions, (2) good flatness of the edges of the specimens, (3) less distortion of the surface metal than is produced by grinding on papers and (4) negligible heating of the specimen during grinding.

Grinding on Lead Laps. Two methods[2, 3] involving the use of lead laps have been described. Both are based on the principle that grit held firmly by the carrying medium (that is, not free to roll during grinding) does not excavate the nonmetallic inclusions, nor widen any cracks or porosity which may be present in the metal. One of these methods, which originated in Sweden, is as follows: On each of three disks is deposited a layer of lead approximately ¼ in. thick and machined flat. The abrasive (emery or tungsten carbide) is applied and "fixed" to the lead lap with a fast-drying varnish previously thinned with benzene. The grinding procedure is carried out in three steps after preliminary "coarse" grinding to obtain a flat surface: (1) grinding with emery of 100 to 40 μ in grain size, (2) grinding with emery of 50 to 25 μ in size and (3) grinding with tungsten carbide having grain size less than 4 μ. It is important that the surface be as flat as possible after the preliminary grinding; if the surface is rounded, the process is greatly delayed in the subsequent step, because the lead lap cuts only in one plane. After the grit has become dull from grinding, it can be "resharpened" by simply passing over the disk a brush dipped in benzene; this softens the varnish and causes the abrasive grains to turn, thus presenting a new sharp face to the specimen. The varnish rehardens in about one minute.

The advantages claimed for this method are: (1) rapid preparation of the specimen, (2) a degree of flatness not obtainable by any of the usual metallographic polishing methods, (3) excellent preservation of the nonmetallic inclusions, (4) the possibility of using finer abrasives and hence shortening the time required for the final polish, and (5) lower operating cost than with abrasive papers.

The other method[3] utilizing lead laps was originated at the Bureau of Standards. It is carried out in two steps, but each step requires two disks, one for the actual grind-

ing, made of 50% Pb and 50% Sn alloy; and the other made of high-strength, fine-grain cast iron, used only for charging and maintaining the flatness of the lead-tin disk.

The cast-iron disk is ground in a precision surface grinder to a maximum deviation of 0.0001 in. from a plane over the entire surface. The disk contains grooves ½ in. apart, milled to a depth of 1/32 in. with a 60-deg milling cutter. This disk is somewhat larger than the lead-tin disk, which contains grooves similar but ¼ in. apart. The surface of the lead-tin disk should be faced flat in a lathe before milling.

Charging of the lead-tin laps is accomplished by mixing water with emery of the proper grades (American Optical Co. No. 302 and 303½), placing the mixture on the face of the cast-iron disk and rotating the lead-tin disk, face down, upon it for about 30 sec. The lead lap is then brushed and washed until free from loose grit.

During the grinding, water is used as a lubricant. Only a very gentle pressure is needed to obtain good cutting action. The advantages of this method are the same as those claimed for the Swedish method.

A widely used modification of this method consists in employing rotating laps instead of the stationary ones recommended by the Bureau of Standards. Three laps are generally used, one charged with coarse, one with medium and one with fine emery—ordinarily American Optical Co. Grades 302, 303½ and 305, respectively. The grit is fed to the laps in the form of a water suspension containing approximately one teaspoonful of grit per liter, from a bottle with a small nozzle. Grades 302 and 303½ can be used as received, but grade 305 should be levigated for approximately one minute before using.

To retain the abrasive and water on the disk during polishing, it is advisable to cut on it a spiral groove approximately 1/32 in. deep and 1/32 in. wide, with a pitch that may vary between ⅛ and 1/32 in. The pitch does not seem to be critical, but it is important that the spiral groove be cut so that it coils opposite to the rotation of the wheel. If the spiral and lap move in the same direction, the wheel tends to dry too quickly.

An automatic polishing method[4] employing cast-iron and lead laps was also recently described. It is not discussed here in detail because it requires specially built equipment.

Rough Polishing. Rough polishing is merely the last stage of grinding, but because it is the most important step in the entire process of metallographic polishing, it must be treated separately. On this step depend (1) the length of time required to finish the specimen, (2) the preservation or dislodgment of the nonmetallic inclusions, and (3) the thickness of the layer of distorted metal which must be removed before the true structure is revealed. This step can be carried out in several ways, of which the most frequently practiced are the following: (1) grinding on billiard cloth or canvas with powders such as 600 alundum, emery or tripoli; (2) grinding on fine abrasive papers such as No. 0000 or 600-grit emery or Carborundum; (3) grinding with 600 or finer emery on wax disks or billiard cloth impregnated with paraffin; or (4) grinding with 305 or finer emery or tungsten carbide powder on lead laps.

Loose Powders on Billiard Cloth or Canvas. These produce fine, even scratches, which disappear readily during the final polish and yield a surface with a minimum of disturbed metal. The main disadvantage is that the prepared surface is likely to be badly pitted as a result of the dislodgment of the nonmetallic inclusions. The method, therefore, is not recommended when the correct preservation of the inclusions is essential to the purpose of the examination.

Grinding Papers. Papers such as No. 0000 or 600 emery preserve the nonmetallic inclusions intact, but cause a considerable distortion of the surface metal and yield scratches of uneven depth, thus frequently retarding the final polish. Finer and more even scratches can be obtained by using a No. 000 or 600 paper which has been partly worn by use and glazed by polishing a piece of graphite on it.

Grinding With 600 Emery on Wax or Paraffined Cloth Disks. This kind of grinding preserves the nonmetallic inclusions quite well, yields fine, even scratches, which are removed easily during the final polish, and does not produce an excessive amount of disturbed metal. The method represents an excellent compromise between the two methods previously discussed.

Grinding With 305 or Finer Powders on Lead Laps. This is probably the best method of rough finishing so far developed. The inclusions are well preserved; the specimen exhibits a degree of flatness not attainable by any of the other methods; the scratches can be made fine and even by judicious selection of the powder and by care to avoid contamination with coarser grit; and distortion of the surface metal is not excessive. This method, however, is applicable only to specimens that have been ground very flat during the prior stages; otherwise the rounded parts of the specimen will not come in contact with the abrasive.

The Final Polish. Usually the specimen is finally polished on a soft cloth with either levigated alumina, rouge, magnesia or other equally fine finishing powders. The selection of the finishing powder is a matter of individual preference, since equally good results can be obtained with any of them, provided they have been properly levigated. Alumina is sometimes selected because it is the cleanest to handle and because an excellent grade can be purchased already levigated.

The type of cloth to use depends on the purpose for which the specimen is being prepared. If it is desired to obtain the best possible preservation of the nonmetallic inclusions, or the graphite flakes in cast iron, then it is advisable to use a hard, pileless fabric, such as the dull side of a heavy silk satin or a good grade of heavy cotton or linen cloth, because it has been observed by many experienced metallographers that the softer materials, such as broadcloth or "kitten's ear", exhibit a pronounced tendency to dislodge the inclusions. On the other hand, the soft fabrics are preferable when the structure of the specimen is to be examined or photographed at high magnification, since these fabrics produce fewer and smaller scratches.

It would be of little value to make precise recommendations concerning the optimum speed to use for the final polish, because experience has shown that satisfactory results are possible at a wide range of speeds. However, the consensus of experienced metallographers is that best results are obtained at low speeds; for instance, a speed of 280 rpm is used for a 9-in. disk.

Defects of Polished Surfaces. The defects most frequently found in metallographic specimens are: scratches, rounding of the corners and edges of the specimen, pits resulting from dislodgement of the nonmetallic inclusions, and distortion of the surface metal.

Avoiding Scratches. This is a question of cleanliness and careful levigation of the finishing powder. Some of the most common causes of scratches are dirty hands, grit under the finger nails, abrasive from the previous operations on the sides of the specimen, and contamination of the finishing fabric with flying grit from other wheels. The remedies suggest themselves: proper levigation of the finishing powder; careful washing of the specimen and hands, particularly before attempting to give the final polish; and keeping the wheels well covered when not in use.

Preserving Flatness of a Specimen. As was pointed out before, flatness depends on the method of polishing and on how the specimen is mounted.

Preventing Pits. Preventing pits that result from dislodgment of the inclusions has already been discussed. It will be well to state here, however, that a pitted surface gives an exaggerated impression of the amount of "dirt" in the steel, and that many a satisfactory heat of steel has been branded "too dirty" because of improper polishing. To rate a steel as dirty is unwise, unless one is sure that the inclusions are preserved intact.

Eliminating Distortion of Surface. Of all the defects of a polished surface, the most misleading, common and subtle is the inevitable distortion of the surface layer resulting when a malleable material is ground with a hard abrasive. It can be said without exaggerating that the greatest progress in metallographic polishing during the last 20 years has been recognition of the existence of this distorted layer and its elimination by the method of alternate polishing and etching to be described below. Although some methods of polishing produce less distortion than

others, none yields an undistorted surface. It is well to assume, therefore, that the structure revealed by etching a highly polished surface is not the true or undistorted structure of the metal. The question is how the true structure can be revealed. Probably the most dependable way of accomplishing this is the following: The polished surface is given a normal etch and its structure is noted under the microscope by using the dry objective that has the highest resolving power available. The surface is then repolished on the final wheel, etched and examined again. The process is repeated as long as changes in the appearance of the structure are noticed. As a rule, two or three repolishes suffice, but occasionally more may be necessary, particularly when working with soft metals. In general, the softer the metal, the greater the distortion, but even hard metals are never completely free from distortion after polishing. An attempt to cut the process short by deep etching usually results in pitting and obliteration of the finest details of the structure.

Summary. The *perfectly* or *ideally* prepared specimen must possess at least the following characteristics: (1) It must be truly representative of the metal in both chemical and physical condition. (2) It must be sufficiently flat, from edge to center, to permit examination at all points at all magnifications. (3) It must be free from scratches, stains and other imperfections which tend to mar its appearance. (4) It must contain intact all nonmetallic inclusions. (5) It must be free from all traces of disturbed metal.

Photomicrography

By J. R. Vilella*

THE purpose of photomicrography is to procure permanent and accurate records of structures too fine for the unaided eye to see. To accomplish this a photomicrograph must meet certain minimum requirements: (1) It must represent the true structure of the metal. (2) The magnification and resolution must be sufficient to show clearly all significant detail. (3) It must be technically correct in a photographic sense.

The True Structure of a Metal. In the preparation of metallographic specimens it is important to bear in mind that the attainment of a specular finish free from scratches does not necessarily constitute a satisfactory polish for photomicrography. Frequently the structure that is revealed by etching a highly polished surface is not the true structure of the metal, but merely that of a layer of metal which has suffered considerable distortion as a result of polishing. The true structure lies below this layer and will not be seen until all traces of distorted metal have been eliminated. The softer the metal, the deeper the distortion; but even hard metals are susceptible to this effect. It is well, therefore, to expect distortion in all polished surfaces and to make certain that it has been eliminated before a photomicrograph is made. For a more detailed discussion of this subject, see the article on "Metallographic Polishing", page 159.

Likewise, a specimen is not ready to be photomicrographed until it has been correctly etched. Correct etching consists of (1) selecting the reagent best suited to the chemical composition and physical condition of the metal, and (2) etching to produce the proper degree of contrast, depending on the element of the structure that is to be emphasized and on the magnification at which it is to be photographed. Obviously, a surface exhibiting stains, etching pits or uneven attack, has not been correctly etched.

What reagent to use is entirely a matter of experience. If any doubt exists, several of the reagents tabulated in the articles on etching reagents should be tried and the photomicrograph should be made after etching with the reagent which most clearly reveals the true structure, since evidently that is the best reagent for the specimen at hand.

The depth of etching or degree of contrast produced in the structure is of great importance in photomicrography. Although it is not possible to give a set of instructions covering all problems, observance of the following will be found helpful:

1 Etch no more deeply than necessary to bring out the significant detail.
2 A degree of contrast satisfactory for low-power photomicrography is generally excessive for the best possible definition of the structure at high magnification.
3 If high contrast is desired, obtain it by photographic means rather than by deep etching, for deep etching obliterates the fine details of the structure.
4 If a specimen is insufficiently etched, thus affording too low contrast, repolish on the finishing wheel and re-etch, rather than to superimpose one etch on another.
5 Do not touch an etched surface with anything, and photograph soon after etching.

Magnification and Resolution. When a specimen has been properly polished and etched, the first question to decide is the magnification and the objective to use in making the photomicrograph. Concerning magnification, there are two rules which are sound but not inflexible:

1 Photograph at the lowest magnification which shows clearly all significant detail.
2 To obtain from a given objective the maximum amount of detail (resolution) and the sharpest image, maintain the magnification between the limits of 400 and 1000 times the numerical aperture (NA) of the objective.

A magnification of at least 400 NA is needed for a person of normal vision to distinguish all the detail resolved by the objective. This magnification, however, renders the finest detail hardly visible, and results in eyestrain and uncertainty. At higher magnification the detail becomes easier to see but, at the same time, the image loses sharpness. Therefore, it is necessary to arrive at a compromise. Experience has established 1000 NA as the highest magnification that will produce images of acceptable sharpness when achromatic objectives are used. With apochromatic objectives of the highest quality it is possible to make photomicrographs at more than 1500 NA which appear acceptably sharp when viewed at a distance of 10 in. from the eye. However, to produce a sharp photomicrograph even at 1000 NA, correct polishing and etching are essential and all other causes of defective images must be eliminated.

Beyond 1000 NA a considerable degree of empty magnification is necessarily involved, but it is justified when the photomicrograph is to be viewed from a distance, as by several observers simultaneously.

Resolving power is the property of a lens which enables it to show distinctly the separation between two elements of the structure that lie close together; for example, the lamellae of pearlite. The degree of fineness of detail which an objective can reveal, that is, the resolving power, increases directly with the NA; but the fact that an objective of high NA possesses high intrinsic resolving power does not necessarily mean that it will resolve a given fineness of detail under all conditions. It merely means that it will resolve that detail if properly used. It is important, therefore, to examine those factors under the control of the metallographer which affect the resolving power of the objective.

In the first place, the specimen must be correctly pol-

*Research Laboratory, United States Steel Corporation, Kearny, N. J.

ished and etched, because not even the objective of the highest NA will show clearly a structure in which the detail has been deformed or obliterated by poor polishing and etching. In addition, the following factors must be considered: (1) the proper adjustment of the illuminating system, (2) the optimum opening of the aperture diaphragm, (3) the wave length of the light used, and (4) the method employed to illuminate the specimen.

Proper Adjustment of the Illuminating System. Precise adjustment is essential because otherwise the image produced can be misleading. It is not possible, however, to make definite recommendations for the correct setting of the illuminating system, because of the varied design of the microscopes used in the metal industry. Failure to keep the illuminating system adjusted in strict accordance with the instructions given by the manufacturer of the instrument, invariably leads to some loss of resolving power.

Optimum Opening of the Aperture Diaphragm. Because the image produced by microscope objectives, particularly those of high NA, is not always so flat as would be desirable, many metallographers "stop down" the aperture diaphragm of the microscope in an effort to secure a larger area in focus, a practice which is equivalent to cutting down the NA of the objective, and therefore its resolving power. High power objectives cannot always be used at full aperture because of the interference of "flare", or internal reflections, but there is an optimum opening for every objective, at which flare is not objectionable, and which should be determined by the metallographer to enable him to use the objective at its highest practicable resolving power. The recent application of antireflection coating to microscope objectives has materially increased the maximum aperture at which objectives can be used without the interference of flare. Lack of flatness of field can be partly remedied by the use of negative oculars designed especially for that purpose, but resolution must not be sacrificed. A small field with maximum resolution is preferable to a large flat field lacking resolution.

Wave Length of the Light Used. The resolving power of an objective is higher, the shorter the wave length of the light illuminating the structure. For maximum resolution, therefore, the shortest wave length should be used for which the objective is adequately corrected; that is, yellow-green for achromatic and blue-violet for apochromatic objectives. Selection of wave length is the principal function of light filters in ferrous metallography, because the structures are seldom highly colored. However, in nonferrous metallography, where brightly colored structures are not uncommon, light filters are also used to bring about a more accurate tonal rendition of the colors. Since photographic emulsions are not equally sensitive to all colors, it is often necessary to filter out or partly suppress some of the wave lengths to which the emulsion is most sensitive, in order to reproduce photographically the correct relative brightness of the colors.

It is generally expected that the use of the electron microscope in metallurgical research will some day contribute greatly to our knowledge of the microstructure of metals. Photomicrographs exhibiting resolution beyond that attainable with the shortest wave length of the visible spectrum have been made from replicas of metallic structures but, chiefly because they are photographs of replicas, their interpretation is not free from uncertainties. As the technique of replica preparation improves, these uncertainties will decrease, and today it appears probable that in the not too distant future it may be possible to make direct electron photomicrographs of metallic structures.

Method Employed to Illuminate the Specimen. Modern metallurgical microscopes are generally equipped with a plane glass vertical illuminator, prism illuminator, dark field illuminator, polarized light, and adjustments designed to produce the effect known as "conical illumination". The plane glass vertical illuminator is the type generally used in photomicrography, because it permits obtaining all the resolving power of the objective. In most microscopes a plane glass illuminator is placed in a fixed position at the factory and requires no further adjustment.

The prism illuminator is supplied for two purposes—to obtain oblique lighting and to provide brilliant illumination for dark structures and for projection. Because prism illuminators utilize only one half of the pencil of light, they cut the resolution of the objective in half. This loss of resolution occurs only in the direction at a right angle to the axis of rotation of the prism. Such illuminators are intended only for low-power work.

Dark-field illumination is characterized by the fact that a reflecting surface, lying perpendicular to the axis of the objective and illuminated by converging rays, reflects no light into the microscope and consequently appears dark. Any part of the structure that is not perpendicular to the axis of the objective reflects into the microscope some of the light which strikes it; thus, such a part appears brightly illuminated. Dark-field illumination has several distinct advantages over ordinary bright-field illumination: (1) Since the objective is not used as a condenser, as in bright-field illumination, there is less "flare" or internal reflection and the objective can be used at full aperture. (2) Extreme contrast (black and white) can be obtained when desired. (3) Surfaces can be examined that are not so highly polished as is necessary for bright field. (4) Frequently detail is clarified that cannot be seen under bright-field illumination, either because of lack of contrast with the surrounding material or because of insufficient resolution. (5) Colored structures are shown in their natural colors.

The use of reflected polarized light in metallography is discussed in "Nonmetallic Inclusions in Steel", page 445.

Conical illumination is a means of illuminating the structure obliquely without sacrificing resolution, as happens when the prism illuminator is used for the same purpose. The relief that it produces imparts a natural appearance to the image, serves to differentiate between parts of the structure which appear identical under axial illumination, and makes fine detail easier to see. Conical illumination, if properly used, yields evenly illuminated micrographs, high in resolution and pleasing to the eye.

Most microscopes are provided with a second iris diaphragm, known as the "illuminated field diaphragm" and placed in the microscope so that the image of the diaphragm is focused on the surface of the specimen when the specimen is in focus. Because of its position, this iris does not affect the resolving power of the objective, but it will be observed that, as it is closed down, the fully illuminated field becomes smaller and the contrast and sharpness of the structure improve perceptibly. In photomicrography, whenever the size of the illuminated field is larger than the plate or film, the iris should be closed down until the diameter of the fully illuminated image is equal to, or less than, the diagonal of the photographic plate. This is especially important in high-power photomicrography.

Photographic Technique. For a photomicrograph to accomplish its purpose, it must show the structure clearly enough to convince the observer that it is a faithful reproduction of the structure. A photomicrograph lacking clearness, because of technical imperfections, generally defeats its purpose, inspiring doubt rather than conviction.

The photographic plates or films suited for photomicrography are those possessing the following characteristics:

1 High sensitivity to yellow and green light; that is, the plates or films must be orthochromatic. (All emulsions are sensitive to blue light; only panchromatic emulsions are sensitive to red light.)
2 Sufficient latitude to yield properly exposed negatives without the need for precise estimation of the exposure time. This latitude is necessary because the intensity of the arc light, generally used in photomicrography, fluctuates considerably even while the exposure is being made, and because the reflectivity of the various parts of the structure varies widely, depending on the polish, composition and amount of etching.
3 A fine-grain emulsion, able to record extremely fine details accurately. Photographic emulsions also possess resolving power; in general, the finer the grain, the smaller the detail that can be recorded in a photograph.
4 An effective antihalation backing. This is important since the presence of halation will shorten considerably the latitude within which the emulsion can accurately reproduce the finest details.

The correct exposure places the brightest and darkest portion of the structure within the limits of the latitude of the emulsion; that is, the brightest parts are not overexposed or the darkest, underexposed. Since the emulsions used in photomicrography are of the "short scale" type, the greater the degree of contrast produced by etching, the more accurate the exposure needs to be. Occa-

sionally such great contrast is produced in the structure through overetching that even though this contrast can be encompassed within the latitude of the negative, it exceeds the latitude of the printing paper, which is always less, and therefore a good print cannot be made. After all, a negative is only a means toward the achievement of a perfect print. For these reasons, care should be taken to avoid etching with excessive contrast.

Whenever there is doubt concerning the correct exposure, an exposure test can be made as follows: The entire plate is given a rather short exposure—for example, 2 sec—and then the dark slide is pushed in approximately one inch and another exposure made, of the same duration. The slide is then pushed in another inch and exposed again, but this time for 4 sec. The process is repeated until a set of exposures is obtained, each double the preceding one.

Standardization of developing practice helps to secure uniform negatives from day to day. The time-temperature method (tank development) lends itself to standardization better than the tray or inspection method, and should be preferred. The developer recommended by the manufacturer should always be used. The length of time required for developing a plate depends on the degree of contrast desired, because contrast increases with the developing time, if the temperature and agitation are constant.

Proper fixing and washing are also important. An active fixing bath containing an effective hardener is sufficient, if the temperature of the bath does not exceed 75 F. Above this temperature, there is danger that the emulsion will soften and reticulate. In hot weather, an advisable practice is to use a "short stop" hardening bath, consisting of 2% chrome alum and 2% sodium bisulfite. The hardener should be freshly prepared and used between development and fixing, and the plate should be left in it for 3 to 5 min with the light off. The negative should then be fixed for at least twice the time required to clear it and should be washed in running water for 30 to 60 min. Insufficiently washed negatives deteriorate in a short time.

In photomicrography, correct printing means reproducing on photographic paper all the detail that the negative was able to grasp, and recording this detail in the proper tonal relations. Two prerequisites are (1) choosing the grade of paper that will complement the contrast of the negative and (2) choosing the exposure that will print through the densest part of the negative where detail must be shown. To accomplish this, photographic papers are available in several grades of contrast. The "soft" papers, affording low contrast, are for use with negatives of high contrast and the "hard" or "contrasty" papers are used with "flat" or "soft" negatives. These various grades can be obtained in a variety of surfaces, but the glossy finish is generally used in photomicrography because the smoother the surface, the larger the scale of contrast reproduced by a photographic paper.

Summary. The aim in photomicrography is to reproduce the significant details and tones of the structure as faithfully as possible. This can be accomplished (1) by polishing the specimen in such a manner that the true structure will appear after etching; (2) by etching to ■ depth or degree of contrast that does not obliterate detail and can be reproduced photographically; (3) by adjusting the microscope correctly so that maximum resolution may be obtained; (4) by an exposure which produces an image within the latitude of the plate or film; (5) by developing this image to a contrast that fits the scale of the printing paper; (6) by using a paper that has the longest possible range of contrast.

For photomicrographic illustrations and a more detailed discussion of the various points emphasized in this article, see the ASM publication "Metallographic Technique for Steel", by J. R. Vilella.

X-Ray Diffraction

By Charles S. Barrett*

THE regular repetition of identical groups of atoms throughout a crystal forms a three-dimensional grating which diffracts a beam of X-rays in much the same way that an optical grating diffracts a light beam. When a small beam of X-rays is directed at a substance and the rays diffracted in different directions from it are photographed, the substance can be classified as amorphous, crystalline, or intermediate; the identity of the substance can often be established; the perfection of the crystal lattice can be determined; single crystals can be distinguished from polycrystalline substances, and the grain size can be estimated. From the X-ray pictures, supplemented by other data, the crystallographer determines space lattices, space groups, and positions of atoms in the unit cell. Diffraction also indicates the orientation of a single crystal and the preferred orientation in a polycrystalline specimen; the dimensions of the unit cell, to a high degree of precision; qualitative and, in some instances, quantitative measurements of residual and applied stresses; information concerning the effect on the lattice of plastic deformation, of heat treatments, or of the mechanism of deposition, crystallization, transformation, age hardening, and precipitation; and the constitution of organic and inorganic systems, minerals, and alloy systems.

Given a parallel set of planes of atoms repeating throughout a crystal and spaced at intervals of d, the condition for X-ray reflection from these planes is, by Bragg's law, $n\lambda = 2d \sin\theta$ where λ is the wave length of the X-rays, measured in the same units as d, n is the order of the reflection (always an integer), and θ is the angle of incidence of the beam on the planes, which is equal to the angle of reflection from the planes. This relation among the spacing of atomic planes, the wave length, and the diffraction angle, known as Bragg's law, and the analogous optical reflection relation are the basis for interpreting almost all practical applications of X-ray diffraction.

* Institute for the Study of Metals, The University of Chicago, Chicago

Apparatus.[3, 9] X-ray tubes for diffraction operate on 30,000 to 60,000 v, rectified or unrectified. Both gas tubes and electron tubes are in common use, gas (or "ion") tubes operating at a critical gas pressure of about 0.01 mm Hg, with a cold cathode, and electron tubes operating at a high vacuum with a hot filament. Tubes of both types may be made demountable so that targets of various elements can be interchanged at will and cathodes replaced when necessary. Electron tubes, highly evacuated and sealed off from the vacuum pumps, are widely used. The sealed-off molybdenum target tubes are the nearest approach to a universal tube for commercial applications, for both monochromatic (characteristic) radiation and general radiation, of which a considerable quantity is emitted, so that the tube can be used with fair success in nearly all methods. Sealed-off tubes require the minimum amount of attention and skill in operating, but demountable tubes permit a greater variety of wave lengths and are advantageous in many research problems where extreme purity of the radiation is important. Complete units, with tubes, transformers and controls fully enclosed, and many types of cameras are available.

Laue Method.[1, 4, 9] The Laue method uses a beam of X-rays containing many wave lengths. A system of pinholes confines a beam to ■ narrow pencil of rays that fall upon a small crystal or penetrate a thin crystal. The usual arrangement is for a photographic film to be placed 4 or 5 cm beyond the crystal and perpendicular to the original X-ray beam, Film A in Fig. 1. (The film B is used only for the back-reflection method referred to below.) On the photographic film the diffracted rays make ■ pattern of spots, as in Fig. 2; each spot is the reflection of a certain

wave length from a certain crystal plane in one or more orders. The X-ray tube, best equipped with a target of tungsten and operated at 40,000 to 60,000 v, gives radiation with a broad band of wave lengths.

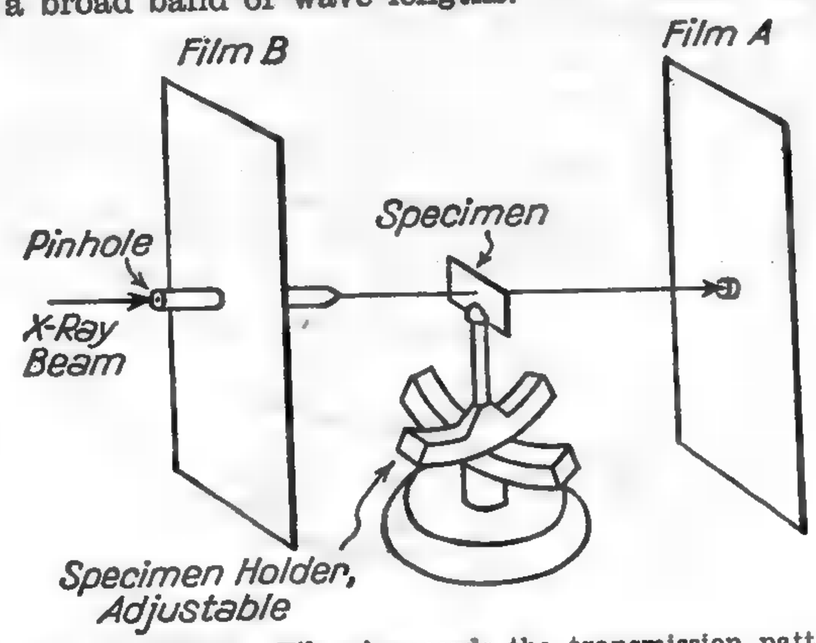

Fig. 1 Laue camera. Film A records the transmission pattern, film B the back-reflection pattern, usually not simultaneously.

Laue photographs show a pattern of spots that are reflections from the differently oriented planes of atoms in the crystal. Identification of the spots is generally accomplished by graphical methods. The Laue method is useful for the determination of the symmetry properties of a crystal. When an X-ray beam passes through the crystal parallel to a fourfold rotation axis, for example, the pattern will coincide with itself if given one quarter-turn about the center (Fig. 2). The elements of symmetry deduced from Laue patterns will always include a center of symmetry, whether or not the crystal possesses one. The Laue method is little used for determination of crystal structure but is often convenient for determining the orientation of crystals; this is done by the aid of stereographic or gnomonic projections of the spot patterns.

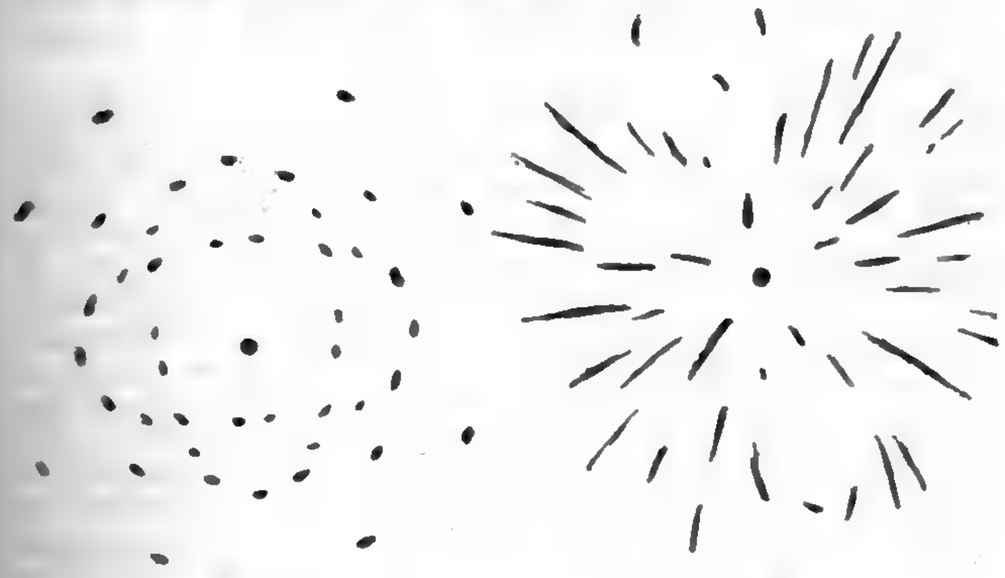

Fig. 2

Fig. 3

Fig. 2 Laue pattern (transmission type) with X-ray beam approximately parallel to a crystal axis of fourfold symmetry. Undistorted crystal.

Fig. 3 Laue pattern of a distorted crystal, showing asterism.

The Laue method reveals imperfections resulting from accidents of crystal growth or from deformation. The Laue spots from perfect crystals are sharp, as in Fig. 2; whereas imperfect crystals or plastically deformed crystals produce blurred images and spots elongated radially, as in Fig. 3, giving the appearance known as "asterism". An analysis of this can give the range of orientation of the reflection planes and can indicate the severity of the deformation received by the specimen, but does not provide a reliable means of measuring stresses quantitatively.

Back-Reflection Laue Method.[9] A convenient arrangement for orientation work is the back-reflection Laue camera, in which the film is mounted over the pinhole system, at B in Fig. 1. Back-reflection Laue patterns for single-crystal orientation are analyzed by stereographic projection. Crystals must be reasonably perfect for this method, because the spots overlap and become indistinguishable if imperfections amount to more than 2 or 3 deg.

The "Pinhole" Method. The "pinhole" method, sometimes called the "transmission method", as distinguished from a "reflection method" in which the rays strike a thick specimen at an angle, is a combined Laue and powder method that is often used in practical work. Because most practical applications of the pinhole method are simple and easily understood, they are presented before the powder method and will serve as an introduction to it. The apparatus is identical with that of the Laue method, except that the radiation used is not general, since it also contains strong monochromatic components. Molybdenum target tubes are used, operating at a voltage of 30,000 to 45,000 v and giving strong monochromatic (characteristic) lines at a wave length of 0.71 A (actually a close doublet of this average wave length) and a weaker line at 0.63 A—the Kα and Kβ lines, respectively. The specimens are polycrystalline materials—either wires or thin strips about 0.004 to 0.010 in. thick.

Patterns from coarse-grained materials contain many spots, as in Fig. 4. Throughout a series of exposures in a given camera, the size of the spots is proportional to the size of the grains and the number of spots is proportional to the number of grains per unit of volume of the specimen, provided the grains are smaller than the effective cross section of the X-ray beam. As the number of spots increases, circular diffraction rings appear (see following section). At first the rings are granular, but as the number of spots increases (that is, as the grain size decreases) the

Fig. 4

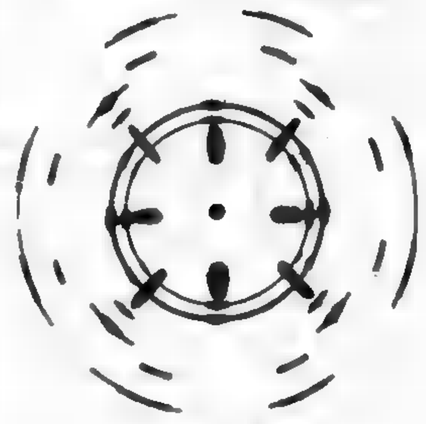

Fig. 5

Fig. 4 Pinhole pattern of undistorted polycrystalline material. Typical of recrystallized metal.

Fig. 5 Pinhole pattern (transmission) of sheet steel having a preferred orientation from cold rolling. (Rolling direction vertical, sheet surface perpendicular to the X-ray beam)

rings become continuous and smooth. Just as in the Laue method, a lengthening of the spots, "asterism", is caused by crystal imperfection or plastic deformation.[2,3]

The distribution of intensity around the diffraction rings reveals the presence or absence of a preferred orientation of the grains (fiber textures). Random orientations produce rings that are uniformly black all around; highly developed orientations give the appearance of Fig. 5, which is a tracing of a pattern from rolled steel. In the cold rolling of steel, preferred orientation begins to be detected at reductions of 20 to 40% in thickness and gradually increases in perfection until the pattern resembles Fig. 5 at 90 to 95% reduction.

Upon recrystallization, the rings break up into spots again and may or may not show the same maximums of intensity. The preferred orientations after recrystallization, analyzed from these patterns, are sometimes found to be the same as in the cold worked material, sometimes different, and frequently the recrystallization produces a random orientation. The presence or absence of preferred orientations can be determined only if there are many spots in the pattern—more than in Fig. 4, for example; with coarse-grained material it is often necessary to shift the specimen during the exposure in order to provide a sufficient number of spots.

If all orientations of the grains are to be studied, it is necessary to make a series of pinhole patterns, with different angular settings of the specimen in relation to the beam. It is customary to plot the data from a series of exposures of this type on a stereographic projection;[4,9] this plot is known as a pole figure.

For interpretation a pole figure is viewed as a stereographic map of a globe that has the sample at the center.

Perpendiculars to a single set of crystal planes—for example (100) planes—extend out radially and puncture the globe at various places; clustering of these punctures in certain areas of the globe indicates clustering of the crystal planes around a certain orientation. The density of the clusters is readily shown by the density of shading at corresponding areas on the stereographic map of the globe. The map must also show the principal directions in the sample. In a rolled sheet, for example, the rolling direction is plotted customarily at the north pole of the map; the cross direction in the sheet, at the right-hand end of the equator; and the sheet normal (which extends toward the observer) is plotted at the center. To facilitate reading angles on the pole figure, determining the areas of clusters and such, use is made of a stereographic projection of latitude and longitude lines of the globe (a Wulff net). Industrial problems can often be solved by taking one or two well-planned exposures without the labor necessary to plot a complete pole figure.

A convenient arrangement for determining the depth of cold work produced by machining is to have the beam strike the specimen at an oblique incidence and reflect from the surface of the specimen, rather than penetrate it. If the surface is cold worked, the spots will be blurred and may overlap into continuous rings, but after etching to a depth sufficient to remove the cold worked layer, the spots become sharp. Back reflection cameras, discussed in the following section, are also used for this purpose.

Powder Method.[1, 3, 4, 8, 9] *Radiation.* The powder method employs monochromatic radiation falling on a powdered crystal specimen or a fine-grained polycrystalline specimen. Radiation is obtained from X-ray targets of relatively low atomic number, giving weak general radiation and relatively strong characteristic radiation. Molybdenum targets may be used but are not satisfactory unless a zirconium filter is placed over the photographic film in the camera or a crystal is placed in front of the camera to serve as a monochromator. Best results are obtained by choosing targets of iron, cobalt, nickel, chromium or copper, or alloys of these. The target is chosen so that the characteristic Kα radiation is of longer wave length than the K absorption limit of the specimen, in order to avoid fogging of the film by fluorescent radiation originating in the specimen. See Table I, where elements listed in the sixth column and elements of lower atomic number than these fluoresce strongly to the Kα radiation listed.

Cameras. Powder cameras are of various types. The common Debye-Scherrer-Hull type (Fig. 6) consists of a cylinder on which is mounted the photographic film, a rod-shaped specimen on the axis of the cylinder, suitable slits or pinholes to direct the primary beam at the specimen, and a device to catch this undiffracted beam or conduct it out of the camera after it has penetrated the specimen, thus avoiding intense blackening where it strikes the film. Focusing cameras are also cylindrical but are designed so that the specimen, the slits, and the photographic film all lie on the circumference of the cylinder (Fig. 7). This arrangement causes diffracted rays from all parts of the specimen to come to a focus on the film and give sharp lines with relatively shorter exposure time. Back-reflection cameras employ large-angle diffracted rays only. They may be constructed with a cylindrical film, with a flat film, or with a photographic plate (see B, Fig. 1); a hole is provided in the film or plate for the passage of the primary X-ray beam. Any of these types may be modified to operate with the specimen at either high or low temperatures, and for use with large-grained samples, the cameras may be provided with devices to rotate, oscillate or shift the specimen, thus permitting more grains to reflect X-rays.

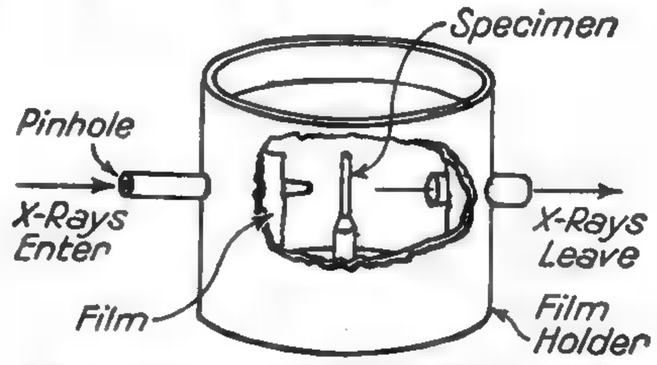

Fig. 6 Powder camera (Debye-Scherrer-Hull)

For studies of cold work and annealing, back-reflection cameras serve well. Cobalt and iron radiation may be used for steel and copper specimens, and copper radiation for aluminum specimens, to give a strong diffraction line at a large angle. The pinholes need not be so small as in cameras used for the precise determination of lattice constants. Cold work is shown by a blurring of the spots lying on the diffraction rings and a broadening of the rings, as indicated in Fig. 8 and 10. Recovery from the strained condition is indicated by a sharpening of the lines (compare Fig. 9, annealed, with Fig. 10), and may or may not go on simultaneously with recrystallization, which is indicated by a return of the spotty type of pattern, as in Fig. 11, indicative of large strain-free grains. This type of camera is not so useful for determining preferred orientations as the "pinhole" camera, which produces its pattern in the forward direction.

The Diffraction Pattern. When a primary beam of X-rays strikes a specimen, the diffracted beams leave the specimen along the generators of a number of cones; each of the cones is concentric with the primary beam. These cones fall on a flat film forming concentric circles, or on a cylindrical film forming curved lines, as indicated in Fig. 9. These circles or lines are frequently called "Debye rings". From the diameter of the circles or arcs on the pattern and the known dimensions of the camera, the apex angles of the cones are calculated, and from these are obtained the angles of reflection, θ, of the Bragg equation. In the camera sketched in Fig. 1, with the film at *A*, if x is the radius of a diffraction ring, and X is the perpendicular distance from specimen to film, then $\tan 2\theta = x/X$. In the camera of Fig. 1, with the film at *B*, $\tan (180 - 2\theta) = x/X$. In the

(a) When Kα_2 is not resolved from the stronger Kα_1, use the average value $(2\lambda\alpha_1 + \lambda\alpha_2)/3$. All wave lengths are kX units, used by Siegbahn and universally adopted for crystallographic work prior to 1947. To convert to angstroms multiply by 1.00202.

(b) Kβ filters should be made of elements listed in this column; thickness in last column reduces Kβ to 1/600 the intensity of Kα.

camera shown in Fig. 6, if s is the circumferential distance from the central undiffracted spot to an arc of the diffracted line, and R is the camera radius, θ is given in radians by the relation $\theta = s/2R$ (1 radian = 57.30 deg); in practice, measurement is best made of the distance $2s$, from arc to arc, rather than s, from arc to central spot. In the camera of Fig. 7 (and frequently in the others also) it is convenient to prepare a calibration chart for reading θ or d directly from the positions of diffracted lines. A sample the lines of which fall at accurately known angles provides the data for such a chart. Tables relating θ to d are available.[5]

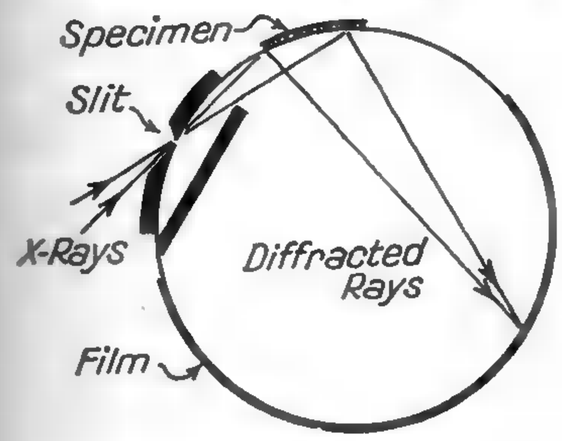

Fig. 7

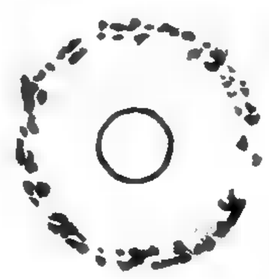

Fig. 8

Fig. 7 Focusing camera (Seeman-Bohlin, Phragmen)
Fig. 8 Pattern from distorted polycrystalline material in a back-reflection camera (Film B, Fig. 1). Blurred spots form a ring surrounding the central hole in the film.

Thus, from the position of the lines on the film, the spacing d of the corresponding atomic planes may be obtained. The sequence of lines on the film corresponds to the sequence of interplanar spacings in the crystal. The pattern in Fig. 9, for example, shows a sequence characteristic of body-centered cubic crystals. Large unit cells have all their interplanar spacings large, and thus their diffracted lines will lie at small angles from the direct beam, while small unit cells will have lines spread out at larger angles. It is the size and shape of the unit cell of a crystal that govern the "positions" of the diffracted rays, while the atomic arrangement within the unit cell controls the "intensities" of the rays. The determination of crystal structure from the powder diffraction patterns is a complex procedure that yields a reliable result in only the simplest cases; various tables, graphs, and other devices aid the investigator.[4,5,8]

Fig. 10 Pattern from cold worked iron. Lines widened and weakened by "microscopic" residual stresses.
Fig. 11 Pattern from recrystallized iron, the large unstrained grains forming spotty lines.

Strictly monochromatic radiation is not usually available; when radiation of two or more wave lengths is present in the beam, each wave length forms a diffraction pattern on the film independently. The Kα lines with closely similar wave lengths fall together and make a single line at low values of θ, but form a doublet at large values of θ (provided the specimen is able to yield sufficiently sharp lines). The Kβ radiation, if not filtered out, produces another superimposed spectrum, which is of single lines instead of doublets and is always weaker than the Kα spectrum. Its lines are recognized by these characteristics and by the fact that the ratio of $\sin\theta$ for Kα and Kβ radiations reflecting from a given atomic plane always equals the ratio of the corresponding wave lengths. The Kβ radiation may be removed by filtering, if desired, using the elements (or compounds containing the elements) listed in Table I under the heading of "Kβ highly absorbed by". The filters are best placed between the specimen and the film, but are also used at the window of the tube.

Precise Lattice Constants.[8,9] The accuracy of lattice dimension measurement with the Debye-Scherrer-Hull cameras and focusing cameras is from 0.1 to 0.02%, depending on the care taken and the operator's skill. Back-reflection cameras are more precise, for these will give from 0.02 to 0.003%. Corrections for errors have been carefully worked out and summarized.

Identification of Phases.[6] A great number of practical problems require no determination of crystal structure, but merely an identification of phases by their powder diffraction patterns, and this may be done without involved calculations, by simply comparing patterns of the unknown material with patterns of chemically or mineralogically identified material. The films are laid side by side or are superimposed, and the similarities are observed directly, or the patterns are compared with those listed in Hanawalt's tables (procurable in card index form from the ASTM). If the crystal structures are simple—for example, cubic—the unit cell dimensions can be computed easily and compared with tables of known structures. For this work large range cameras are required, so that many lines will be obtained. For identification to be certain, every line of the pattern must be accounted for. Important advantages of this X-ray method of identification are that only small quantities of material are required (a few mg), and that different compounds or states of combination of the same elements are distinguishable from each other, since they possess different crystal structures. Thus, chemical compounds are distinguishable from mixtures. The method is widely used for the identification of alloy phases; it is more direct and positive than metallographic methods, but is generally inapplicable when a phase constitutes less than 1 to 5% of the weight of the alloy. If more than one variety of crystal is present in any specimen, each will produce its spectrum independently, and the pattern will consist of superimposed spectra with relative intensities depending on the relative amounts of the two phases. Amorphous materials, glasses, liquids, and gases give only broad halos instead of sharp lines; better patterns are obtained when a crystal monochromator is used.

Solid Solutions. The presence of solute contracts or expands the dimensions of the unit cell of the pure solvent material. This change is registered on the powder photograms by a displacement of the lines to either greater or smaller diffraction angles, unless the effect is too small to be recorded. The effect is ordinarily proportional to the atomic percentage of the dissolved element (Vegard's law) or closely approximates this. The expansion or contraction comes to an abrupt halt at the solid solubility limit, and throughout the two-phase region beyond the limit the lattice dimensions remain constant in binary alloys. This behavior enables an accurate determination of the solubility limit (and its variation with temperature) provided certain precautions are taken. A thorough homogenization treatment is necessary and the surface must be free from sublimation, oxidation, or other reactions which would alter the surface concentration. If the specimen is to represent the condition of the alloy at the homogenization temperature, the quenching from this temperature must be sufficiently rapid to prevent changes; yet quenching stresses must not be introduced into the specimen. These stresses can best be avoided by quenching small wires or fine powders.

The interstitial or substitutional nature of the solid solution can be determined by comparing the measured density with the density calculated from the dimensions of the unit cell and the number and atomic weight of the atoms assumed to be in the cell. Solid solutions are ordinarily random arrangements of the different kinds of atoms on the lattice points. When one kind of atom migrates to a particular set of atomic positions in preference to others, a superlattice is formed. This is recognized in the diffraction pattern by the additional "superlattice lines" which appear after suitable low-temperature annealing of certain alloys.

Stress Measurement.[9] Residual and applied stresses in

metals may be studied with powder diffraction cameras. When an interplanar distance d is altered by stresses, the diffraction angle changes accordingly. If the elastic strain varies from grain to grain in a polycrystalline metal, the angle of diffraction will also vary, giving a widened diffraction line in the powder photograph, as in Fig. 10. The amount of widening beyond the normal width of an annealed stress-free material indicates the amount of variation of stress from point to point in the metal, the relative intensity of "microscopic" stresses. Other factors than stress, however, may contribute to the widening and must be considered in interpreting the photograph; namely, inhomogeneity in composition of the specimen and small size of the reflecting grains. If stresses are of equal intensity in all the reflecting grains, forming a homogeneous stress system, the diffracted rays from all grains will superimpose to produce sharp lines displaced from their normal unstressed positions. The diffraction pattern can then be used to calculate the homogeneous "macroscopic" stresses. Back-reflection powder cameras, arranged so that the X-ray beam falls perpendicularly on the surface of the specimen, give data from which is calculated the sum of the two principal stresses lying parallel to the surface; cameras providing oblique incidence of the rays are used to calculate the principal stresses individually. An accuracy in stress measurement by these methods of about 2,000 psi can be attained with annealed steel under laboratory conditions. Cold worked or quenched steels give diffuse lines which increase the errors to plus or minus 10,000 psi. The stresses measured are those in the surface layers of the specimen, for the radiation used does not penetrate deeply.

Rotating Crystal Method. *Photogoniometers.*[4,8] Types of cameras seldom used in practical work, but indispensable in determination of crystal structure, are those in which a single crystal is mounted so as to oscillate or rotate around a definite crystallographic axis. Monochromatic radiation is used, and the simpler cameras are similar to Fig. 6. Modifications of this are particularly helpful for solving complex crystals. Tne most common of these is the Weissenberg photogoniometer, which permits a photographic film to be shifted in synchronism with the oscillation of the crystal and is provided with a slit through which only selected rays from the crystal will pass. Spacings of the layers of spots in rotating crystal patterns give the distance between lattice points in the direction of the axis of rotation of the crystal. The orientation of single crystals may also be determined with these cameras.

Spectrometers.[1,2,3] The most accurate method of measuring the intensity of diffracted rays involves the use of an ionization chamber or a Geiger-Müller counter mounted on a spectrometer somewhat similar to an optical spectrometer. The current in the chamber, measured by an electrical device, is proportional to the intensity of the X-ray beam. The method is used in crystal structure determination and in quantitative analysis of mixed powders or mixed phases. Chemical analysis is accomplished by X-rays through the use of spectrometers that record the characteristic X-ray emission lines or absorption edges of the sample to be analyzed.[7] Favorable combinations of elements permit extreme sensitivity in the detection of small percentages of an element in a compound or mixture (independent of its state of chemical combination) and also, with care, permit fair precision in quantitative analysis.

X-Ray Diffraction Micrograph[11] A fine-grained photographic plate may be placed very close to a specimen irradiated by characteristic radiation. Images formed on the plate by diffraction of the characteristic radiation are micrographs that can be enlarged 25 to 250 diam, depending on the photographic emulsion. The images distinguish cold worked from recrystallized grains, and indicate microscopic imperfections and concentrations of strains over the surface of individual grains.

Summary of Applications and Methods Usually Employed

Preferred Orientations of Grains, Fiber Textures. Pinhole method, with beam transmitted through the specimen or reflected from the surface of the specimen, noting maximums of intensity around Debye rings (Fig. 5).

Cold Work; Recrystallization. Pinhole, Laue or powder method (Fig. 4, 8).

Identification of Phases. Powder method with cameras that have a wide range of reflection angles (Fig. 9).

Precision Lattice Dimensions; Boundaries of Regions in Phase Diagrams; Studies of Solid Solution and Aging. Powder method, back-reflection cameras.

Grain Size. If larger than 10^{-3} cm, pinhole method or powder method, noting size of spots (Fig. 4, 11). If smaller than 10^{-5} cm, powder method, noting line width (Fig. 10).

Perfection of Lattice in Grains. Pinhole, Laue, or back-reflection powder methods, noting sharpness of spots.

Residual Macroscopic Stresses or Applied Stresses. Back-reflection powder method, with measurement of lattice dimensions.

Residual Microscopic Stresses and Recovery. Back-reflection powder method, noting width of lines.

Orientation of Individual Grains. Laue, back-reflection Laue, or rotating crystal methods, or photogoniometer.

Determination of Crystal Structure. Powder method only in very simplest cases; rotating crystal or photogoniometer method.

Structure of Amorphous Solids, Glasses, Liquids, and Gases. Powder method or spectrometer.

Chemical Analysis. Spectrometer, registering emission lines or absorption edges.

Dilatometry

By Peter Hidnert* and Wilmer Souder*

ONE of the most frequently measured physical properties of materials is thermal expansion. Virtually all materials undergo a change of dimensions when they are heated or cooled. In isotropic bodies, the expansion or contraction is the same in all directions, but in anisotropic bodies, the expansion or contraction is different in different directions. Allowances for differences in thermal expansion of various materials must be made in many scientific and industrial applications.

* National Bureau of Standards, Washington, D. C.

If L_o is the length of a solid body at 0 C, then its length at any temperature $t°C$ may be represented by the following equation:

$$L_t = L_o (1 + at + bt^2 + \ldots) \qquad (1)$$

where a and b are constants depending on the material. Equations of this type are empirical. In most instances, these constants a and b are positive, because bodies usually expand at a more rapid rate as the temperature increases.

Similarly, if V_o is the volume of a liquid or solid at 0 C,

then its volume at any temperature t°C may be represented by the following empirical equation:

$$V_t = V_o (1 + \alpha t + \beta t^2 + \ldots) \qquad (2)$$

where α and β are constants depending on the material.

The average coefficient of linear expansion between any two temperatures t_1 and t_2 may be determined from equation (1) as follows:

$$_{t_1}a_{t_2} = \frac{L_{t_2} - L_{t_1}}{(t_2 - t_1) L_o} \qquad (3)$$

where $_{t_1}a_{t_2}$ is the average coefficient of linear expansion between t_1 and t_2, L_{t_1} and L_{t_2} are the lengths at t_1 and t_2, respectively, computed from equation (1), and L_o is the initial length (usually at 0 C or at room temperature). The lengths L_{t_1} and L_{t_2} may be obtained from the original data or plotted curve without using derived equation (1).

Similarly, the average coefficient of cubical expansion between any two temperatures t_1 and t_2 may be determined from equation (2) as follows:

$$_{t_1}\alpha_{t_2} = \frac{V_{t_2} - V_{t_1}}{(t_2 - t_1) V_o} \qquad (4)$$

where $_{t_1}\alpha_{t_2}$ is the average coefficient of cubical expansion between t_1 and t_2, V_{t_1} and V_{t_2} are the volumes at t_1 and t_2, respectively, and V_o is the initial volume. The average coefficient of cubical expansion of an isotropic solid may be considered equal to three times the average coefficient of linear expansion within a high degree of approximation.

The following equations were obtained by differentiation of equations (1) and (2):

$$a_t = a + 2bt + \ldots \qquad (5)$$

$$\alpha_t = \alpha + 2\beta t + \ldots \qquad (6)$$

In these equations a and α represent the instantaneous coefficients of linear expansion and cubical expansion, respectively, at 0 C, and a_t and α_t represent the instantaneous coefficients of linear expansion and cubical expansion, respectively, at any temperature t°C. Instantaneous coefficients of expansion at t°C may be designated simply as coefficients of expansion at t°C.

Dilatometric Methods. Determinations of dimensional changes of materials, of coefficients of linear and cubical expansion, and of the temperatures and magnitudes of dimensional changes during transformations at constant temperature and with slow or relatively rapid heating and cooling rates (including quenching), are important for progress in science and industry. Dilatometric methods have an advantage over the thermal method (temperature-time cooling curves) in investigating transformations, for the transformation temperatures may be passed through slowly or quickly, or the sample may be held at a given temperature for any length of time, in order to attain equilibrium, and the heating or cooling then resumed. Various types of dilatometers have been used for these determinations.

Eight dilatometric methods will be described. These methods give reliable results if they are used with an intelligent realization of their limitations.

Precision Micrometric Method. The National Bureau of Standards uses micrometric thermal-expansion apparatus for the most precise work on the linear thermal expansion of solids between minus 150 C and plus 1000 C. This apparatus is of two types: (1) the air-type heating chamber, shown at the left of Fig. 1, in which the sample is surrounded by air or a neutral gas; and (2) the stirred liquid bath, shown at the right of Fig. 1, in which the sample is surrounded by a suitable liquid.

In both types of apparatus, heating is effected by passing electric current through heating coils; likewise, both types are equipped with thermocouples and a potentiometer for measuring temperatures. Cooling, for determinations at low temperatures, is secured in the stirred liquid bath by expanding compressed air from a liquid air interchanger through coils immersed in the bath.

The positions of the ends of the sample in the air chamber are indicated by fine wires (0.001 or 0.002-in. diam) weighted and hanging vertically from the ends of the sample through slots in the bottom of the chamber. Two micrometer microscopes, mounted horizontally on a traveling comparator and separated by a lateral distance approximately equal to the length of the sample (10 to 50 cm), are used to measure the length changes of the sample, as indicated by the changes in separation of the two vertical wires hanging freely from the ends of the sample. In the stirred liquid bath, tungsten wires (0.001-in. diam) in contact with the ends of the sample, extend from a fixed horizontal bar above the sample to hinged fingers, inserted beneath the ends of the sample. Here the length changes of the sample are proportional to the changes in the distances between the wires in the plane of the microscopes.

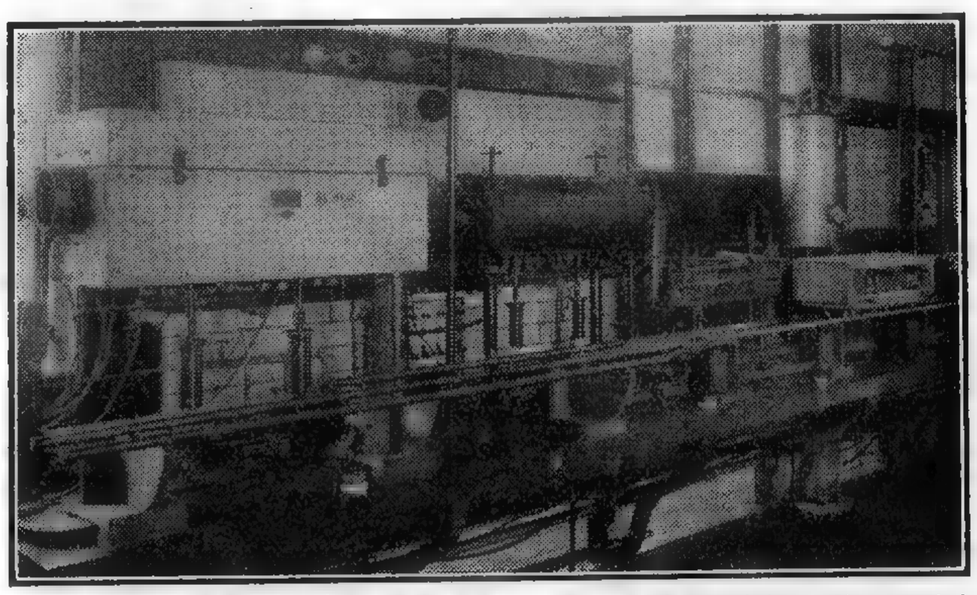

Fig. 1 Furnaces, standard bar and comparator of precision micrometric thermal-expansion apparatus

The sample is in the form of a straight rod or bar of uniform cross section. The usual length is 300 mm, and the diameter (or diagonal, if the rod has a rectangular cross section) is 5 to 10 mm. The sample is prepared with cylindrical ends that have radii of curvature equal to one-half the length of the sample. Provision has been made for handling samples of other lengths and diameters. The limits of length are the length of the furnace for long samples (50 cm) and the limit of contact approach of the two micrometer microscopes for the short samples (10 cm).

When a sample must be heated in the air furnace to a temperature at which oxidation or scaling is expected, the furnace may be filled with a neutral gas. When this gas is not available, it is possible to minimize the effects by placing the observation wires in sharp V grooves cut around the sample near each end.

A vane (5 to 25 g), attached to the bottom of each observation wire in the air-type heating chamber, is suspended in oil to damp out vibrations from the building and surroundings. The wires are annealed before observations are started, by passing sufficient electric current through the wires to heat them to a visible glow. For determinations below 700 C, chromel wires 0.001 or 0.002 in. in diam may be used. For determinations from 20 to 1000 C, platinum-osmium, platinum-rhodium or platinum-ruthenium wires 0.002 in. in diam may be used.

With the air furnace it is possible to make measurements between 20 and 1000 C. The stirred liquid bath is used for temperatures between minus 150 and plus 300 C. The stirred liquid bath, by reason of the circulation and intimate contact of the heated or cooled liquid, permits more rapid observations than the air furnace. Observations are recorded when the sample has reached the temperature of the furnace. This condition may be established by waiting until the observation wires show no movement in the microscopes. After readings are completed the heating current is adjusted for the next temperature. The immersion of samples in the liquid bath is limited to those samples not attacked by the liquids used. The general practice is to employ a light engine oil (Esstic 42) for the temperature range 20 to 300 C. For the range minus 65 to plus 60 C, Dow Corning Fluid No. 500 (kinematic viscosity 2.0 centistokes at 25 C) is used, and 2-methylpentane is used at low temperatures to about minus 150 C. A water

coil in the liquid bath is used to hasten cooling between 300 and 20 C.

The observation wires on which microscope settings are made are illuminated by 10-w Mazda frosted spherical lamp bulbs placed behind the wires. Resistances in the lamp circuit are used to reduce the illumination to a satisfactory intensity. An excellent arrangement for high-precision measurements is secured by the parallel spider lines on the reticle frames moved by the microscope micrometers.

The air furnace has control rheostats for each side and end of the heating chamber. The external heat loss from these rheostats is reduced by using a transformer for the lower temperatures.

With these types of apparatus it is essential that the position of the samples be maintained horizontal during the determinations. A further requirement for the stirred liquid bath is that the readings be made at a known distance above each end of the sample and that the ratio of distances (level of observation to upper supports of wires and ends of sample to upper supports of wires) be known and maintained.

The arrangement of the furnaces, standard bar and comparator is shown in Fig. 1. The air-type heating chamber or furnace is shown at the extreme left of the figure. A smaller air-type furnace is shown at the right of the large furnace. The standard bar of fused quartz and the micrometer comparator appear in front of the window. The interchanger and stirred liquid bath are partially visible near the right margin of Fig. 1. Vacuum bottles used in icing the thermocouple junctions appear at the right of the two furnaces in this figure. Connections to the potentiometer are made through lead-covered cables and a selector switch. Triple thermocouple junctions are placed in the air furnaces. A single thermocouple junction in the stirred liquid bath is sufficient. The forced circulation of the bath liquid by a motor and a propeller maintains uniformity of temperature. Platinum–platinum-rhodium thermocouples are used for the 1000 C air furnace. For the smaller air furnace (600 C), gold-palladium–platinum-rhodium thermocouples are used. A copper-constantan thermocouple is employed in the stirred liquid. The interchanger is of the regular air-liquefying type. The cooled air, compressed to about 2500 psi, is expanded through coils in the stirred liquid bath when temperatures between plus 20 and minus 150 C are required.

This method for determining linear thermal expansion is believed to be the most precise method known. Under most favorable conditions, coefficients of expansion accurate to 0.1% are possible with this apparatus.

Additional information about this equipment is given in publications by Hidnert[1] and Souder and Hidnert.[2] Blueprints giving details of construction are on file at the National Bureau of Standards and may be borrowed.

Interference Method. When only small samples of material (about 10 mm or less in length) are available, the Fizeau-Pulfrich interference method is especially useful for determinations of linear thermal expansion. The method is also useful for determinations of the linear thermal expansion of crystals or other solids in different directions. The sample is placed vertically between two transparent fused-quartz plates, each about 4 mm thick and free from bubbles and other imperfections. The surfaces of each plate should be flat within one-fifth of a fringe and should be inclined toward each other at an angle of about 20 minutes. The sample with the two fused-quartz plates is set in an electric furnace or cooling chamber for heating or cooling. When the plates are illuminated normally with monochromatic light, a set of interference fringes is produced by the interference of the light reflected between the lower surface of the upper plate and the upper surface of the lower plate, when the angle between these surfaces is slight. The fringes are observed by means of a viewing device. Changing the temperature of the sample, brings about a change in length, which causes the distance between the plates to change with a corresponding movement of the interference fringes past a reference mark on the lower surface of the upper plate. From the observed displacement of the fringes, the change in length or linear thermal expansion can be determined. The temperature of the sample may be determined with a thermocouple, resistance thermometer or interference thermometer.[3] This method may be used at low temperatures and at elevated temperatures to about 1000 C.

If the sample is maintained in a vacuum during the determinations, the linear thermal expansion for a given temperature interval may be computed from this equation:

$$\Delta L = \frac{\lambda N}{2L} \qquad (7)$$

where ΔL is the change in length or linear thermal expansion per unit length, λ is the wave length of monochromatic light, N is the number of fringes that passed the reference mark, and L is the initial length of the sample. However, if the sample is heated or cooled in air, a correction should be applied to the value of ΔL computed from equation (7). This correction, known as the "air correction", varies with the pressure and the temperature of the air. The average coefficient of expansion may be computed by dividing ΔL (corrected if necessary) by the change in temperature.

Austin[4] stated that the maximum errors of the interference method with his vacuum furnace should not be greater than 1% at 300 C or 0.7% at 600 C, and the probable error will be much less than this. When the sample is heated in an air furnace, the errors may be greater as a result of the uncertainty caused by the presence of an air film between the sample and the interferometer plate and the oxidation or scaling of the sample.

Additional information about the interference method has been published by Peters and Cragoe,[5] Merritt,[6] and Saunders.[7]

Trowbridge,[8] Arnulf,[9] Sinden,[10] Nix and MacNair,[11] and Saunders,[12] described methods of photographing interference fringes.

In 1916, Meggers[13] indicated how the determination of the exact order of interference or the optical measurement of length can be made with the aid of certain wave lengths of neon radiation. In 1919, Peters[14] described the use of the interferometer in the measurement of small dilations by observing fractional orders caused by several wave lengths, following the method described by Meggers. Willey and Fink[15] have recently used this method in determinations of coefficients of expansion of aluminum alloys. With this method, it is not necessary to count the interference fringes that pass the reference mark during heating or cooling. The method does not require the photographing of interference fringes nor the constant attention of the observer. The method has been used for many years at the National Bureau of Standards for determinations of the lengths of gage blocks at room temperature.

Fused-Quartz-Tube and Dial-Indicator Method. A fused-quartz-tube thermal-expansion apparatus may be used for determinations of linear thermal expansion for various temperature ranges between minus 190 and plus 1000 C. This type of apparatus, as improved by Hidnert and Sweeney[16] beyond a similar type used abroad, is recommended for commercial laboratories where data of the highest precision are not required. With this apparatus it is possible to obtain an accuracy of 2%.

Figure 2 shows a fused-quartz tube closed at the bottom, with a sample (20 cm) in the tube ready for heating or cooling. A movable fused-quartz rod rests on top of the sample and extends above the open end of the tube. The bottoms of the tube and the movable rod are ground concave and the ends of the sample, convex, in order to secure satisfactory contacts. The top of the movable rod, on which a dial indicator rests, is flat. Heating is effected by placing the tube containing the sample in a water or oil bath or in an electric furnace (Fig. 3) extending well above the top of the sample. Low temperatures are secured by using suitable cooling baths, such as: liquid air; solid carbon dioxide in a mixture of equal parts of carbon tetrachloride and chloroform; ice and sodium chloride; and melting ice. A thermocouple, placed inside the fused-quartz tube near the center of the sample, indicates the temperature. A dial indicator, fastened near the top of the tube, registers the differential expansion between the sample and an equivalent length (20 cm) of fused quartz. A small correction is made for the linear expansion of fused quartz. Prints showing details of this apparatus may be secured

from the National Bureau of Standards by persons interested in constructing this equipment.

Modifications of the fused-quartz-tube thermal-expansion apparatus, for use with shorter samples or with a load on the samples, have been described by Hidnert[17] and by Hidnert and Dickson.[18]

Walters and Gensamer[19] modified this type of apparatus so that the expansion of a sample can be determined in a vacuum or an inert gas between minus 200 and plus 1000 C. Kingston[20] modified the apparatus to a recording dilatometer by means of a contact mechanism, transmission shaft, recorder and electronic relay. He also made provision for the use of various atmospheres.

Autographic Optical-Lever Method. Souder, Hidnert and Fox[21] designed and constructed an autographic optical-lever thermal-expansion apparatus for use in commercial laboratories. It was found to give more accurate results than previous apparatus of similar type. With this apparatus it is possible to obtain expansion curves photographically or to observe points on the expansion curves of materials during the progress of the test.

A general view of the autographic expansion apparatus is shown in Fig. 4. The apparatus consists essentially of an adjustable furnace, *F*, mounted on a common base with a camera box, *C*, and an adjustable source of illumination, *I*. The back of the camera is provided with a hinged book-form plate holder for 8 by 10-in. photographic plates, films, sensitized paper, or ground-glass screen for photographic or visual observations. The over-all length of the apparatus is approximately 64 in., height 19 in., and width 14 in.

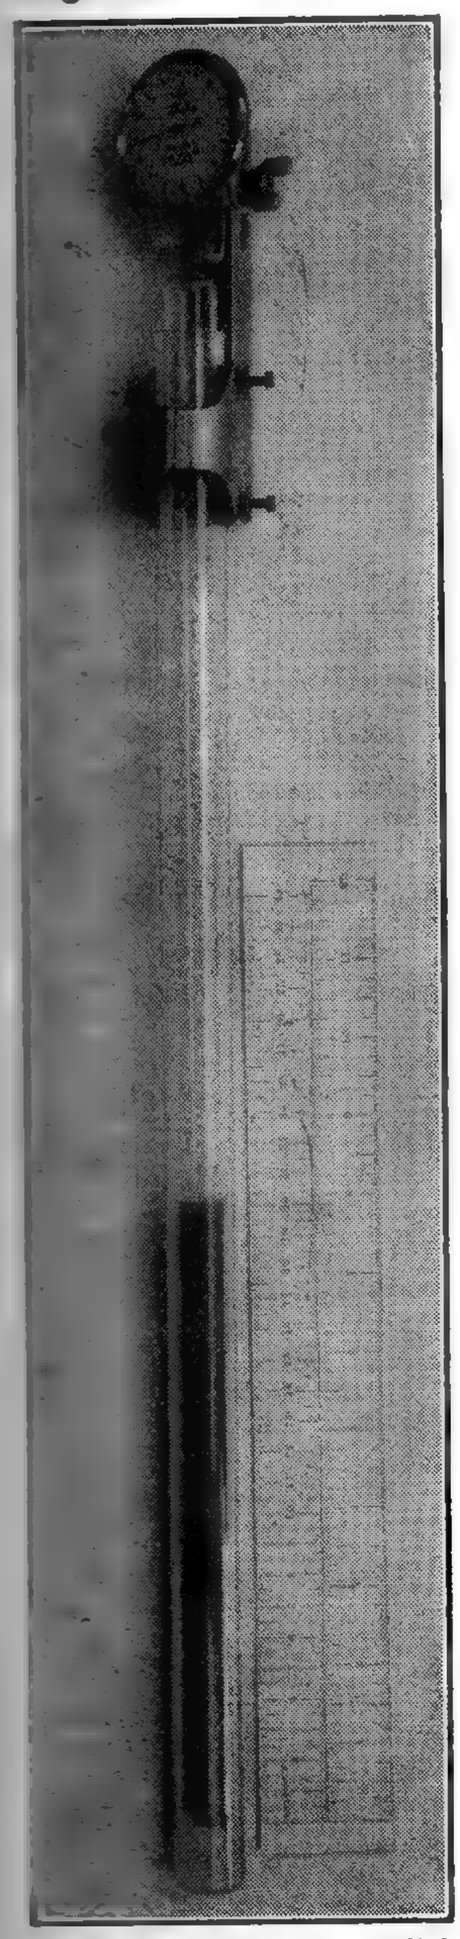

Fig. 2 Fused-quartz tube, dial indicator, and sample

The temperature-expansion relations are projected to the camera by a mirror (Fig. 5) held against three fused-quartz rods that extend from the end of the furnace. Lines joining the points of contact of these extensions against the mirror form a right-angled triangle. The extension which touches at the intersection of the two lines forming the right angle is from a fused-quartz rod in the furnace and is regarded as the "stationary" axis. The sample being tested is situated below this, and as it is heated, its expansion causes the mirror to deflect a spot of light vertically. The third rod, which has a regular rate of linear thermal expansion, causes the mirror to deflect the spot of light horizontally. The spot of light describes a curve, the resultant of these two expansions vertically and horizontally.

For materials having coefficients of expansion approximately equal to those for ordinary steel, the error of the autographic expansion apparatus is about 6% for the range from 20 to 100 C, and about 3% for the range from 20 to 500 C. The apparatus is not sufficiently sensitive for tests on low-expanding materials. It is not satisfactory at temperatures where softening occurs in the sample or for materials that bend at elevated temperatures. It is, however, a convenient, trustworthy, and efficient apparatus and fills a definite need.

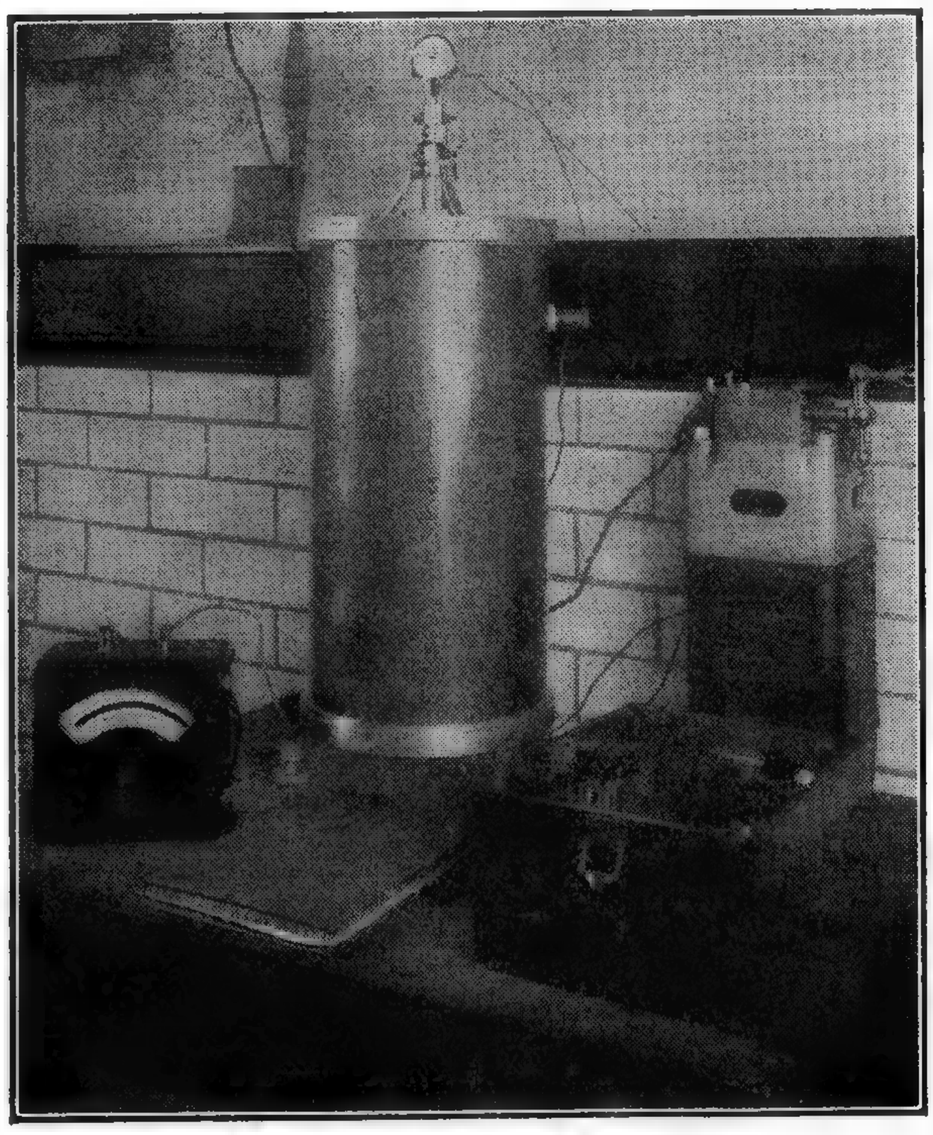

Fig. 3 Fused-quartz tube and dial-indicator thermal-expansion apparatus

Chevenard[22] and other investigators used other forms of the optical lever method for determinations of the linear thermal expansion of materials.

Liquid-Micrometer Method. A liquid-micrometer method for determining linear thermal expansion of solids has been described by Andrew, Rippon, Miller and Wragg.[23] The sample (in the form of a hollow cylinder, 2 in. long, ¾ in. in diam, with a ⅜-in. hole through the center) is placed horizontally in a silica tube of 1-in. internal diam.

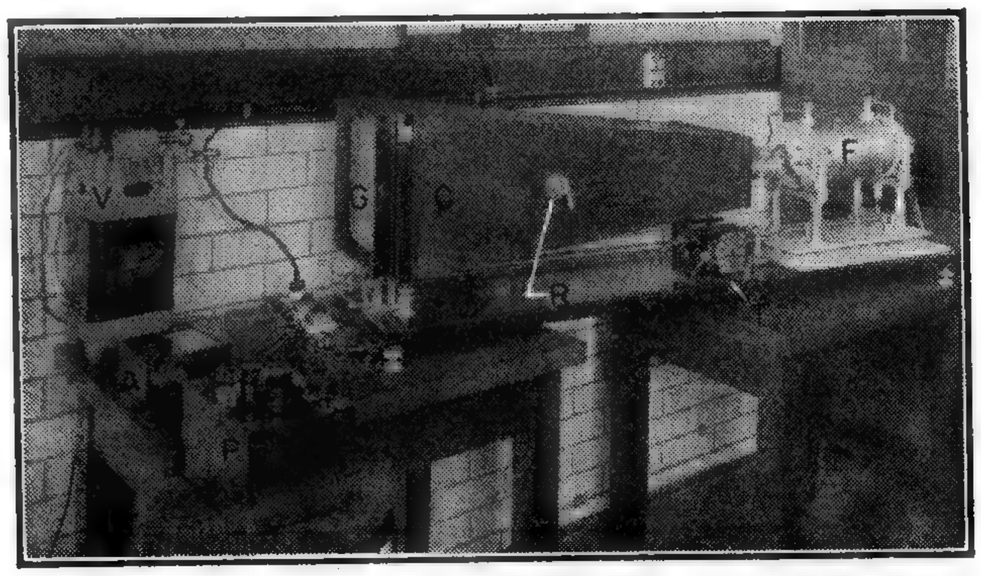

Fig. 4 Autographic expansion apparatus. *A*, ammeter; *C*, camera box; *F*, furnace; *G*, glass screen; *I*, illuminator; *P*, potentiometer indicator; *R*, internal reflecting mirror; *T*, transformer; *V*, induction voltage regulator.

The heating coil consists of a platinum wire wound around the silica tube over a length of 9 in. Two silica disks, accurately ground, are placed on the ends of the sample, which have been ground parallel and polished. These disks are pressed against the ends of the sample by means of two silica tubes, which transmit changes in the length

of the sample. One of the latter silica tubes is butted up against a heavy cast-iron block, and the other silica tube is pressed against a measuring device butted to a large lead block.

The relative movement of the silica tube is measured by a hydraulic device, consisting of a thick steel disk, 8 in. in diam, with a saucer-like depression on the face and a thin disk of saw steel clamped over this face. The space so enclosed is filled with colored water. A pipe runs through the back of the steel disk, connecting this liquid

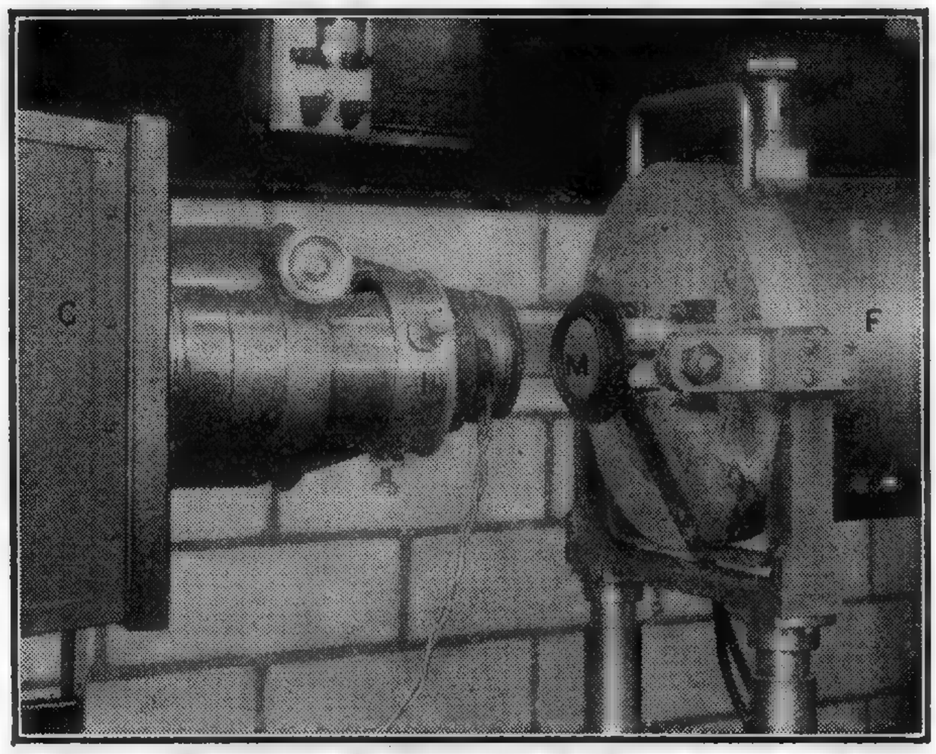

Fig. 5 Stellite mirror in contact with the fused-quartz rods and the "stationary" axis extending from the left face of the furnace. *C*, camera box; *F*, furnace; *I*, illuminator; *M*, optical lever mirror.

with a horizontal glass tube to which a scale is attached. A small reservoir with a stopcock is also fitted for adjusting the amount of liquid in the system. This liquid micrometer is bolted to the lead block, so that the thin steel disk is vertical. A steel disk with a flat surface 1 in. in diam, transmits the movement of the silica tube to the thin steel diaphragm. It was found that with a glass tube of about 2-mm bore, the movement of the meniscus magnifies the displacement of the silica tube two thousand times. The temperature of the sample is measured by means of a thermocouple placed at the center of the sample. Figure 6 shows a sketch of the apparatus.

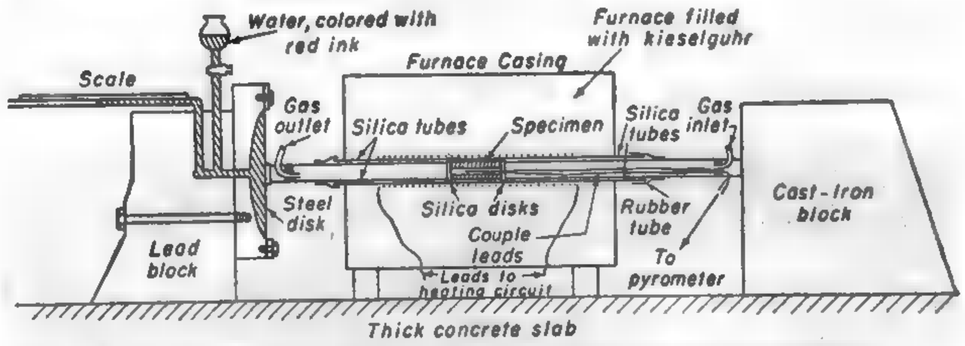

Fig. 6 Diagrammatic sketch of liquid-micrometer dilatometer

A flexible gastight joint is made by means of tubes of thin rubber fixed on the ends of the furnace tubes and then wired to the moving silica tubes. Through holes drilled in these two silica tubes, gas may be circulated around the sample to prevent oxidation.

It is necessary to calibrate this apparatus with samples of known expansion.

The apparatus was modified by Haughton and Griffiths,[24] the changes being the method of rendering the apparatus autographic, the method of mounting so as to enable adjustment of zero and resetting to be easily performed, and various minor modifications which, while by no means vital to the apparatus, simplify its arrangement and use. With this modified dilatometer, using a 2 in. sample, it is possible to record changes of the order of 10^{-6} in., though neither the sensitivity nor the accuracy is normally so high.

Because it is under pressure both in the original apparatus and in that modified by Haughton and Griffiths, the sample may become deformed at high temperatures.

Induction-Furnace and Dial-Indicator Method. A furnace of the high-frequency induction type was used by Heindl[25] for determinations of the linear thermal expansion of refractories between 20 and 1800 C. The heat was generated through the medium of a cylindrical graphite muffle, 12 in. long, 6 in. in diam, and having a wall ½ in. thick. A dial indicator, independent of the furnace, was supported by a framework with fused-quartz tubes for legs.

The setup of the sample (about 6 in. long) is indicated in Fig. 7. This setup formed a continuous system which expanded and contracted, independently of the furnace. Tungsten plates, ⅞ in. square and 0.015 in. thick, were placed between the sample and the graphite parts. The sample was placed within a muffle prepared from zirconium silicate.

Temperatures were measured with two platinum–platinum-rhodium thermocouples up to about 1500 C. Then the couples were removed from the apparatus and higher temperatures were observed with an optical pyrometer.

From a comparison of dial readings, with this apparatus, on a bar of artificial graphite between 20 and 1800 C and on a bar of fused quartz of known expansion between 20 and 1000 C, a curve was derived which gives corrections to be applied to the apparent expansion of a sample at various temperatures between 20 and 1800 C. The portion of the correction curve from 1000 to 1800 C was extrapolated, since the apparent expansion of artificial graphite showed no irregularities between 1000 and 1800 C.

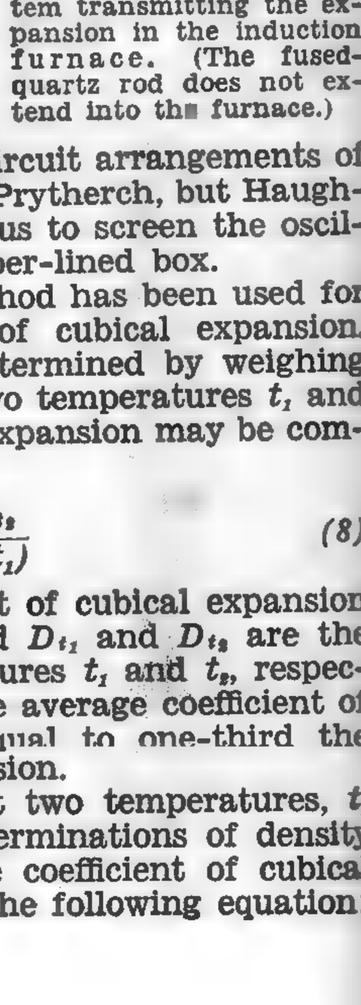

Fig. 7 Specimen, specimen support, and the system transmitting the expansion in the induction furnace. (The fused-quartz rod does not extend into the furnace.)

Capacitance Method. A capacitance dilatometer was developed by Prytherch[26] for use in the metallurgy department of the National Physical Laboratory. An oscillatory valve circuit is used and the sample (about 2 cm long) is made to actuate the moving plate of a small capacitor, which constitutes part of the series grid capacitance of the circuit. Small changes in this capacitance bring about relatively large changes in the mean steady anode current of the valve. A continuous record of the anode current of the valve is made on a thread recorder, which also simultaneously records the temperature of the sample. The changes in length of the sample can be correlated with temperature. Haughton and Adcock[27] altered this apparatus somewhat, in order to examine samples at temperatures as high as 1300 C in a controlled atmosphere. The circuit arrangements of the oscillator are those described by Prytherch, but Haughton and Adcock found it advantageous to screen the oscillator completely by means of a copper-lined box.

Density Method. The density method has been used for determinations of the coefficients of cubical expansion. If the densities of a sample are determined by weighing it in a liquid of known density at two temperatures t_1 and t_2, the average coefficient of cubical expansion may be computed from the following equation:

$$_{t_1}\alpha_{t_2} = \frac{D_{t_1} - D_{t_2}}{D_{t_2}(t_2 - t_1)} \qquad (8)$$

where $_{t_1}\alpha_{t_2}$ is the average coefficient of cubical expansion between temperatures t_1 and t_2, and D_{t_1} and D_{t_2} are the densities of the sample at temperatures t_1 and t_2, respectively. If the sample is isotropic, the average coefficient of linear expansion may be taken equal to one-third the average coefficient of cubical expansion.

If the volumes of the sample at two temperatures, t_1 and t_2, are obtained during the determinations of density or by another method, the average coefficient of cubical expansion may be calculated from the following equation:

$$t_1 \alpha\, t_2 = \frac{V_{t_2} - V_{t_1}}{V_{t_1}(t_2 - t_1)} \qquad (9)$$

where V_{t_1} and V_{t_2} are the volumes of the sample at temperatures t_1 and t_2, respectively.

The density method has been used previously by Matthiessen[28, 29] and Dewar[30] for determinations of the coefficients of cubical expansion of various materials. By this method it is possible to make determinations with small irregular pieces of materials.

Other Dilatometric Methods. Space will not permit descriptions of other methods for determining the thermal expansion of materials. References to publications describing various types and modifications of dilatometers are available at the National Bureau of Standards.

Relations Between Expansion, Temperature and Other Properties. From the data obtained on a sample by means of one of the dilatometric methods, it is possible to plot a curve that shows the relationship between expansion and temperature during heating and cooling. The curve during cooling may or may not coincide with the curve during heating, depending on the sample. From the expansion curve it is possible to compute average coefficients of expansion for various temperature ranges, or an empirical equation may be derived from the original data. For example, the linear expansion of tungsten may be represented by the following equation:

$$L_t = L_o\,[1 + (4.28\,t + 0.00058\,t^2)\,10^{-6}] \qquad (10)$$

where t is any temperature between minus 105 and plus 502 C. Coefficients of expansion may be calculated from this equation as indicated in the introduction.

Dilatometric methods permit the investigation of slow or rapid reactions and a quantitative description of transformations. These changes, observed during the heating and cooling of a sample, are caused by transformations of the constituents (allotropic phase transformations, anomalous transformations without change of phase, and decomposition of phases) and by the reactions between phases. Iron may be cited as an example of a metal which undergoes a transformation with change of phase. When alpha iron (body-centered cubic crystal structure) is heated, it undergoes an allotropic transformation $\alpha \rightarrow \gamma$ at about 910 C, with a contraction for several degrees higher. On being further heated above this temperature (Ac_3), gamma iron (face-centered cubic crystal structure) expands. On cooling, gamma iron undergoes an allotropic transformation $\gamma \rightarrow \alpha$ at about 900 C with an expansion. On further cooling below this temperature (Ar_3), alpha iron contracts.

Figure 8 shows the linear expansion of a carbon steel on heating and cooling between 20 and 900 C. This steel expanded regularly, while being heated to 729 C (Ac_1) and then contracted to 759 C (Ac_3). During heating through this range from 729 to 759 C, alpha iron transformed to gamma iron and iron carbide went into solution in gamma iron. At 759 C, the steel resumed its expansion at higher temperatures. On cooling, the steel contracted regularly to 685 C (Ar_3), when expansion started with a transformation to alpha iron. The expansion continued on cooling to 659 C (Ar_1). On further cooling to 20 C, the steel contracted in a normal manner.

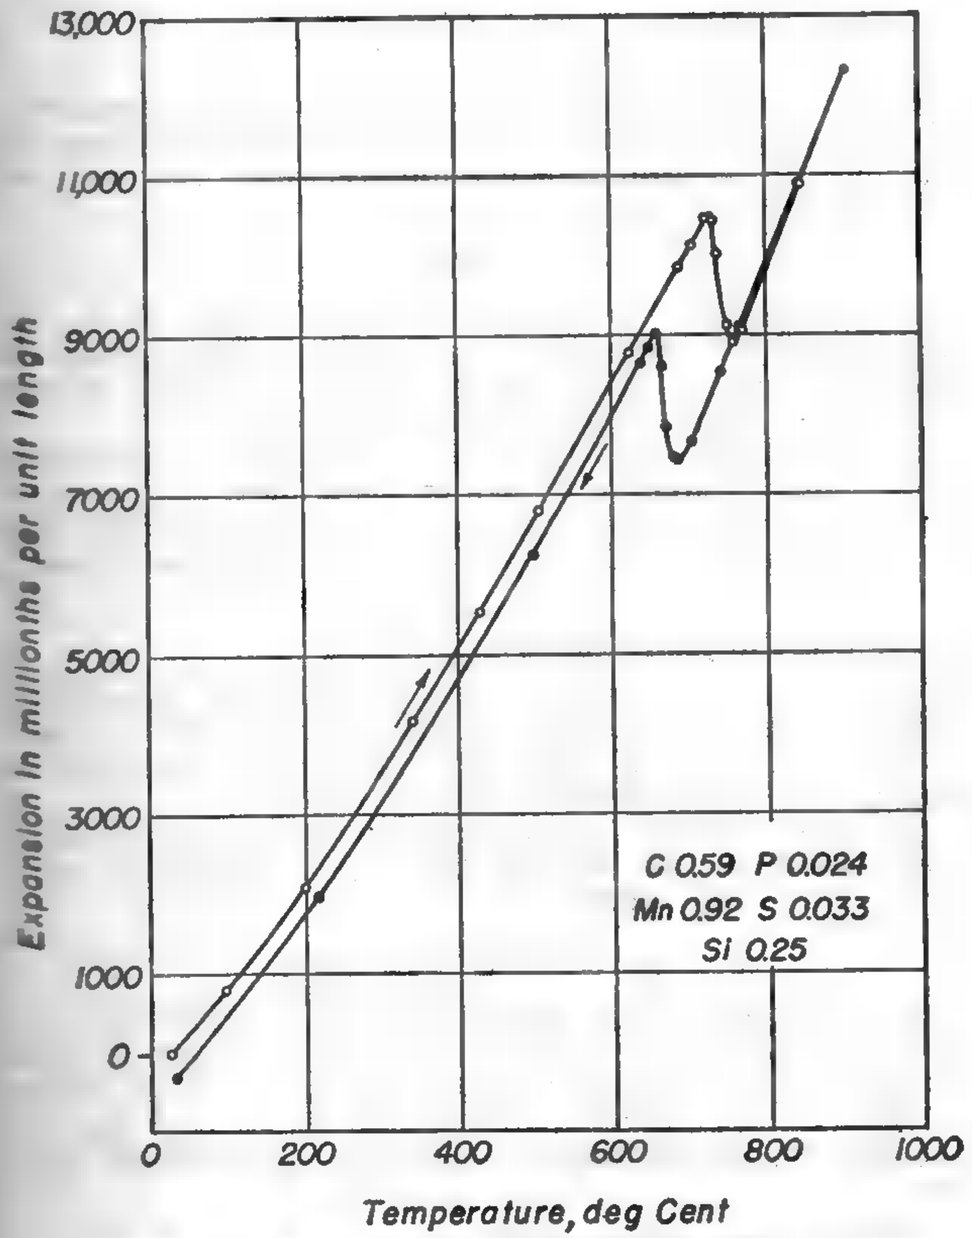

Fig. 8 Curve showing linear thermal expansion and transformations of steel

Dilatometric data may be used for obtaining relationships between thermal expansion and temperature; for investigations of the constitution of metals and alloys, investigations of dimensional changes in steels on hardening, aging phenomena of alloys and steels, kinetics of transformation of austenite during cooling of steels and during

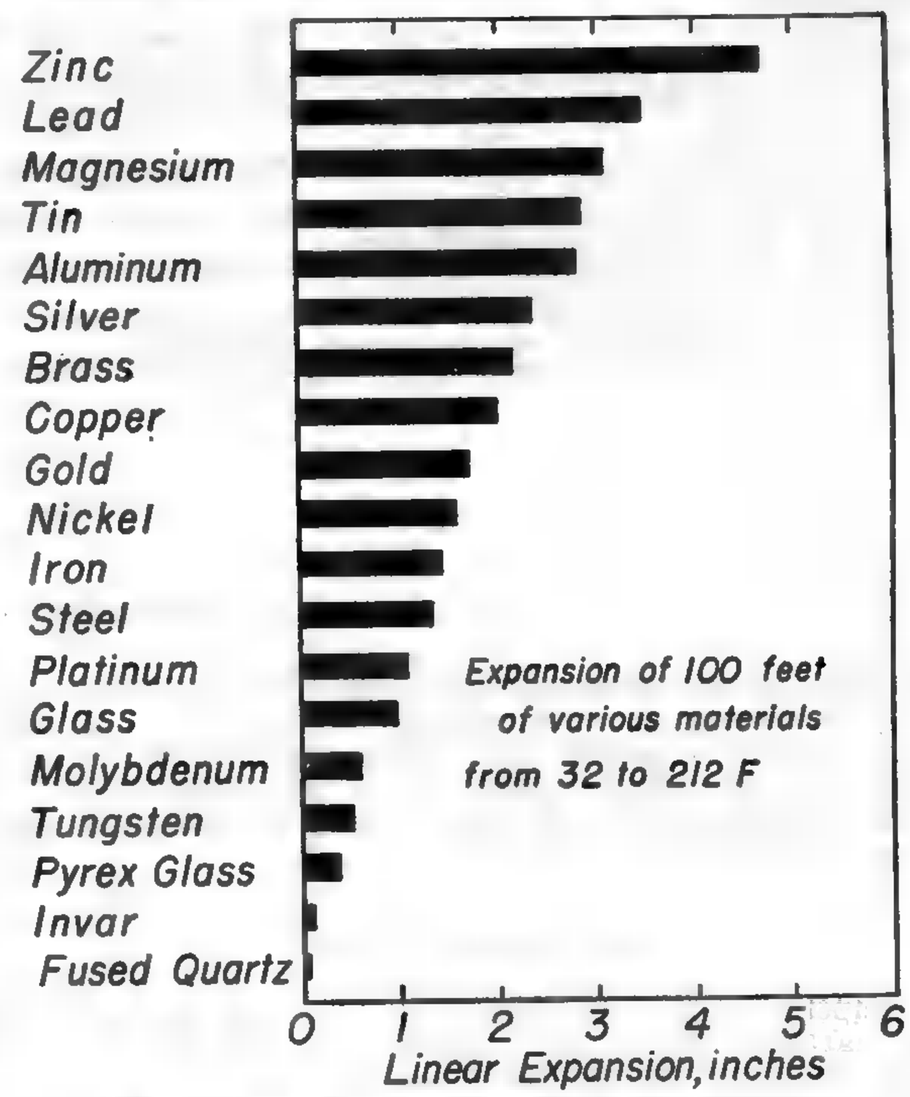

Fig. 9 Linear thermal expansion of 19 materials from 0 to 100 C (32 to 212 F)

isothermal holding below the eutectoid temperature, and of graphitization of cast iron; and for obtaining relationships between thermal expansion, chemical composition, thermal and mechanical treatments of materials, and the like. For example, the following equation shows the relationship between linear thermal expansion and chemical composition of cold rolled copper-zinc alloys:

$$a_{50} = (22.923 - 0.06833\,X + 0.0000695\,X^2)\,10^{-6} \qquad (11)$$

where a_{50} is the instantaneous coefficient of expansion at 50 C and X is the weight percentage of copper. This equation is based on measurements made on samples containing more than 62% Cu.

Grüneisen's law,[31] first deduced empirically in 1908, states that, for a metal, the ratio of the coefficient of linear expansion to its specific heat at constant pressure is constant at all temperatures. This law is a fairly good approximation but does not hold in all instances.

Data on Thermal Expansion. Data on thermal expansion of various materials may be found in the following

publications: International Critical Tables, Landolt-Börnstein Physikalisch-Chemische Tabellen, Smithsonian Physical Tables, Circular of the National Bureau of Standards C447, "Mechanical Properties of Metals and Alloys," and in this Handbook (see especially pages 25 and 309 to 312).

A chart indicating the linear thermal expansion of 19 materials on heating from 0 to 100 C (32 to 212 F) is shown in Fig. 9. Letter Circular LC679, "Thermal Expansion of Solids: Publications by Members of the Staff of the National Bureau of Standards", gives a list of publications that supply data on the thermal expansion of metals, alloys and other materials for various temperature ranges.

Pyrometry

By the Subcommittee on Pyrometry*

PYROMETRY deals with the measurement of all temperatures higher than about 950 F or 500 C. The principal methods of pyrometry in industrial use are the thermoelectric, resistance, radiation and optical methods. All these, except the optical method, can be extended easily to temperatures below 950 F.

Temperature Scales

Temperature is now universally expressed either on the International Temperature Scale[1] or on a scale derived from this scale and hence in conformity with it.

On the International Scale, temperatures are designated as degrees Centigrade (deg Cent, C, °C). Other scales in general use are the Fahrenheit (deg Fahr, F, °F) and Kelvin (deg K, K, °K). These scales are related in the following way:

$$n°\text{C} = (n + 273.16)\ °\text{K} = (1.8n + 32)\ °\text{F}$$

The basis of the International Scale is as follows:

(*a*) From 0 to 660 C the temperature t is deduced from the resistance R_t of a standard platinum resistance thermometer by means of the equation

$$R_t = R_0\ (1 + At + Bt^2)$$

The constants R_0, A, and B are determined by measuring R_t at the ice point, steam point, and sulfur boiling point, which are defined as 0 C, 100 C, and 444.60 C, respectively.

(*b*) Below 0 C the temperature is also deduced from the resistance of a standard platinum resistance thermometer, but the equation used is

$$R_t = R_0\ (1 + At + Bt^2 + C(t - 100)\,t^3).$$

The constants R_0, A, and B are determined as in (*a*) above, and the constant C is then calculated from the measured value of the resistance at the normal boiling point of oxygen (defined as minus 182.97 C).

(*c*) From 660 to 1063 C, the temperature is deduced from the electromotive force e of a standard thermocouple made of pure platinum versus the alloy 90 Pt–10 Rh, with one junction at 0 C and the other at t, using the equation

$$e = a + bt + ct^2$$

The constants a, b, and c are calculated from measured values of e at the freezing points of antimony (determined with a standard resistance thermometer for the specimen actually used, about 630.5 C), pure silver (defined as 960.5 C), and pure gold (defined as 1063.0 C).

(*d*) Above 1063 C the temperature t is deduced from the Wien radiation law for the intensity J of light of wave length λ at temperature t:

$$J_{\lambda t} = c_1\lambda^{-5}e^{-\frac{c_2}{\lambda(t+273)}}$$

in which c_1 and c_2 are experimentally determinable constants. For the International Scale, c_2 is defined as 1.432 centimeter-degrees and the melting point of gold is defined as 1063 C. In practice, only ratios r of intensity are measured, which eliminates constant c_1. The working equation is:

$$\log_e r = \log_e \frac{J_{\lambda t}}{J_{\lambda 10 6 3}} = \frac{1.432}{\lambda}\left(\frac{1}{1063 + 273} - \frac{1}{t + 273}\right)$$

* All the material on pyrometry in the 1939 edition, including separate articles on temperature measurements of aluminum and brass, which are now incorporated in the present article, has been revised for this edition by the subcommittee consisting of R. B. Sosman, *Chairman* (United States Steel Corporation), G. T. Evans (The Bristol Company), C. O. Fairchild (Consulting Engineer), W. E. Forsythe (General Electric Company), T. R. Harrison (Brown Instrument Company), J. C. Peters (Leeds & Northrup Company), Wm. F. Roeser (National Bureau of Standards), H. T. Wensel (General Staff, War Department).

Thermoelectric Pyrometry

Thermoelectric pyrometers may be used satisfactorily for measuring temperatures up to about 3000 F.

Principle of the Thermoelectric Pyrometer. If two dissimilar wires are joined together at both ends and one junction is heated, an electromotive force (emf) or voltage is generated in the circuit. This discovery led to the development of the thermoelectric pyrometer, a simple form of which is illustrated in Fig. 1. It consists of a millivoltmeter connected to two wires of different metals, the other ends of which are joined together and placed in a furnace. These two wires constitute the *thermocouple;* one wire is the positive element and the other is the negative element. The millivoltmeter is an instrument to measure the emf or voltage generated.

Most thermocouples consist of two elements in the form of wires, but a few are made in the form of a wire element within a tubular element.

In the thermoelectric circuit shown in Fig. 1 there are three junctions, as follows: the junction of the two wires inside the furnace, often called the "hot junction", now generally referred to as the "measuring junction"; and the two junctions between the elements of the thermocouple and the copper wires connecting them to the millivoltmeter, A and A_1. Although there are two such junctions in the arrangement show in Fig. 1, the pair is commonly treated as a unit and is often called the "cold

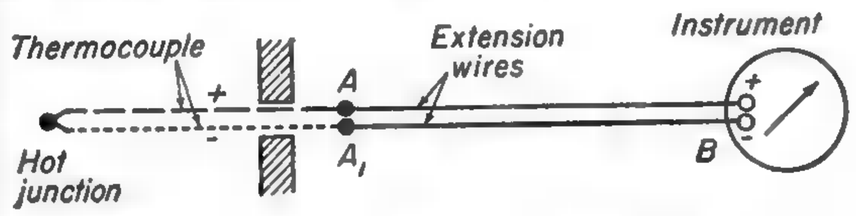

Fig. 1 Simple thermoelectric pyrometer circuit

junction", now more generally referred to as the "reference junction". Since this article concerns only high temperatures, it will be better to adhere to the terms "hot" and "cold", which can lead to no misunderstanding.

The total emf generated in a thermoelectric circuit, and measured as in Fig. 1, depends on the temperatures of all the junctions of dissimilar metals in the circuit. Consequently, if all the junctions but one (the hot junction) are maintained constant, then the resultant emf, as measured by the millivoltmeter, varies only with the temperature of the hot junction.

Thermocouple Materials. The number of metals and alloys suitable for commercial use in thermocouples is limited, because at high temperatures such materials must be resistant to oxidation, recrystallization, melting, and contamination; they must develop an emf high enough to be measured without the use of delicate apparatus; and finally, they must be reproducible and readily obtainable in uniform quality.

The following combinations of materials are in common commercial use for thermocouples: platinum versus the alloy 87% Pt plus 13% Rh; platinum versus the alloy 90% Pt plus 10% Rh; Chromel versus Alumel; iron versus constantan; and copper versus constantan. The last three pairs are commonly referred to as "base-metal couples".

The useful life of a thermocouple depends not only on the maximum temperature to which it will be subjected, but also on the atmospheric conditions.

Platinum versus platinum-rhodium thermocouples may be used at temperatures as high as 3000 F, but they are easily contaminated and must be protected suitably at all times. Continuous subjection to temperatures above 2800 F is not recommended.

There is no completely satisfactory material for long service in the presence of reducing gases. Stainless steel (iron-chromium-nickel alloy) is being used to a limited extent paired with Chromel, but the couple has not been standardized by the instrument companies.

The Chromel-Alumel thermocouple will generally be more satisfactory than the iron-constantan when used in oxidizing atmospheres at 1200 to 2200 F. Chromel-Alumel may be used intermittently up to a temperature of 2400 F. The emf of this couple is subject to change when the wires are exposed to a reducing atmosphere.

The iron-constantan thermocouple is not recommended for continuous use in air at temperatures above 1400 F. At this temperature, No. 8 gage wire of either element of the couple will last about 1000 hr in air. Ordinarily the iron-constantan couple will have a longer life and be more satisfactory than Chromel-Alumel in a reducing atmosphere up to 1800 F.

The copper-constantan thermocouple is satisfactory for continuous use as high as 700 F and for intermittent use as high as 1000 F.

The life of any base-metal thermocouple will be relatively short when exposed continuously to temperatures above 2200 F. Alternately reducing and oxidizing conditions are especially detrimental to any base-metal couple.

Construction of Couples. The hot junctions of all thermocouples should be welded; however, they may be silver soldered in base-metal thermocouples for use at comparatively low temperatures (below 1000 F). Borax is a satisfactory flux for silver soldering any base-metal thermocouples or for welding iron-constantan. Fluorspar is better for Chromel-Alumel thermocouples. Plenty of flux should be used. No flux is required for welding platinum thermocouples. Greater mechanical strength can be obtained at the hot junctions of base-metal thermocouples by twisting the two wires together for about two turns before making the weld.

When base-metal thermocouples have burned out or have become so contaminated that they give incorrect readings, they should be destroyed to prevent accidental reuse.

When platinum thermocouples have become contaminated and give incorrect readings, it is sometimes possible to prolong their usefulness by annealing them with an electric current in air and cleaning with fused borax. However, it has not been demonstrated conclusively that platinum-rhodium thermocouples, after contamination, can be greatly improved in homogeneity by prolonged heating in air, although it is logical to suppose that certain impurities can be driven off or, through oxidation, rendered less detrimental.

Cold Junctions. Every thermoelectric pyrometer is calibrated for a particular cold-junction temperature, generally 0 F, 32 F or 75 F. During subsequent use the cold junction need not necessarily be maintained at that particular temperature, as long as the actual temperature is known, because it is possible to compensate for the difference between the actual cold-junction temperature and that for which the instrument was calibrated.

It is generally more feasible to compensate instrumentally for different cold-junction temperatures than to maintain them at the particular temperature for which the pyrometer was calibrated. However, it is highly desirable to eliminate rapid variations in the cold-junction temperature.

Extension Wires. Unless the two wires forming the thermocouple are long, the cold junctions will be so close to the furnace that they will be subject to extensive temperature variations. Since it is desirable to place the measuring instrument some distance away from the furnace, and since it is often impracticable to make the thermocouple long enough to reach to the instrument, "extension wires" are used to connect the thermocouple to the instrument.

If in Fig. 1 the wires are of copper, the cold junction is close to the furnace at A. If, on the other hand, the extension wires consist of a pair made of the same materials as the thermocouple, or of some less expensive pair made of materials that have the same thermoelectric characteristics as the thermocouple pair, the cold junction will be located not at the furnace but at the binding posts of the instrument B, a position of more nearly constant temperature.

The extension wires of base-metal thermocouples are usually made of the same materials as the thermocouple wires. Sometimes copper-constantan extensions having suitable characteristics are used with Chromel-Alumel couples. With platinum – platinum-rhodium thermocouples, a copper extension wire is connected to the platinum-rhodium and a special copper-nickel extension wire to the platinum. Although the temperature-emf relation of

the copper–copper-nickel extension wires is virtually the same as that of platinum–platinum-rhodium thermocouples, the individual extension wires are not identical thermoelectrically with the thermocouple wires to which they are attached and, therefore, the two junctions where the extensions are attached to the thermocouple should be kept at the same temperature. This means that special care must be taken that this pair of junctions is not heated unsymmetrically. Such precautions are unnecessary for base-metal thermocouples where the thermocouple wire and the extension wire attached to it are of the same material. The temperature of the points of connection between the extension wires and the thermocouple should be limited to that at which the calibration of the extension pair departs from the couple calibration by the maximum amount permissible for the purpose at hand.

In general, extension wires intended for a thermocouple made of one pair of materials should not be used with a thermocouple made of a different pair of materials.

The positive and negative extension wires, identified by color of insulation or otherwise, must always be connected respectively to the positive and negative elements of the thermocouple. If there is doubt as to the identity of the positive and negative wires of extensions, the wires should be tested with a millivoltmeter or potentiometer. It is possible to have the extension wires wrongly connected to the thermocouple and also wrongly connected to the instrument, so that the instrument will read up-scale, yet read wrong. An up-scale reading is no guarantee of correctness in the setup. A safe way to connect the circuit is first to connect the extension wires alone to the instrument; then to twist the other end of the extensions together and heat the junction with a match. The instrument should read up-scale. Then the extensions should be connected with the thermocouple, the terminals should be allowed to cool, and the couple junction should be heated. The instrument must again read up-scale; if it reads down-scale, the extensions should be reversed at the couple, not at the instrument.

There are a few simple methods of using extension wires to remove the cold junction to a position of constant temperature, and of making one cold junction serve several thermocouples.

The arrangement shown in Fig. 1, with extension wires to remove the cold junction to the indicator, is the simplest, but the cold junction is still subject to variations in room temperature, which will introduce errors into the reading unless the indicator is equipped with an automatic cold-junction compensator.

Cold-Junction Compensation. If the temperature at the cold junction is not maintained constant, but is allowed to assume the temperature of the air, as in most pyrometer installations, correction or compensation must be made for this fluctuating temperature.

If the measuring instrument (*see* later paragraphs for description) has no manual or automatic device for compensating for the cold-junction temperature, the correction can be made with the aid of tables of emf versus temperature for the thermocouple that is being used. It is wrong simply to add an air-temperature correction to the reading of the instrument without regard to the temperature-emf curve.

When a millivoltmeter is used with no automatic cold-junction compensation but with a scale reading in degrees, variations in the temperature of the cold junction can be compensated for by making the zero or open-circuit position of the instrument pointer on the scale agree with the actual temperature of the cold junction. This can be done by means of the "zero adjustment" provided. This adjustment should be checked at frequent intervals because the cold-junction temperature may have changed, or the zero setting of the pointer may have been disturbed accidentally.

When a millivoltmeter is used that is equipped with an automatic cold-junction compensator, the zero position of the pointer should agree with a specified temperature on the scale or with the actual cold-junction temperature, depending on whether the compensator is operated electrically or mechanically, as when a bimetallic spring, "Breguet Spiral", is attached to the moving coil. For either type of compensator the manufacturer's instructions should be followed.

With a potentiometer, a cold-junction compensator, operated either manually or automatically, is generally provided. If this compensator is manually operated, the dial should be adjusted at frequent intervals to agree with the actual temperature of the cold junction.

The element of the compensator that is sensitive to temperature should be kept close to the cold junction of the thermocouple and the two should be shielded or wrapped so that the temperature of the one will always be the same as that of the other. The reader is referred to the manufacturers for detailed descriptions of the different types of compensators in common use.

Figure 2 illustrates the use of extension wires when a number of thermocouples are connected to a distant instrument equipped with an automatic cold-junction compensator. Instead of being extended from each thermocouple all the way to the instrument, the extension wires are extended only to a centrally located common zone box and a single auxiliary couple is extended from the common zone box to the element of the automatic cold-junction compensator that is sensitive to temperature. The cold junction for the system is at *B*.

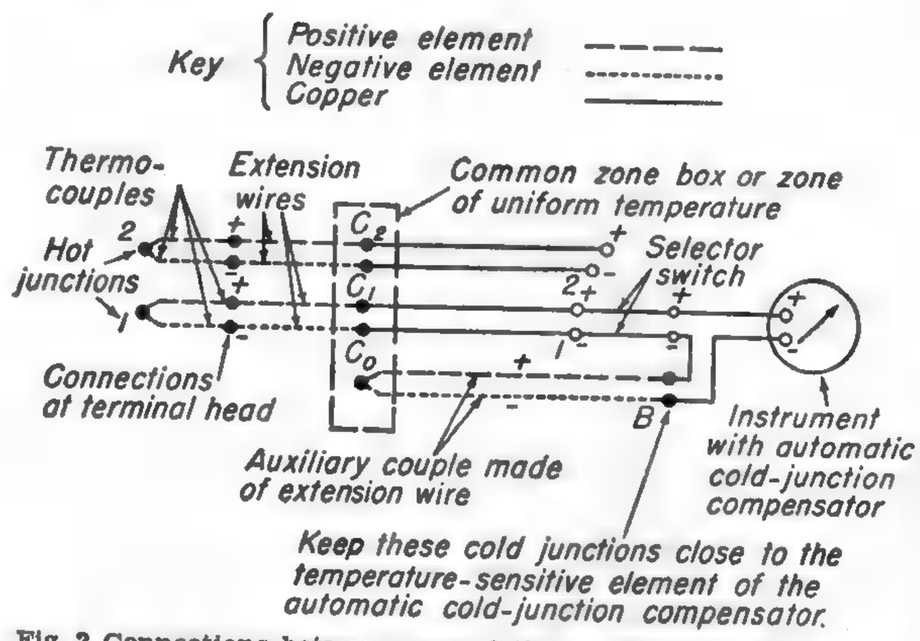

Fig. 2 Connections between several thermocouples and a distant instrument equipped with an automatic cold-junction compensator

This arrangement is solely for the purpose of reducing the length of the extension wires required and is advantageous only when it results in a reduction in the total cost of installation.

Relation of Emf and Temperature. Until recent years each manufacturer of thermoelectric pyrometers had his own source for thermocouple alloys and his own curve for the relation of emf to temperature. The platinum metal thermocouples were the first to be standardized, and the tables of emf versus temperature for both the 10% Rh and the 13% Rh couples have been determined accurately by the National Bureau of Standards. These tables are now accepted as standard by most if not all of the manufacturers of pyrometers in the United States.

Next came Chromel-Alumel. The composition and properties of these two trademarked nickel alloys can be kept under good technical control. Having found that the alloys can be reproduced to specifications, the Bureau of Standards has published a standard table that is now in general use by the manufacturers of pyrometers.

Constantan is no longer a trademarked name, but applies to a limited range of copper-nickel alloys containing a little manganese. Since the several alloys of this type differ somewhat in thermoelectric power, there are no "standard" tables for iron-constantan and copper-constantan couples. A range of thermoelectric characteristics is obtained by varying the composition suitably.

There is no difficulty in obtaining reproducible pure copper. At the National Bureau of Standards it has been found that constantan is regularly available which, when used with pure copper, conforms to L. H. Adams' table (1914, 1920, 1926).

Pure iron is difficult to make, and the wire actually used in thermocouples contains from 99.5% to 99.9% Fe,

with small amounts of various elements that influence the thermal emf. The National Bureau of Standards has published a table for a thermocouple consisting of the more nearly pure iron and the same constantan as that used with copper to reproduce the L. H. Adams table. Most manufacturers of pyrometers use iron having principally a higher manganese content in conjunction with constantan of a composition somewhat different from that required for the Adams table.

Table I contains the accepted data for platinum–platinum-rhodium and Chromel-Alumel thermocouples, together with the data published by the National Bureau of Standards for iron-constantan and copper-constantan couples, and the data for the iron-constantan couples supplied by most manufacturers of pyrometers. At the head of each column, in the name of the couple, the positive element is named first. Many other combinations have been used in thermoelectric pyrometry, but none has been accepted as generally as those listed in Table I.

Table I. Representative Tables of Emf versus Temperature for Principal Commercial Thermocouple Combinations

Emf is in millivolts. Cold junction, 32 F

(a) Bur Standards RP 530 (1933). (b) Bur Standards RP 767 (1935). (c) Bur Standards RP 1080 (1938). (d) Data applicable to much of the wire supplied by pyrometer manufacturers.

For accurate temperature readings (better than 1% of scale) reliance should not be placed on Table I, but the individual thermocouple and instrument should be calibrated. (*See* page 180.)

Protection Tubes. One of the reasons why certain materials have come into common use for thermocouples is that they are reasonably stable thermoelectrically when heated in a clean oxidizing atmosphere. The standards of performance generally accepted for the various combinations of thermocouple materials are based on the behavior of these combinations in air. Although it has not been shown that a reducing atmosphere, in itself, necessarily contaminates or alters the thermoelectric properties of all thermocouple materials, it is nevertheless generally observed that exposure of thermocouples to such atmospheres is accompanied by contamination or change in the chemical composition, which seriously alters the readings of thermoelectric emf. Consequently, in order to obtain the best performance of thermocouples, it appears necessary to maintain them in an atmosphere having essentially the same oxygen content as air. The selection of a proper tube for protecting the thermocouple from vapors, fumes or furnace gases is sometimes as important as the selection of the thermocouple materials.

Contamination results from such causes as the following:

1 Metals (solid, liquid or vapor) coming into contact with the thermocouple materials and altering their chemical composition.
2 Furnace gases and fumes coming into contact with the thermocouple materials. Sulfur and sulfur compounds are particularly deleterious.
3 Materials normally stable in an oxidizing atmosphere coming into contact with the thermocouple material in a reducing atmosphere. One common cause of contamination, which is serious in rare-metal thermocouples, is the reduction of silica (usually present in insulating and ceramic protection tubes) to silicon, which readily combines with the thermocouple materials.
4 Preferential oxidation and reduction of base-metal alloys, when these are exposed alternately to oxidizing and reducing atmospheres. This results in a gradual change in chemical composition, because all the elements that comprise an alloy cannot be expected to oxidize and reduce at the same rates under all conditions.

Many types of protection tubes are required in order to meet all needs. Often the conditions under which thermocouples are used are such that two tubes are necessary to provide the desired protection. For instance, a primary tube of porcelain or fused silica may be placed inside a secondary tube of metal, silicon carbide or fire clay. The primary tube of low volatility is intended to provide the imperviousness to gases at high temperatures, and the secondary tube provides the resistance to thermal and mechanical shocks and to corrosion.

However, in thus providing protection for the thermocouple, it is important to remember that a thermocouple can perform its function only when the conditions of heat transfer are such that the measuring junction will attain or at least approximate the temperature to be measured. When a tube of large cross section or more than one tube is used, particularly if the tubes have high thermal conductivity, it should be considered carefully whether the depth of immersion is sufficient to insure that the temperature of the thermocouple junction is reasonably close to the temperature to be measured. Short heavy tubes may cool the junction so much that indications will be comparatively worthless.

Platinum to platinum-rhodium thermocouples are particularly susceptible to contamination and should be protected by ceramic tubes that are impervious to gases and vapors at all operating temperatures. If furnace gases are not present, metal tubes usually provide sufficient protection for base-metal thermocouples. The oxide coatings on the thermocouple wires are fairly effective in protecting the wires from contamination by metallic vapors. Metal tubes that provide sufficient protection in an oxidizing atmosphere may be entirely unsatisfactory if large amounts of furnace gases are present.

Primary ceramic tubes that meet most requirements of stability and imperviousness to gases are made of the following materials: highly refractory porcelain, sometimes called "Sillimanite" or "Mullite", for temperatures up to 2800 F; vitreous silica (fused quartz) to 1900 F and Vycor glass, to 1800 F, both in an oxidizing atmosphere; Pyrex glass, to 1100 F.

The secondary or metal tube most suitable for a particular application depends to a large extent on the type of corrosion encountered. Nickel tubes are useful above 2100 F. Tubes of nonscaling alloys such as nickel-chromium and nickel-chromium-iron are suitable for many applications at temperatures up to 2000 F. Tubes of iron and steel are suitable for numerous applications up to 1500 F. Calorized wrought iron is impervious to certain gases and meets certain needs up to 1800 F. Fire clay, silicon carbide and graphite meet certain requirements of secondary tubes at temperatures above the useful limit of metal tubes.

Numerous other types of secondary tubes have been developed for specific purposes. Information regarding the best type of tube for any particular purpose is usually available from the pyrometer manufacturer.

Insulators. Except at the hot junction where the two wires should be welded together, the two elements of a thermocouple must be electrically insulated from each other. Fire clay or porcelain beads, and even asbestos for low temperatures, are satisfactory for base-metal thermo-

couples. However, for platinum thermocouples, *clean* porcelain beads or tubing should be used.

The insulation on the thermocouples should be kept intact, because if the wires come in contact with each other, another junction may be formed, causing the indicator to register some temperature other than that of the intended hot junction of the thermocouple.

Terminal Heads. Terminal heads for thermocouples are not absolutely necessary because the extension wires can be soldered, brazed or welded directly to the elements of the thermocouple, but they serve to simplify installation and replacement of thermocouples as well as to keep contaminating dirt and dust out of the protection tube and to provide a good connection between thermocouple and extension wire. Therefore terminal heads are recommended.

Measuring Instruments

The electrical instruments used with thermocouples as well as with radiation pyrometers (*see* page 181) may be classified for present purposes as indicators, recorders, controllers, indicating controllers and recording controllers. They are all characterized by the high sensitivity required in electrical pyrometry, in which the voltages to be measured or detected range from a few microvolts (millionths of a volt) to about 60 mv (60 thousandths of a volt), and hence differ essentially from electrical power instruments. Accordingly, they should be treated with some care, kept reasonably clean and cool, and not subjected to severe vibration.

Indicators. These may be defined as instruments for showing the magnitude of a measurable variable, such as temperature or voltage, by the coincidence of a pointer or reference line with a point on a calibrated scale. The two main classes are millivoltmeters and potentiometers, either of which can be portable or designed primarily for mounting on a wall or panel. Portable instruments are particularly useful in experimental tests or investigations, and for the checking of permanently mounted instruments. Indicating potentiometers (particularly those for permanent mounting) may be balanced either manually or automatically.

Millivoltmeter Indicators. The common form of millivoltmeter consists of a moving coil mounted with pivots to turn in jewel bearings between the pole pieces of a permanent magnet, and constrained by two spiral springs to turn through an angle proportional to the current through the coil. A long pointer is attached to the coil and moves over a scale usually graduated in degrees. Many such instruments are provided to advantage with automatic cold-junction compensation; ordinarily this is simply a bimetallic spring to move the pointer in correspondence with the temperature of the cold junctions, which are preferably housed in the case of the instrument so that junctions and bimetallic device are at the same temperature. The indicator should not be subjected to rapid changes in temperature while in use.

Since the deflection of this type of indicator depends on the *current* through the coil, and the temperature of a thermocouple is measured by its *emf*, it follows that any change in the *resistance* of the circuit of the thermocouple, extension wires and indicator will be accompanied by a corresponding error. For this reason millivoltmeter indicators are preferably provided with a series resistor of manganin, 10 to 500 ohms or more, to reduce the percentage change in resistance resulting from a change in temperature of the couple or extension wires, or in contacts of connections. The calibration is good for only one value of the external resistance (extensions plus thermocouple), and it is considered good practice for the maker to mark the instrument with both the value of the internal resistance, and that of the external resistance for which the calibration is correct.

Potentiometer Indicators. A simplified potentiometer circuit is shown in Fig. 3. With this circuit, the emf of a thermocouple can be balanced against the IR drop in the slide-wire resistor by moving the contact along the wire until the galvanometer connected through the *TC* switch shows no current flowing through it, by standing at no deflection from its open-circuit position. Before a measurement is made, the current through the slide-wire is adjusted to a standard value corresponding with the scale of the instrument (millivolts or degrees), by connecting the galvanometer and standard cell in series across the resistor marked *"SC coil"* and turning the rheostat until the galvanometer stands at "zero", that is, no deflection. The IR drop across this coil now equals the voltage of the standard cell (approximately 1.019 v), and the current I has a selected value—for example, 2 ma—when the resistance of the standard coil is 509.5 ohms. The resistance of the slide-wire for the 60-mv scale is then 30 ohms.

The galvanometer, or other form of detector used with a potentiometer, serves only to detect unbalances of emf. It need not be calibrated but must be sufficiently sensitive and have good zero stability. The potentiometer is relatively free from errors caused by changes in resistance of the thermocouple circuit. In explanation of this, assume an internal potentiometer resistance of 40 ohms, plus 10 ohms external resistance, making a total of 50 ohms, and assume that an unbalance of 1 °F can be detected. If the external resistance is now increased from 10 to 60 ohms, doubling the total, the minimum detectable change will merely be increased from 1 to 2 °F.

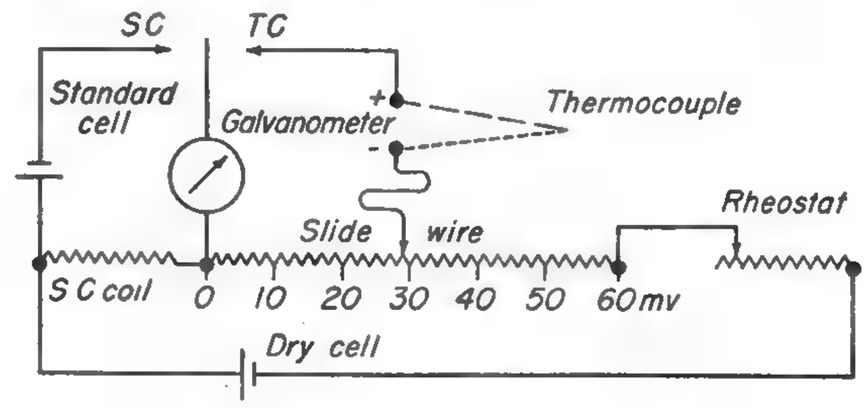

Fig. 3 Diagram of potentiometer circuit

The circuit shown in Fig. 3 is in many instruments modified to take care of the emf of the cold junctions, either manually by the setting of an auxiliary dial, or automatically by the change in resistance with temperature of a cold-junction compensating resistor suitably arranged in ■ branch circuit. If there is no compensation for the cold-junction temperature, the proper correction must be applied to the reading after measuring the cold-junction temperature with a thermometer or by other means. If the compensation is by manual adjustment of a dial, then again the cold-junction temperature must be measured and the dial must be set accordingly. If the compensation is automatic, it applies to one particular type of couple only.

Each circuit has special advantages and limitations. Automatic compensation and a scale graduated in *temperature* are usually preferable for a permanent installation. For a portable indicator that is to be used for general checking, including other potentiometers, it may be preferable to use an instrument without automatic compensation with the scale calibrated in *millivolts*. This type of instrument may have provision for manual cold-junction compensation by setting of an auxiliary dial, calibrated in millivolts.

The accuracy of a potentiometer, aside from that attained by the maker in the original calibration, depends primarily on the constancy of the voltage of the standard cell. Although this deteriorates at the rate of only one or two hundredths of a per cent per year under average circumstances, it should be checked occasionally. This checking can be done directly by measuring the cell voltage with a potentiometer suitable for the value of approximately 1.019 v, or indirectly by comparing results obtained before and after substituting a standard cell known to be of correct voltage. A voltmeter must not be connected to a standard cell, and appreciable current should not be drawn from it by any other means.

Potentiometers for permanent installation are frequently of the self-balancing type in which the emf of the thermocouple is automatically balanced against that of the potentiometer, particularly when they serve also as automatic controllers. With some instruments, standardization of the potentiometer by comparison with a standard cell is also automatic.

Self-balancing means may be broadly classified as (1) mechanical, or (2) electronic. In the mechanical type, deflection of a galvanometer is mechanically detected, and power for balancing is obtained through mechanical means of amplification.

The electronic type may or may not involve a galvanometer, but in any case, it uses electronic devices in the scheme for rebalancing. In one arrangement a light beam from a galvanometer mirror is caused to fall upon a photocell to an extent that depends on the degree of emf unbalance. The photocell current is electronically amplified to operate relays that start and stop a balancing motor. In another scheme there is no galvanometer; the unbalanced voltage is converted to alternating current, which is amplified and used directly to operate a motor that moves the slide-wire in the direction required to restore the balance.

An automatically balanced potentiometer may be of the multiple-point type with an automatically operated switch for the purpose of connecting the same instrument to two or more thermocouples in turn. Multipoint instruments will be further discussed in the next section, on Recorders.

Recorders. Recorders generally retain the indicating feature, and have the added feature of a moving chart on which the temperature is recorded by suitable means, either intermittently or continuously.

Millivoltmeter recorders are available in which a record is produced by a mechanism that depresses the pointer at regular intervals, causing an intervening inked tape to make contact with a strip chart at the pointer position. With multipoint instruments, arranged for the connection in turn of several thermocouples, different colors of ink are often used for purposes of identification.

Recording potentiometers are made with either round or strip charts. Because there is ample power to overcome friction between a pen and the chart, continuous ink records are usual with single-point instruments. With multipoint instruments the printwheel type of marker is commonly supplied; the connected couple is usually identified by a number and sometimes also by color of ink.

Multipoint recorders are practical when the interval between successive records of a given temperature is not too long. The advent of electronic potentiometer recorders with their higher balancing speeds has made it practical to switch from one thermocouple to another every several seconds, whereas previous recorders required as much as one minute per point. Several manufacturers have offered recorders in which switching takes place upon balance on a given point, not on a uniform time-interval basis.

An important application of high-speed potentiometers is in connection with the measurement of the temperatures of moving objects such as rails and billets, with the radiation pyrometer. In this application both the radiation pyrometer and the recorder must respond rapidly.

Instruments for Automatic Control.* Both millivoltmeters and potentiometers, in the form of either indicators or recorders, may be obtained with added signaling and automatic control features. With millivoltmeters, suitable actuating contacts may be made through the action of a depressor bar that presses the pointer against contact-operating members; or the required action may be obtained without mechanical contact with the pointer, through change of inductance or capacitance as the pointer approaches the operating position.

With potentiometers of the self-balancing type, control actions may be initiated through the making and breaking of suitably arranged contacts, movement of contacts over slide-wires, or by a combination of the two methods. If a control valve is to be pneumatically operated, control actions are usually initiated by movement in the instrument of a small "pilot valve", which is frequently of the flapper-and-nozzle type.

If automatic control only is desired, a simple potentiometer instrument without the self-balancing feature may be used. A dial is set for the desired control point. The balance indicator (usually a galvanometer) then shows no unbalance when the temperature is correct, and appropriate control actions are initiated in accordance with deviations.

Program controllers are available to carry automatically the temperature of a particular operation through a predetermined temperature-time cycle. Additional features are frequently applied in adapting instruments to particular control problems.

Installation and Use of Thermoelectric Pyrometers

Installation. *Instruments.* The selection of a place for the instruments is very important. A few precautions observed at the time of installation will reduce maintenance to a minimum and prolong the life of the instruments. They should be placed where they will be (1) free from excessively high or low temperatures, (2) free from excessive vibration or shock, (3) free from mechanical damage, (4) free from dirt or dust.

Thermocouples. Place the hot junction of the thermocouple as close to the work as practicable. The opening around the well or tube protecting the thermocouple should be sealed. It is desirable but not essential that provision be made to insert a second thermocouple alongside the furnace thermocouple for purposes of checking and possible calibrating; consequently, a suitable opening should be provided and kept sealed when not in use.

Extension Wires. A thermoelectric circuit operates in the range of microvolts to millivolts, voltages far too low to break down the contact resistance of oxidized, corroded or loose connections. Hence all connections in the thermocouple circuit, except where electrical connectors are provided, should be soldered (using none but a nonacid soldering flux). It is vitally important to respect polarity markings and color code of extension wires, since this is a d-c circuit. Also the circuit must be well insulated from high-voltage power circuits, and protected against overheating and wetting.

It is essential to disconnect all instruments before checking out the circuit. Checking may be done by using a magneto, dry cell and bell, or the like. Pyrometer measuring circuits are not rated electrically to stand power-line voltages.

If a thermocouple must be grounded, all other sections of the circuit *must* be well insulated, including the battery for the potentiometer.

Thermoelectric Pyrometer Troubles. Pyrometer troubles are either external or within the measuring instrument. The details of design of instruments in use today are so varied that it would be futile to attempt a discussion of troubles possible in the instruments themselves. Therefore it is recommended that the manufacturer's manual be consulted in regard to maintenance of the instrument. Some manufacturers conduct brief courses of instruction in maintenance and repair for users of their instruments.

Circuit Troubles. If the pyrometer reading is erratic or obviously wrong, the first suspicion is that one wire of the thermocouple may be completely oxidized or broken. This should be, but is not always, apparent during examination. Visual examination of the extension wires and connections to binding posts and such, may disclose a poor connection or open circuit. If, by visual inspection, the trouble is not apparent, it is recommended that a complete check be made of the external electrical circuit with the aid of a magneto or dry cell and bell, but before such a check begins, it is imperative to disconnect all instruments. Short circuits occur also, and can be detected in the same way. The difficulty is sometimes caused by a faulty selector switch. Grounding of both the thermocouple and the instrument can cause large errors, since there are often large differences of ground potential at different points in an industrial plant using electrical power. If both must be grounded (as is possible with electronic recorders) a ground wire should be run so that only a single connection to "earth" is used.

Incorrect and erratic readings on instruments may have other causes; for example, a deteriorated thermocouple, wrong thermocouple, increased resistance of extension wire or a cross circuit through a high resistance. For a complete explanation of these troubles and their correction, the best source is the maintenance manual prepared by the manufacturer of the instrument.

* *See also* section on **Principles of Automatic Control, page 185.**

Recalibration of a Thermoelectric Pyrometer. *Comparison Method.* A very satisfactory and practical method of checking the calibration of a thermoelectric pyrometer is by comparison with another thermoelectric pyrometer of known accuracy, such as a portable indicating potentiometer of tested quality, in conjunction with a calibrated thermocouple. It is well to have two calibrated thermocouples, one to be kept as a primary standard and used only for rechecking the calibration of the second, which is used for checking the calibration of the furnace pyrometer. It should be remembered that the complete pyrometer includes a thermocouple and an indicating or recording instrument, and that there are chances of error in both.

During the calibration, the hot junction of the standard thermocouple should be kept in intimate contact with the hot junction of the furnace thermocouple to insure that they will be at the same temperature. It is often advisable to bind base-metal thermocouples together with wire of a material that will not contaminate the couples and will resist the furnace temperature. Both thermocouples should be inserted in the same protection well for satisfactory results. Platinum–platinum-rhodium thermocouples should never be inserted in a furnace unless they have a protection tube—not even during a calibration.

It is important to maintain the furnace temperature nearly constant at the various check points before taking any reading, and always to take at least three readings at each point. Both thermocouples should be at the same depth of immersion in the furnace.

If the pyrometer being checked or calibrated is found to be in error, it may be for one of the reasons mentioned under Pyrometer Troubles. All the possibilities should be investigated before concluding that the calibration has changed.

Potentiometric or Pyrometer Test-Set. Several manufacturers of instruments market a pyrometer test-set, which is a special potentiometer having extra units and electrical circuits capable of making a complete check or calibration of a pyrometer, or of the installation in general. This test-set is a valuable instrument in locating troubles in pyrometer installations and is indispensable if a plan of routine service is in effect for maintaining pyrometers and their accessories. Whatever standard is used in the recalibrating or checking of pyrometers, the accuracy of the standard must be assured in advance. This applies to the portable indicating potentiometer, the pyrometer test-set, or the portable indicating pyrometer, which is used quite frequently for checking.

It is always a good practice to immerse the thermocouple hot junction in crushed ice when everything is ready for operation. If the instrument does not read 0 C or 32 F, it is evident that something is wrong.

Calibration by the Freezing-Point Method. This is the method used by the National Bureau of Standards and a few well-equipped laboratories for making primary calibrations of thermocouples. The proper procedure requires considerable expertness and careful attention to details and, except in a few limited instances, is not recommended for the majority of pyrometer users.[2]

Measurement of Temperature with Thermocouples. A thermoelectric pyrometer measures only the temperature of the hot junction of its thermocouple. Therefore it is essential to know what difference of temperature exists between the junction and the object or material of which the temperature is to be measured. In some instances, as with a gas that is cooler or hotter than its enclosing walls, the difference can be much larger than is suspected.

When a solid metal with a dull or rough surface is concerned, the temperature of the work material in a furnace can sometimes be estimated by comparing the brightness of the material with that of the hot end of the thermocouple, which must be as close to the work as practicable, and in such a position that both can be observed through a small hole in the furnace wall or door. It is necessary to ascertain that neither work metal nor thermocouple is licked by any flame, and that reflected light from a hot surface licked by flames or from a combustion chamber does not cause either to appear hotter than it really is. When the work metal and the hot junction are of equal brightness, as nearly as can be determined by eye, the temperatures of the two will be the same for all practical purposes, at least within plus or minus 15 to 25 F.

The heads or terminal ends of rare-metal and Chromel-Alumel couples must be kept relatively cool, because the extension wires are a thermoelectric fit for these couples only over a limited range of temperature.

Thermocouples for Measuring the Temperature of Molten Metals. In measuring the temperature of molten aluminum-base and copper-base alloys in pouring ladles, it is often necessary that the readings be obtained easily and quickly. This precludes the use of heavy protection tubes. In many installations a bare Chromel-Alumel thermocouple, about No. ■ gage, has been found satisfactory. The junction may be welded or left open. If the junction is left open, the thermoelectric circuit is completed through the molten metal. A slightly steadier reading is obtained if the junction is welded, but the cost of maintenance is higher. The effect of slags and of the cooler metal at the surface is minimized by immersing the tips of the thermocouple wires 4 to 6 in. in the metal and, after several seconds, quickly raising the wires until only the tips are in the metal. The maximum reading obtained in this process is taken as the temperature of the metal.[3]

With aluminum-base alloys, the surface effects can be virtually eliminated by insulating both of the thermocouple wires with a continuous felted layer of asbestos. The asbestos becomes brittle and rubs off but, with reasonable care, the rate of loss of insulation approximately equals the rate of solution of the wires.[4]

With copper-base alloys, the surface effects can be eliminated completely by enclosing the thermocouple wires and junction in a metallic protecting tip. The manufacturers of different types of tips state the advantages obtained with their particular design but, in general, the most desirable is the one that gives the quickest reading. Protective tips made of ferrous alloys containing a high percentage of chromium usually have a longer life in brasses than tips made of ferrous or nonferrous alloys containing nickel.[5]

For research work and special melts, the temperature of molten cast iron can be measured with a platinum–platinum-rhodium thermocouple in a porcelain and graphite protection tube.[6] The temperature of molten steel can be measured satisfactorily with a platinum–platinum-rhodium thermocouple encased in a protection tube made of vitreous silica (fused quartz).[7] Special types of thermocouple, such as the graphite versus silicon carbide couple,[8] have also been used in liquid metals.

Resistance Thermometry

The operation of a resistance thermometer depends on the variation with temperature of the resistance of an electrical conductor. A high temperature coefficient of resistivity might, accordingly, appear of primary importance. Certain oxides possess this property, having a resistance at room temperature from a hundred thousand to a million times that at 800 F. However, the resistance of a suitably mounted material can be determined easily and accurately, so a high temperature coefficient is rarely, if ever, the deciding factor in the choice of the material. The fundamentally important property is reproducibility and constancy of resistance. A further desirable feature is a simple and convenient relation between temperature and resistance.

For industrial purposes, resistance thermometers are made usually of copper, platinum or nickel; nickel is the most satisfactory for temperatures below 600 F. Although the resistance thermometer is of great importance in the laboratory, for work of extremely high precision, its employment for industrial processes requires many precautions easily overlooked. Bad contacts in the line, a broken strand in a flexible cable, or such, may cause large errors. The thermometer is fragile and the calibration of it may be altered by severe handling, by the slightest contamination, or by volatilization of the wire that forms the coil.

In most industrial processes carried out above 600 F, the thermoelectric pyrometer is to be preferred. When very small changes or intervals of temperature must be meas-

ured with high precision, the resistance thermometer may be employed effectively. In certain processes where an integrated or average temperature is required over the entire bulb, the resistance thermometer is highly desirable. A homogeneous thermocouple indicates the temperature of its hot junction, while a resistance thermometer indicates the average temperature of the entire coil or bulb, which may be constructed to be as long as desired. There are no cold-junction corrections for the resistance thermometer, a decided advantage over the thermocouple, but one that is offset by the disadvantages mentioned. A more complete treatise on resistance thermometry is given elsewhere.[9]

Temperature and Radiation*

Some other type of pyrometer must be used when the temperature becomes too high, or the object is too inaccessible, to permit use of a thermocouple. Since all bodies emit radiant energy with intensity dependent on the temperature, the temperature can be determined by measuring this radiant energy. The total radiant energy from any temperature-excited radiator increases about four times as fast as the temperature, while the spectral radiant energy in the red part of the spectrum increases about 18 times as fast as the temperature at 1832 F, and about 10 times as fast at 3632 F. Thus, the percentage error in measuring the temperature is much smaller than in measuring the energy.

Principles. *The Blackbody and the Blackbody Laws.* The standard radiator is the "blackbody", which is defined as a body that absorbs all the radiant energy that falls upon it. From this simple definition and some very plausible assumptions, it can be shown that the radiancy (total radiant flux density) increases with the fourth power of the absolute temperature, that is,

$$W = \sigma T^4$$

which is known as the Stefan-Boltzmann Law. σ is one of the fundamental physical constants. It can also be shown that the spectral radiancy for any interval of wave length is given quite accurately, for not too high a temperature and not too long a wave length, by the Wien equation on page 174. This equation holds with all the accuracy needed for industrial optical and radiation pyrometry. Thus the temperature of the blackbody can be obtained from measured values of either the total radiancy or the spectral radiancy of it for a definite interval of wave length.

The Practical Blackbody. The name "blackbody" was chosen for the standard radiator because at room temperature it is actually black. No material exists in nature that is a blackbody for all wave lengths, but some forms of carbon and some finely divided metals may be very nearly black. A cavity with opaque walls of uniform temperature contains blackbody radiation, corresponding to the temperature of the walls. If an opening, small compared with the area of the walls, is made into the cavity, the radiation escaping from the opening will be blackbody radiation of this temperature. Thus, to construct a working blackbody, it is necessary only to make a small opening into a cavity having walls that can be heated to a uniform temperature. From the definition, it can be shown that the blackbody will emit more energy, both total and spectral, than any other temperature-excited radiator at the same temperature.

Emissivity. The ratio of the energy emitted by any radiator not a blackbody to that from the blackbody at the same temperature is called the "emissivity" of the material studied. Emissivity depends both on the composition of the material and on the condition of its surface; the emissivity is smaller for well-polished than for dull metallic surfaces. The total emissivity of different materials covers a wide range; for example, that of polished silver is about 0.02 to 0.05, while carbon may have an emissivity of 0.95. Furthermore, the spectral emissivity of a given material may vary over a wide range for different intervals of wave length, and it may also change with the temperature.

* Revised with the collaboration of E. Q. Adams

Types of Pyrometer. Three types of pyrometer are used industrially to determine the temperature of blackbodies from measurement of their "steradiancy" (areal radiant intensity of the source): (1) the *total radiation pyrometer,* which determines the temperature from a measurement of the intensity of the radiant energy at a distant point, utilizing nearly all the wave lengths radiated by the source; (2) the *partial radiation pyrometer,* which measures this same intensity of radiant energy, but only in a selected part of the spectrum, by some such device as a photoelectric cell or a thermoelectric radiation pyrometer having a glass lens (*see* page 183); (3) the *optical pyrometer,* which determines temperature by measuring the brightness of the source in a selected part of the spectrum, generally the red, utilizing the human eye as a part of the instrument and consequently reading temperatures only above approximately 1100 F.

Radiation Pyrometry*

Principle of the Instrument. The basis of radiation pyrometry is the Stefan-Boltzmann Law ($W = \sigma T^4$). Most radiation pyrometers are more strongly influenced by certain bands of wave length than by others; hence their response never exactly follows this law.

The usual radiation pyrometer includes (1) a blackened receiver that absorbs and is heated by incident radiation from a source of which the temperature is to be measured; (2) a housing that has a fixed aperture or apertures to limit the cone throughout which the receiver can be irradiated by the source; (3) in most instances, a lens or a mirror by means of which this cone is completely filled with rays emanating from a relatively small area of the source. To measure the rise in temperature of the receiver, use is made of a thermocouple or thermopile, a bolometer or some other device sensitive to temperature. The thermopile, which is most widely used for the purpose, may have its hot junctions attached to a receiver made of a separate thin metal disk, or the hot junctions may be made flat and suitably blackened to serve directly as the receiver.

When the pyrometer is sighted on a blackbody at elevated temperature T_1, the receiver will be heated quickly to a temperature T_2, such that the radiant energy absorbed in unit time by the receiver, both from the blackbody and from the surrounding housing at temperature T_3, equals the energy radiated by the receiver plus that conducted away from it through the wires of the thermopile and, unless in vacuo, through the air.

In the measurement of high temperatures, the temperature attained by the receiver is much lower than that of the source, and the relation between these temperatures is then given by the equation

$$T_2 - T_3 = \frac{X_1 T_1^4}{A}.$$

The emf developed by the thermopile is more or less directly proportional to the rise in temperature of the hot junction above the pyrometer housing temperature T_3, that is, to $T_2 - T_3$ as given in the above equation. If the housing temperature T_3 rises, T_2 must also rise; hence no "cold-junction compensation" in the usual sense is required for the thermopile. However, the term A increases when the housing temperature increases, so when T_3 rises, as by ambient temperature change, T_2 rises by a smaller amount. This causes a small decrease in the emf developed in response to a given source temperature, T_1. Therefore, where the pyrometer is to be used under conditions of considerably varying ambient temperature, it is advisable either to take steps to minimize the variations in the temperature of the pyrometer housing, or to provide the pyrometer with automatic ambient-temperature compensation of some kind.

The term X_1 in the above equation represents the fraction to which the radiant energy received from the source at temperature T_1 is reduced, as a result of reflection and

* The term "radiation pyrometer" is commonly used in referring to the total radiation pyrometer and to other heat-absorbing radiation instruments having windows and lenses that absorb enough of the energy in certain parts of the spectrum to render them actually partial radiation pyrometers.

absorption by the lens or protecting window (and absorption by the mirror when one is used), as well as by reflection from the receiver itself. For a pyrometer equally sensitive to radiant energy of all wave lengths, X_1 would be a constant and the energy absorbed by the receiver would vary as the fourth power of the temperature of the source sighted upon. Such a pyrometer would be a true *total* radiation pyrometer.

Because of their resistance to heat shock, fused silica and Pyrex glass are used to a considerable extent as lenses for radiation pyrometers. These materials are relatively opaque to wave lengths longer than approximately 3.8μ and 2.6μ respectively. In consequence, when lenses of these materials are used, the term X_1 increases rather rapidly (and at different rates for the two materials) as T_1 increases. Thus, with increase in T_1, the product $X_1T_1^4$ increases at a rate higher than that of the fourth power of T_1, causing a correspondingly higher rate of increase in pyrometer emf. On the other hand, most mirror materials exhibit greater reflectivity at long than at short wave lengths; consequently, unless reflection and absorption by a window affect it otherwise, X_1 for a mirror pyrometer decreases as T_1 increases, so when T_1 changes, $X_1T_1^4$ varies at a rate lower than that of T_1^4.

Emissivity Corrections. When sighted on an object in the open at absolute temperature T_a and having an emissivity ϵ that is less than unity, the pyrometer will read the same as if sighted on a blackbody at temperature T_1 where

$$\epsilon X_a T_a^4 = X_1 T_1^4$$

Here X_a applies for a blackbody temperature T_a in the same way that X_1 applies for T_1, and emissivity ϵ applies for the limited range of wave lengths that is absorbed by the receiver. By means of this relation, the true temperature T_a can be deduced, if the values of the other terms are known.

In certain instances, e may differ somewhat from total emissivity e_t. However, the values given for total emissivity that are available from various tables,[10,11,12,13] may be used with reasonable accuracy for a radiation pyrometer equipped with either a fused silica or a Pyrex lens, as well as for a true total radiation pyrometer.

The ratio of X_a to X_1 in the above expression depends on the material of the lens; therefore the correction to be added will differ for pyrometers having lenses of different types. In a recent article[11] tables and curves are given for the determination of emissivity corrections for radiation pyrometers that have fused silica and Pyrex glass lenses. Corrections for total radiation pyrometers, for which $X_a = X_1 =$ constant, are published elsewhere.[10]

Table II illustrates the magnitude of the emissivity corrections that may be required with a radiation pyrometer sighted on different substances in the open. These values, condensed from the previous issue of this Handbook, apply for the *total* radiation pyrometer. Smaller corrections are required with radiation pyrometers that have fused silica or Pyrex glass lenses.

Table II. Emissivity Corrections for a Total Radiation Pyrometer

(To be added to observed temperatures)

Observed Temperature, deg Fahr	Corrections in degrees Fahrenheit: Iron Oxide	Nickel Oxide	Copper Oxide	Molten Iron	Molten Copper	Platinum
1000	60	210	200	...	890	970
1400	75	170	250	695	1130	1100
1800	90	135	300	835	....	1235
2200	105	100	...	...	....	....

When the object sighted upon is surrounded by walls at the same temperature as itself, energy radiated by the walls is reflected by the object, thus augmenting the energy emitted by the object, so that the total equals blackbody radiation and no correction is needed. When the walls are at a higher or lower temperature than the object, special treatment is required. Some examples are discussed in an article[11] referred to above.

In many industrial applications where uniformity and reproducibility of conditions are the principal objectives in view, it is often unnecessary to determine actual temperatures; hence corrections for emissivity are not required.

Checking Radiation Pyrometers. It may be desirable to check a radiation pyrometer, either to ascertain the physical condition of it or to determine the accuracy of the readings as installed, taking into account emissivity and other factors.

For ascertaining the physical condition of a radiation pyrometer, comparative readings are taken between the pyrometer under test and a suitably located thermocouple, an optical pyrometer, or another (standard) radiation pyrometer. The radiation pyrometer under test should be sighted into a uniformly heated enclosure through an adequate opening. If the pyrometer is sighted into a closed ceramic tube, the closed end should be heated uniformly over a length four or five times the internal diameter.

To check the effect of emissivity and the like, on the apparent temperature of an object as read by a radiation pyrometer, it is desirable to compare the readings of the radiation pyrometer with the readings of a thermocouple in good thermal contact with the object in question, or with readings of an optical pyrometer sighted into a crack or crevice in the object. If no such crack or crevice is in view, and the object is surrounded by walls no hotter than itself, the readings of an optical pyrometer will usually be more nearly correct than those of the radiation pyrometer, and the use of an inexact value of emissivity in deducing the true temperature will lead to a smaller error with the optical pyrometer than with the radiation pyrometer. The full correction for emissivity should never be applied unless the walls are much colder than the object or unless the object is in the open; no correction is required when walls and object are at the same temperature. If the walls are hotter than the object, the reading taken on the surface by the optical pyrometer may be in greater error, because of low emissivity (high reflectivity) of the object, than the readings of the radiation pyrometer.

Relative Dimensions in the Pyrometer System. Radiation pyrometers are arranged for the receiver to be irradiated through a cone of fixed dimensions limited by a suitable aperture. The area irradiated is either the total area of the receiver, or it is fixed by a second aperture, sometimes a small one, immediately in front of the receiver. Frequently extra diaphragms are employed to prevent stray radiation from reaching the receiver by internal reflection.

The calibration is substantially independent of the size of the source of radiant flux or its distance from the pyrometer (in the absence of absorbing mediums in the path of the rays), provided the area of the source is large enough that its radiation fills the above-mentioned cone.

When no condensing lens or mirror is used, the area of the source must be sufficient to fill the entire cone. In this instance, each point on the receiver will receive radiant energy from the entire area of the source lying within the cone. The use of a condensing lens or mirror reduces the area of the source required to fill the cone, and each point on the receiver will be irradiated by energy emanating from a smaller area of the source. If the lens or mirror is located so that the source and receiver are at conjugate focuses, each point on the receiver will receive all its irradiation from a corresponding point on the source and an image of the source will be formed on the receiver. This is the condition requiring the minimum area for the source. However, for purposes of temperature measurement, it is not necessary for an image of the source to be formed on the receiver, since the heating effect is the same regardless of whether or not the source is focused on the receiver, as long as the cone to the receiver is filled with radiant energy emanating from the source.

Radiation pyrometers with adjustable focus are arranged to provide for such focusing without altering the dimensions of the cone subtended from the receiver by the limiting aperture, in order to permit adjustment of focus without altering the calibration of the pyrometer.

The fixed-focus types, illustrated here, are widely used industrially. The focus is set suitably for the majority of industrial applications and the manufacturers supply tables showing the minimum diameter of source required for different distances.

A fixed-focus mirror type of radiation pyrometer is shown in Fig. 4. The cone determining the sensitivity is the cone α subtended by the mirror M, at points on the

receiver *R*. The receiver and the end of the pyrometer shield tube *B*, are at conjugate focuses of the mirror. The tube serves to prevent stray rays from beyond limiting lines *AA* from reaching the receiver or the adjacent thermocouple wires. When the tube is in use, care must be taken to avoid heating the end, because it would then become a source of extra radiant energy and would affect the reading. The source must fill the angle β as defined by limiting lines *AA*.

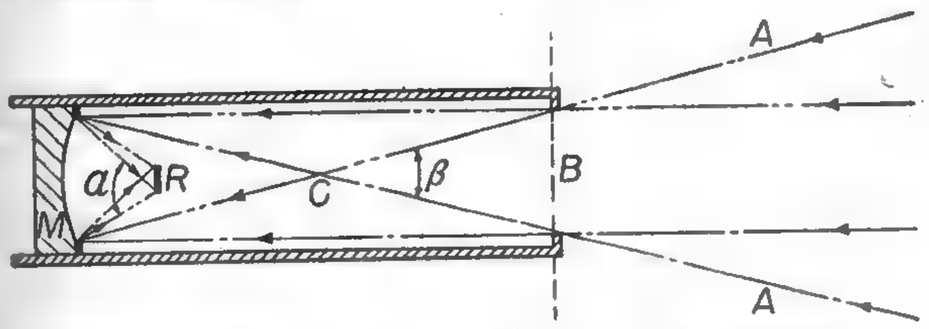

Fig. 4 Diagrammatic section of a radiation pyrometer; fixed focus, mirror type

A type of fixed-focus radiation pyrometer having a lens is shown in Fig. 5. The cone a at points in the small aperture in D_1 in front of receiver *R*, subtended by the aperture in diaphragm *D*, determines the sensitivity of the pyrometer. The conjugate focal plane of the lens *L*, with respect to the position of the aperture in diaphragm D_1, is at *B*, which lies at some position in space in front of the lens. The source may be at *B* or at some position in front of or behind *B*. The source must be large enough to include either the limiting lines *AA*, diverging at angle β, or the lines *A'A'*, whichever are outside at the position of the source. Diaphragm D_1 prevents irradiation of the receiver or thermopile wires by external sources outside of limiting lines *AA* or *A'A'*, thus limiting the area of source required.

The index of refraction of the lens material varies with the wave length; hence the lens gives rise to a family of limiting lines *AA* and *A'A'*. The source must be large enough to include the outermost of these limiting lines corresponding to the wave lengths transmitted by the lens.

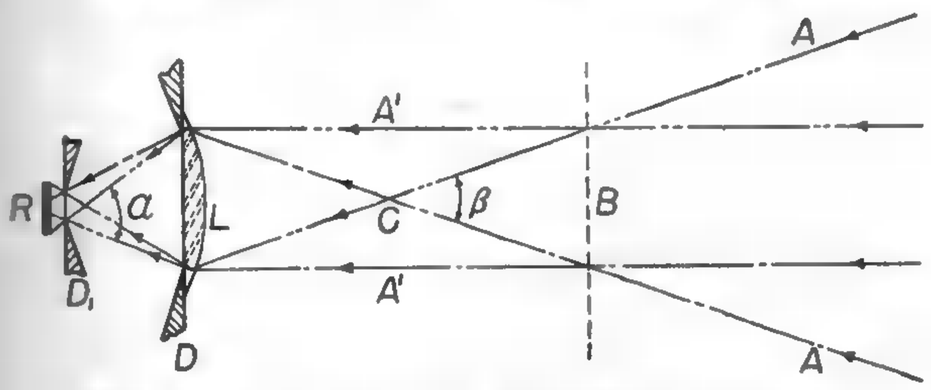

Fig. 5 Diagrammatic section of a radiation pyrometer; fixed focus, lens type

In practice, dimensions of apertures and focal length of mirror or lens are selected to meet the requirements of the application for which the pyrometer is designed.

Photoelectric Pyrometry[14]

In principle, a photoelectric pyrometer may be regarded as another variety of radiation pyrometer, from which the more familiar variety just described might be differentiated by calling it a "thermoelectric radiation pyrometer". In accordance with common usage, however, these instruments will be designated here as "photoelectric pyrometers" and "radiation pyrometers", respectively. The difference between the two is that either a photoemissive surface or a photovoltaic surface is substituted for the receiver of the thermopile used in the conventional radiation pyrometer.

The optical arrangements may be much the same as those illustrated in Fig. 4 and 5, though since the photoelectric surfaces are usually of relatively large area, the mirror of Fig. 4 can be replaced directly by such a surface, while in Fig. 5 the photosensitive surface might be located far enough to the left of diaphragm D_1 to receive the energy passing through the aperture in D_1, over a rather large area.

One type of photovoltaic cell that has been used in a pyrometer,[14,15] the Weston Photronic cell, responds to a band of wave lengths closely similar to that to which the human eye responds (approximately 0.3 to 0.7μ). Spectral emissivities and emissivity corrections that apply to the optical pyrometer* should be reasonably applicable to a Photronic pyrometer. This cell generates its own current, at an emf of the same order of magnitude as that of industrial thermocouples. The cell responds within about 98% almost instantaneously to changes in temperature, so that the time lag encountered is usually determined by the lag of the measuring instrument.

The vacuum type of photoelectric cell (photoemissive) employs a battery or other source of energy so that large changes in voltage may be produced by variations in the amount of radiation received by it. Thus the cell is adapted to the direct operation of vacuum-tube amplifiers for operating recording or controlling instruments.[8] Such a cell is even more rapid than the Photronic cell. The cesium+cesium oxide + silver photoelectric cell has its important response in the wave-length band 0.5 to 1.0μ, and

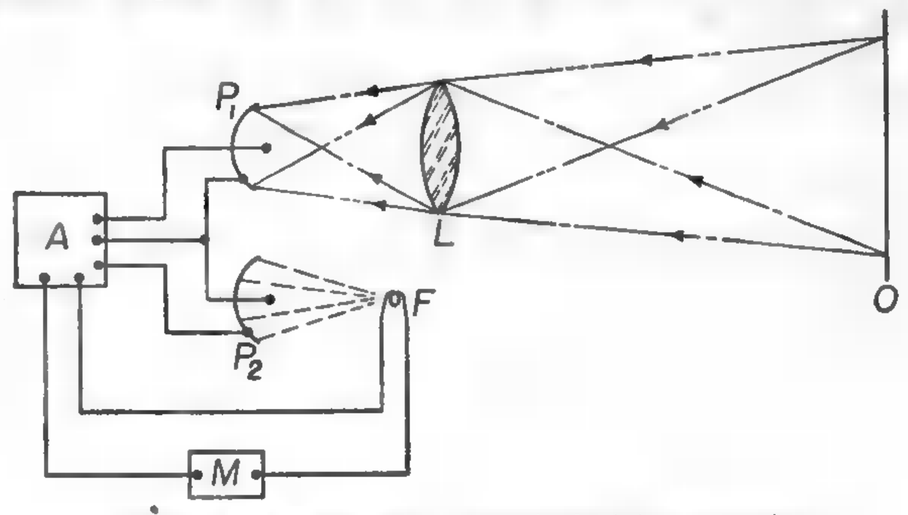

Fig. 6 Comparison type of photoelectric pyrometer

is thus most responsive in the near-infrared band of wave lengths where the radiant energy from a blackbody at the usual industrial temperatures is much more intense than it is within the band of wave lengths to which the Photronic cell responds. Emissivity corrections applying for the band of wave lengths from 0.5 to 1.0μ are not available, though the optical pyrometer corrections might be employed with moderate accuracy.

Because of the shortness of the wave lengths to which the photoelectric and Photronic cells respond, their response varies according to a high power of the temperature. Consequently the scale is compressed to insignificance in the low-temperature range and expands rapidly with increasing temperature. The Photronic scale is even more extreme in this respect than is the cesium photocell, a characteristic advantageous for measuring or controlling high temperatures over a relatively small range, and disadvantageous where operation over a wide range of temperature is desired.

A photoelectric pyrometer that utilizes a comparison principle is illustrated in Fig. 6. An electric lamp *F* irradiates P_2, one of two photoelectric cells, P_1 and P_2, connected in series. The other cell, P_1, is irradiated by the source *O*, the temperature of which is to be measured. The amplifier *A* adjusts the current continuously through the lamp to keep the response of the two cells in balance, so that the temperature of the lamp varies approximately in direct proportion to the temperature of the source. A recording d-c milliammeter *M*, responding to the current through the lamp, may be calibrated to read in degrees of temperature. Because of the relation between the current through the lamp and the corresponding filament temperature, the resulting scale tends to approach linearity, with the result that a wide range of temperatures may be read or recorded on the same scale.

Precautions. Water jackets and protective glasses must be used to prevent heating the photosensitive surfaces above 140 F. The surface of the Photronic cell and cer-

* See Table III, page 185.

tain parts of the circuit of a photoelectric cell must not be exposed to excessive humidity. Since the currents involved are extremely small, special care must be taken to avoid electrical leakage.

Optical Pyrometry

For the general principles on which optical pyrometry is based, the reader may refer to page 181. Several forms of optical pyrometer have been developed, but the form most widely used in industry is the "disappearing-filament" type.

The Disappearing-Filament Optical Pyrometer. This pyrometer has the form of a telescope that is sighted on the object of which the temperature is to be measured. Figure 7 is a diagram of the arrangement of the pyrometer parts. The objective lens *L* is focused to form an image of the object in the plane of the filament of a small tungsten-filament pyrometer lamp *F*. The eyepiece *E* is focused on the filament of the pyrometer lamp and on this image; both are simultaneously in focus, with the pyrometer filament crossing the image of the source.

In making settings, a photometric match is brought about either by varying the temperature of the filament in the pyrometer lamp or by keeping the filament at a definite temperature and varying the apparent brightness of the hot body by means of an absorbing screen. To make the light approximately monochromatic, which simplifies obtaining the photometric balance, a red glass filter that transmits only a narrow band of the visible spectrum, is mounted in the eyepiece of the telescope. The value of the wave length to be used in the equation on page 174 is the "effective" wave length of the light transmitted by the red glass filter. The red glass filters used with most optical pyrometers have an effective wave length centering at about 0.65μ.

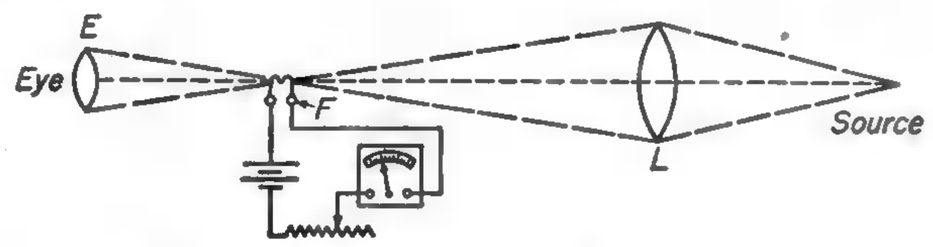

Fig. 7 Optical pyrometer of the disappearing-filament, variable-current type

In an observation with the first type of optical pyrometer, the current through the pyrometer filament is adjusted until the tip, or some other predetermined part of this filament, as observed through the eyepiece, has the same apparent brightness as the source being viewed. When this condition is reached, the comparison portion of the filament is indistinguishable from the portion of the image of the hot body that it crosses. The value of the current in the lamp at disappearance of filament is read by means of a milliammeter or potentiometer; the corresponding temperature is then read from a table or directly from the scale of the current-measuring instrument. In order to avoid deterioration of the filament and blackening of the bulb, the lamp should not be operated at temperatures above 2700 F. For higher temperatures, standardized absorption glasses are placed between the lamp and the objective, so as to diminish the intensity of the light from the object under observation. The amount by which this filter increases the range of the pyrometer may be ascertained by calculation, using the Wien equation (page 174) and the measured transmission of the filter. This increase in range for different temperatures may also be made a part of the calibration.

In the type of optical pyrometer that has a disappearing filament of constant intensity, the filament operates at a definite brightness obtained by setting the current through the lamp at a standard value. A semicircular wedge of black absorbing filter, which can be rotated through any desired angle, is mounted just in front of the pyrometer lamp. By varying the angular position of this wedge, a thicker or thinner portion is brought into the line of sight and the brightness of the image of the source viewed may be matched with the brightness of the filament. A scale attached to the wedge may be calibrated directly in degrees Fahrenheit for both high and low range. For temperatures above the range of the wedge, an additional absorbing filter is used in front of the lamp or the objective lens.

A check of the disappearing-filament pyrometer should include a check of the milliammeter calibration. This check is at least as important as that of the lamp.

Calibration of the Optical Pyrometer. The standard method of calibrating is by direct comparison with a blackbody at certain definite temperatures. The Wien radiation law is the basis for the calibration. However, an optical pyrometer can be calibrated without a knowledge of this law, by the use of a blackbody that can be heated to known temperatures through the entire range of the calibration. For checking the calibration where a blackbody is not available, the pyrometer may be compared with a tungsten-ribbon filament lamp so calibrated that its brightness, through the same or a similar red filter, for certain currents, corresponds to that of a blackbody at certain temperatures. This filament should be about 3 mm wide to enable making a good match of brightness and should be about 3 cm long to obtain a uniform area. A small notch shows where the match should be made.

The National Bureau of Standards will certify the readings of commercial types of disappearing-filament, variable-current optical pyrometers in good condition, to an accuracy ranging from ± 9 F to ± 6 F at 2000 F and to $\pm$ 0.3% at higher temperatures. Readings with the same instrument, under shop conditions, can be repeated by a practiced operator within about one-half these limits.

Precautions. When the optical pyrometer is adopted for a particular use, the limitations imposed by the laws of radiation must be carefully considered; either blackbody conditions must exist, or correction for the lack must be made, since this pyrometer determines the true temperature only for a blackbody. Under some conditions, the radiation emitted from a furnace, or from an object within it, is so nearly that of a blackbody that true temperatures are determined by a measurement of the brightness of radiation. If, however, the temperature of the furnace walls differs considerably from that of an object, within the furnace, on which the pyrometer is sighted, or if flames are present, or if it is possible for bright daylight or artificial light to enter the furnace and be reflected back to the pyrometer, a considerable error may result.

Large errors that occur because of departures of a furnace from blackbody conditions, usually result from lack of uniformity of temperature within the furnace. When a mass of cold material is to be inserted into a hot furnace, before the mass has been heated appreciably, the radiant energy reflected from it will give a false indication of its temperature. If the material reflects all or nearly all the light that falls on it, it will appear as bright as the furnace appeared previously, and an optical pyrometer will indicate that it is at the temperature of the furnace. On the other hand, if the mass of material has an emissivity of nearly 1, the material will absorb all the light falling on it, and consequently no light will be received from it until it has been heated to the point at about 1100 F where it begins to emit light of its own.

One method of reducing stray reflections in a heat treating furnace is to sight into a deep cavity in the metal being heated. Temperatures of closed furnaces can be read by the use of a refractory tube, closed at one end and so placed that the pyrometer can be sighted through the open end on the closed end, which is inserted in the furnace. Before the tube can be used in making temperature readings, it must be burned out thoroughly in order to remove any tendency to produce smoke.

Care should be taken not to sight through smoke or visible fumes. A considerable depth of clear, nonluminous flame may be sighted through without introducing an important error, but it is safer to turn off the flame while reading, or to sight to one side of it.

For taking temperatures of bodies outside a furnace, blackbody conditions will not exist, generally, unless a closed-end tube is used, or its equivalent, such as a deep cavity in the body. The radiation from surfaces of carbon and of a few oxides in the solid condition, such as iron oxide, closely approximates the radiation from a blackbody,

so the optical pyrometer gives temperatures that are accurate for practical purposes on such surfaces in the open. The temperature of steel billets or of sheet free from loose scale, can be measured successfully in the open with the optical pyrometer.

The emissivity of molten metal surfaces free from oxide is low, and there is a characteristic emissivity for each material, which must be known so that the corresponding correction can be applied to the apparent or brightness temperature to get the true temperature. When it is desired merely to repeat conditions on a given material, and there are no complicating factors, such as the changeable film on cast iron (Table III), apparent temperature will serve as well as true temperature and the correction for emissivity need not be known. Since liquid metal surfaces are good reflectors, readings should be made from such a position that reflections from flames, lights or windows

(a) Below transformation point in surface brightness

(b) Above transformation point in surface brightness. Based on emissivity 0.40, the value which is now in general industrial use for iron and steel. Recent measurements indicate that the emissivity of molten pure iron, plain carbon steel and cast iron, increases with temperature; the corrections are therefore smaller than shown in the table.

do not enter the pyrometer. Table III gives the corrections in °F to be applied to readings made with an optical pyrometer employing a red filter glass that transmits a mean wave length of 0.65μ.

A tapping or pouring stream of steel usually shows a set of bright streaks on a darker background. The dark surface is the flat or convex clean metal to which the emissivity of 0.40 is applicable, on which are based the corrections in column 3 of Table III. It is known that certain alloying elements, such as chromium and manganese, increase the emissivity above 0.40 and consequently lead to high readings of the temperature if the customary scale based on 0.40 is employed.

Size of Object. In order to determine sharply the disappearance of the filament, the image of the hot body, as seen in the telescope, should be at least four times as wide as the image of the filament. In practice, using instruments generally available, the smallest object that can be sighted on with convenience and certainty must have a diameter not less than 0.1 in. In principle, however, there is no objection to measuring the temperature of much smaller objects by the comparison of brightness.

To measure the temperature of a furnace in which blackbody conditions are approximated, the pyrometer may be sighted on an opening in the furnace from a position that receives direct radiation from the interior.

Advantages and Disadvantages of the Optical Pyrometer. Some of the advantages of the optical pyrometer have been brought out in the preceding discussion. These include its utility for measurement of high temperatures; for measurements, at both high and low temperatures, on inaccessible bodies, moving bodies and small bodies, the temperature of which would be affected by the attachment of a thermocouple; and for occasional readings when the installation of a thermocouple would not be economical or feasible. Other advantages are that no part of the instrument is exposed to the destructive effects of heating; and that the indicated temperature derives directly from the temperature of the heated body under test and not from the temperature of some adjacent body (for example, a thermocouple) that can only be assumed to be at the same temperature as the test material.

The principal disadvantages are the ease with which errors may be introduced by absorbent screens of smoke or by incandescent gases between the observer and the object under test; and the fact that with most instruments, each reading is the result of a photometric match made by an individual observer, thus affording an opportunity for accidental errors and biased judgment. Errors introduced by uncertainty as to both the amount and the constancy of the departure from blackbody conditions, have been pointed out in the discussion of the instrument.

Principles of Automatic Control

Elements of an Automatic Controller. Figure 8 is a diagrammatic representation of an *automatic controller** applied to a fuel-heated furnace. For convenience, the

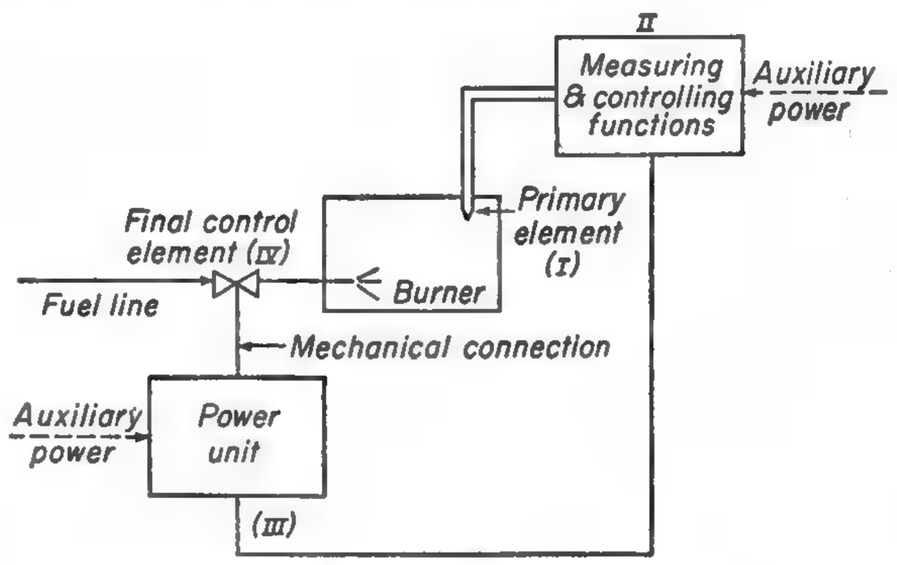

Fig. 8 Diagrammatic representation of a controller applied to a furnace

controller has been broken down into four units (marked I to IV), designated by general terms. The *primary element* is shown as a thermocouple with emf (representative of the temperature) transmitted to unit II, which has both measuring and controlling functions. Through suitable mechanism, the voltage of the thermocouple is interpreted to the control elements to initiate control actions. The control elements of unit II may be extremely simple or fairly complex. Through them the operation of a *power unit* (III) is directed to position the fuel valve (IV) in accordance with predetermined relationships, to be discussed later.

Depending on the requirements of the particular application and on personal preference, the primary element may be a resistance thermometer, a radiation or photoelectric pyrometer, a liquid expansion thermometer, a vapor or gas pressure thermometer, or a bimetallic strip or other metallic differential-expansion element.

The power unit may be electric, pneumatic or hydraulic.

The *final control element* may be a valve (as shown), a variable speed pump, a rheostat, a variable-voltage transformer, a saturable core reactor, or simply the contacts of an electrical contactor.

Lack of space prevents discussion of other than gen-

* Italicized terms are defined in "Automatic-Control Terms", a report by the Terminology Committee, Industrial Instruments and Regulators Division, American Society of Mechanical Engineers, published in Mechanical Engineering, 68, 134–138 (1946) and reprinted as a 16-page pamphlet.

eral details of mechanisms. In the simplest *self-operated* controllers, the final control element is supplied with power directly from the primary element and there is no indication of temperature on a scale. On the other hand, many control instruments provide both an indication and a record of the temperature.

Types of Action of Automatic Controllers. Upon receiving indications of temperature from the measuring part of the controller, the controlling mechanism may introduce valve motion in accordance with various laws. The most commonly applied types of controller action are: *two-position* (with or without differential gap), *proportional-position, floating, proportional-plus-reset, proportional-plus-reset-plus-rate.* In the field of temperature control, floating controller action is seldom used alone, but is important in that it provides the "reset" action in proportional-plus-reset control.

Two-Position Control. This has also been known as "open-and-shut" and "on-and-off" control. With two-position control the heat is supplied alternately at two different rates, one of which is too low and the other too high to meet the average demand. In the simplest instance a temperature record like that in Fig. 9*a* is obtained. As the temperature decreases to value *L*, full heat is applied. The temperature immediately starts to rise and continues until temperature *H* is reached, when the heat supply is suddenly changed to the lower rate and the temperature again begins to fall. This repeated rise and fall continues indefinitely. In general, decreasing the *differential gap* $(H - L)$ increases the frequency of controller operation and decreases the magnitude of temperature variations.

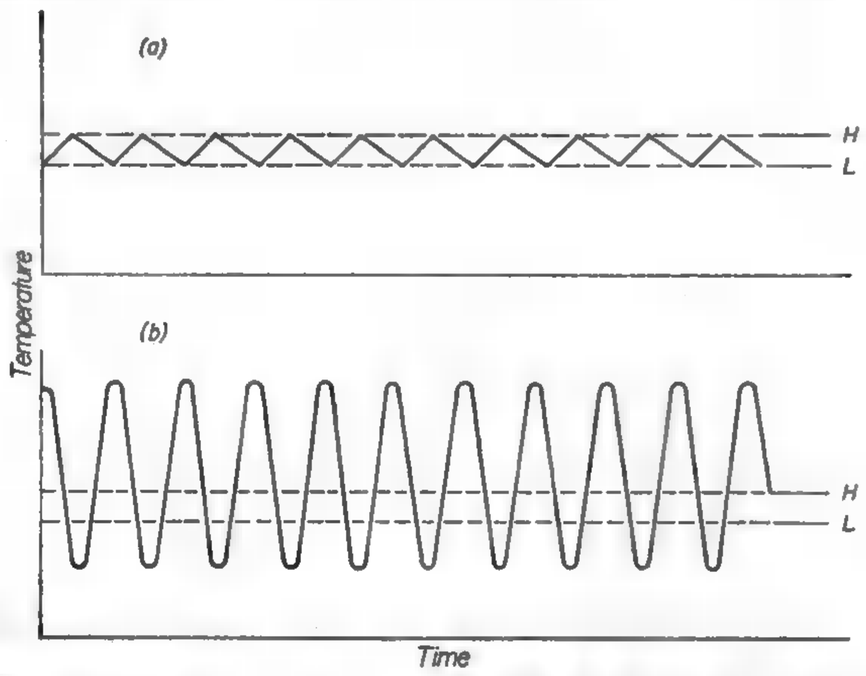

Fig. 9 Two-position control records, (*a*) as obtained under highly favorable conditions; (*b*) as obtained under very unfavorable conditions.

A record similar to that of Fig. 9*a* is obtained only when no unfavorable lags exist in the furnace and in the measuring and controlling means. Mainly because of the effects of heat-storage capacity and thermal resistance, the form of the record is more likely to be represented by Fig. 9*b*. The differential gap $(H - L)$ is the same as before, but the temperature trend does not change suddenly when the rate of fuel supply to the burner is changed. Reducing the differential gap will, in general, reduce somewhat the magnitude of oscillations, but even with zero gap the range of temperature variation may be so great as to be objectionable.

Proportional-Position Control. This is one of a number of types capable of positioning the valve with any degree of opening, and allowing the temperature to remain steady when the requirement for heat is steady. The simple valve action involved is that which would be obtained if the pointer of a powerful temperature indicator could be connected to move the valve directly. Valve movement is proportional to temperature change and in the proper direction to counteract it.

The range of temperature change required to full-stroke the valve (the *proportional band*) must be adjustable to suit the application. The optimum width of the proportional band may be 2° of temperature in one instance and 20° in another. Figure 10 shows the effect of the same sudden change in heat requirement when, for successive tests (*b*, *c* and *d*), the proportional band settings were in the ratio of 4, 2 and 1. It is characteristic of this type of control that the control point moves within the proportional band when the heat requirement changes. The shift from the desired value, caused by this phenomenon, is called *offset*. Offset can be reduced by narrowing

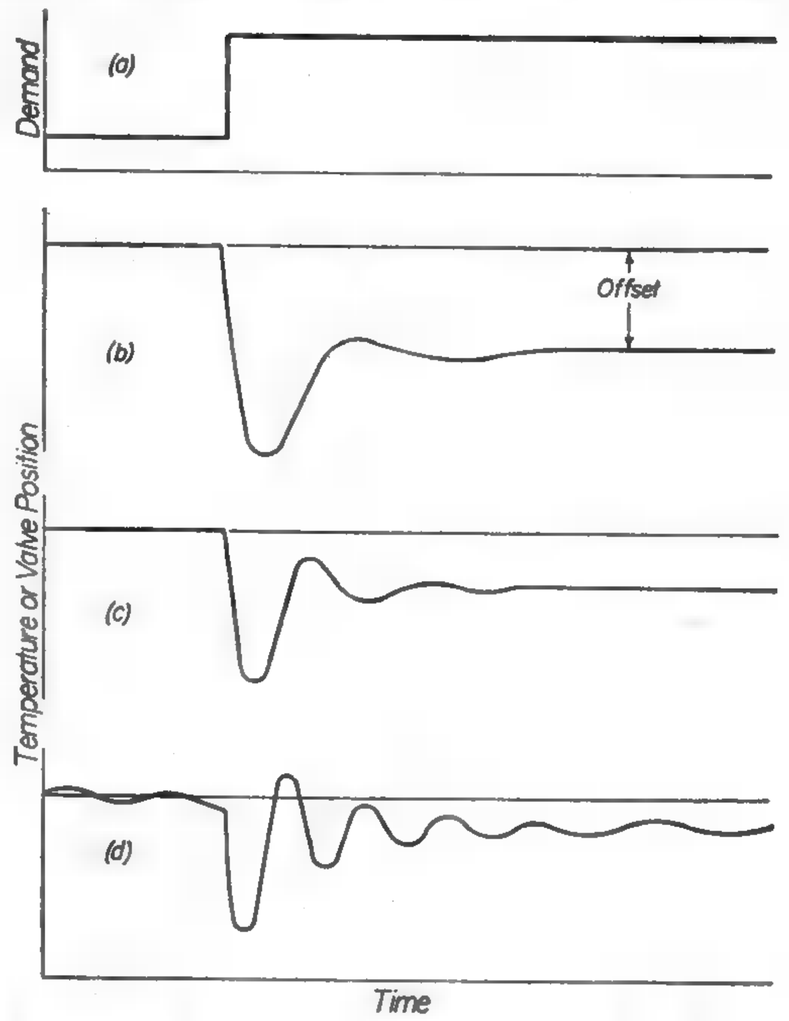

Fig. 10 Responses of a proportional-position controller to change in demand, with successive reduction in proportional band from 4 to 2 to 1 (curves *b*, *c* and *d*)

the proportional band to the point where undesirable oscillations appear, as noted by their progressive increase in Fig. 10 (*b*, *c* and *d*).

Floating Control. The chief use of *floating controller* action in temperature control is in combination with proportional-position action. By adding the actions of the two types, stable control without offset is obtained.

Three types of floating action are illustrated in Fig. 11. In each, the valve is moved continuously in the closed direction when the temperature is high, and in the opposite direction when the temperature is low. The graphs

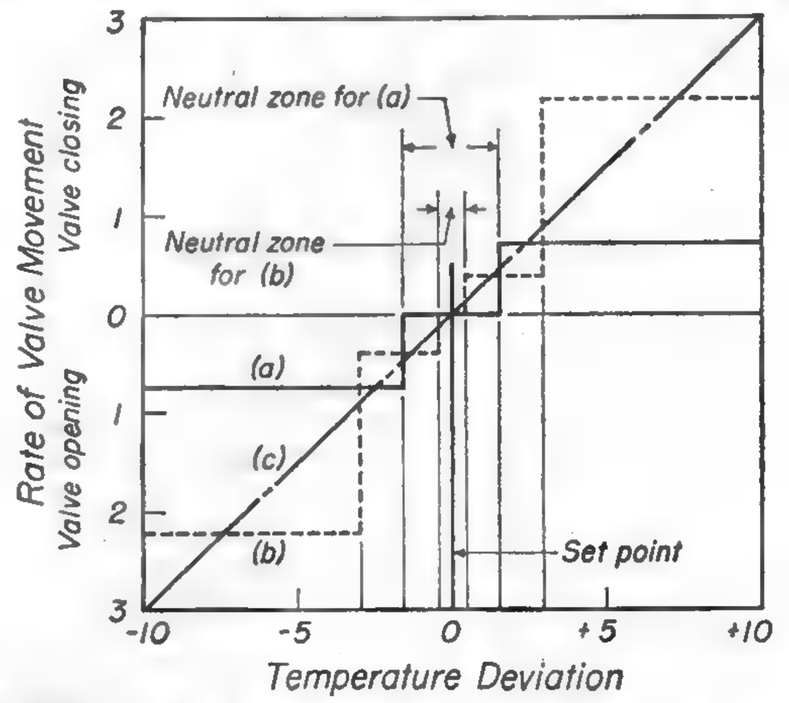

Fig. 11 Responses of valve movement to changes in temperature for floating controllers with a single speed, two speeds and proportional speed

are of rate-of-valve-movement versus temperature. When the temperature is at the control point, no valve movement occurs. Curve *c* illustrates *proportional-speed floating* control in which the rate of valve movement is proportional

to deviation from the *set point*. In *single-speed floating action* (curve *a*) the valve moves at the same speed regardless of the deviation, provided the deviation exceeds the limits of a *neutral zone* within which no valve motion takes place. Two-speed floating action (curve *b*) provides a second fixed higher rate of valve motion when the deviation exceeds a predetermined value.

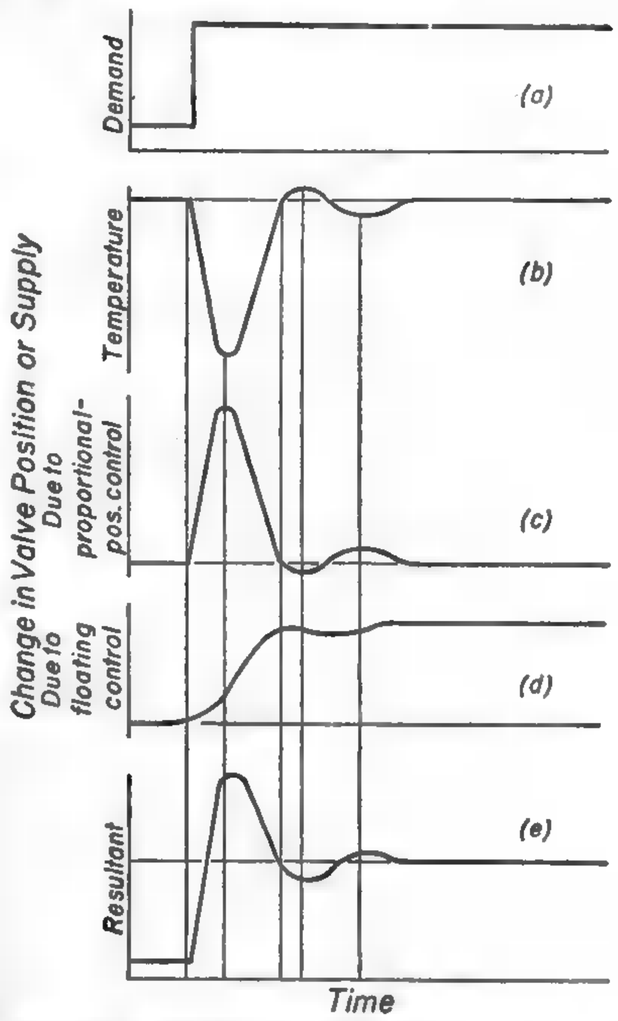

Fig. 12 Responses of temperature and valve movement to change in demand with a proportional-plus-reset controller, showing effect of individual components

Proportional-Plus-Reset Control. When proportional-position and proportional-speed floating actions operate simultaneously to determine the valve position, the resultant action is known as *proportional-plus-reset control*, analyzed in Fig. 12. A sudden change in demand (curve *a*) results in temperature deviation as shown in *b*; the return to the set point is accomplished through valve movement as indicated in *e*. Curve *c* shows the component of the valve movement caused by proportional-position action, to which is added the proportional-speed floating component *d*. It will be noted that the algebraic addition of *c* and *d* gives the resultant curve *e*.

Rate Action. This action is sometimes applied to supplement proportional-position and proportional-plus-reset control. It reduces deviations by moving the valve by additional amounts with variations in the rate of change of temperature.

Average-Position Action. This refers to a method for obtaining the effects of those previously discussed control actions that require the rate of heating to be continuously variable, even though only two instantaneous heating rates are possible. By alternating between the two instantaneous values with suitable timing, any intermediate average rate of heating may be obtained. If the frequency of alteration is made great enough, the effect of the average, rather than the instantaneous, heating rate appears in the temperature record.

Statistical Methods as a Guide in Control of Operations and of Quality of Product

By H. J. Hand,* W. O. Clinedinst* and F. G. Norris†

MODERN statistical methods are as well suited to problems of quality in the metallurgical industries as the methods of calculus are suited to the study of mechanics or electricity. Under conditions of plant operation, when attempts are made to follow the same procedure repeatedly in order to achieve a given final result, sameness is not obtained. Instead, results vary within a range of values, and the frequency of occurrence within the range varies from one extreme to the other with more or less well-defined mathematical regularity. These conditions arise because observed results depend on a multiplicity of factors. If the influential factors are constantly present, the observed results are distributed according to some law of chance, and occur as a result of the chance combinations

* Analytical Research Engineer, National Tube Company, Pittsburgh
† Director of Research, National Tube Company, Pittsburgh
* Assistant Metallurgical Engineer, Steubenville Works, Wheeling Steel Corporation, Steubenville, Ohio

of the influencing factors whose magnitudes always vary from time to time. Sometimes certain of the influencing factors cease operating altogether, or new factors of influence may enter the system, making the observed results a combination of chance and assignable causes. The same situations exist even under the "controlled" conditions of a research laboratory, although the observed results are generally confined to much narrower ranges of reproducibility. Modern statistical techniques are appropriate for industry because they are designed scientifically to cope with problems of variation and to distinguish between chance variations and variations that result from assignable causes.

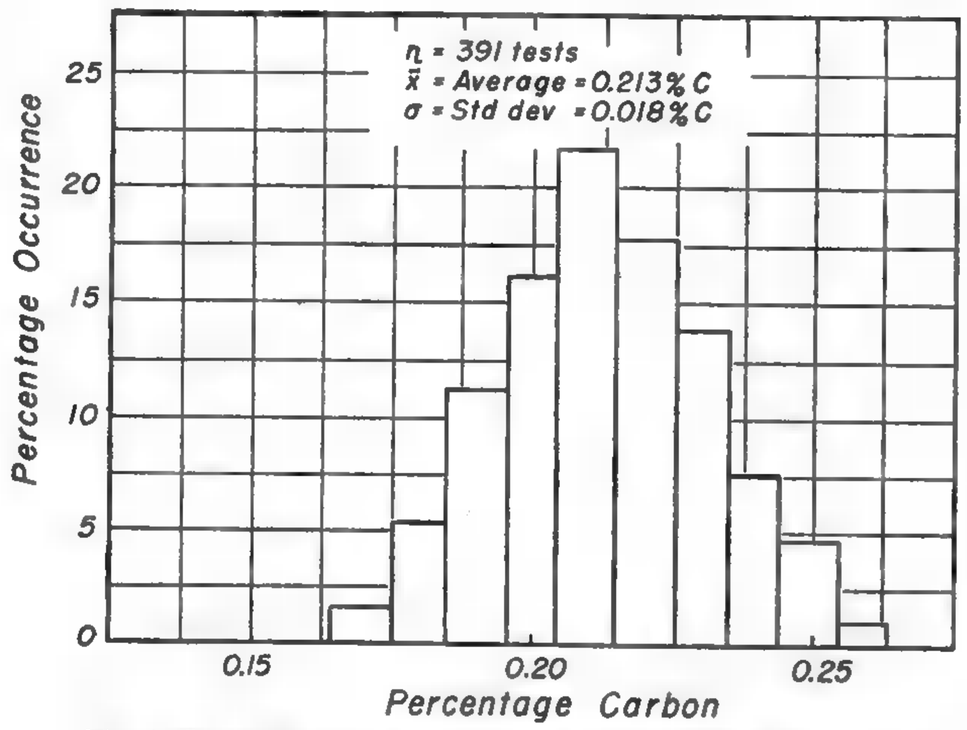

Fig. 1 Frequency histogram showing distribution of carbon in a given grade of hot rolled open hearth steel

In order to describe the quality of a process, a distribution of observed results must be shown. Simple averages or statements of the percentage defective are not sufficient. The references[1-4] give detailed descriptions of typical ways of assembling the data and presenting it effectively. Typical distributions of a quality characteristic are shown in Fig. 1 and 2.

From these distributions, the following important features of quality are evident: mode (most common value), median (middle value), minimum, maximum and percentage of values within any range. The average and the standard deviation (measure of degree of dispersion) can be calculated readily, as can other parameters such as those relating to skewness (lopsidedness) or kurtosis (flatness), which portray other characteristics of the distribution.

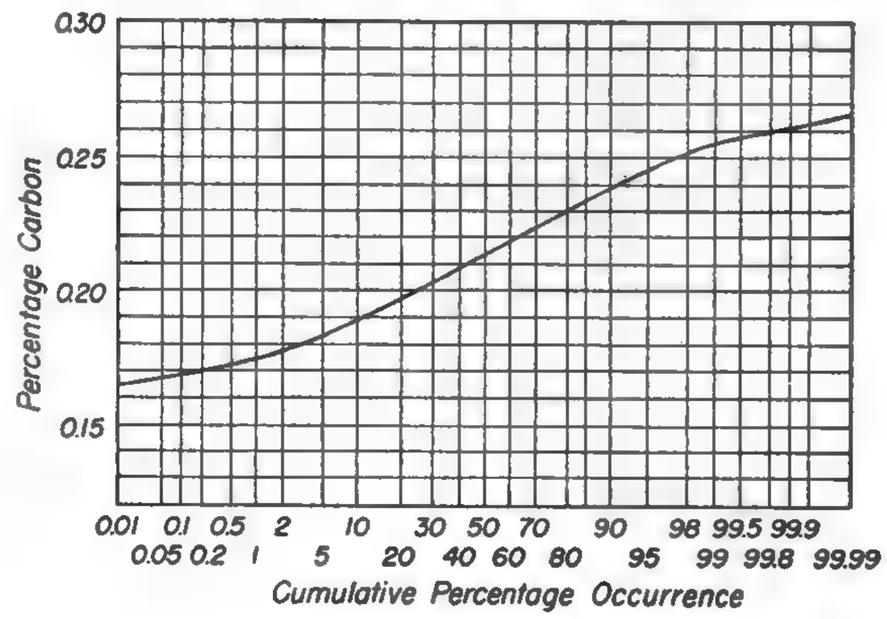

Fig. 2 Cumulative distribution for the frequency histogram of Fig. 1

Two processes may have the same average, yet may vary widely in quality because of differences in uniformity or standard deviation. If such variations exist, when it is desired merely to meet a minimum specification and when it costs appreciably more to obtain higher values, frequently considerable amounts can be saved by taking advantage of the greater uniformity and producing work at a lower average *(see* Fig. 3).

In order to tell, from samples or small-scale tests, which of two or more compared conditions or methods of procedure is superior, the differences observed must be greater than can be attributed to chance. In evaluating such differences, difficulties arise since, even when samples are

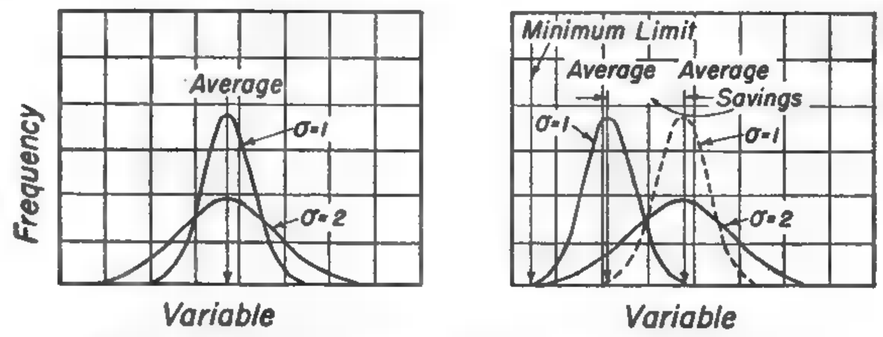

Fig. 3 Frequency curves showing differences in uniformity or standard deviation

taken from a distribution resulting from the operation of a constant system of chance causes, considerable variation in the characteristics of small samples is to be expected because of chance, as illustrated in the following:

Universe	Sample Size, N	Anticipated Variation in Sample: Average, $\bar{X}$	Anticipated Variation in Sample: Standard Deviation, σ
$\bar{\bar{X}}$ = Average = 60,000	5	55,980 to 64,020	0 to 5370
σ = Std Deviation = 3000	25	58,200 to 61,800	1636 to 4182
	100	59,100 to 60,900	2363 to 3637

It will be noted that the expected variation in the averages and the variability of samples decreases with increasing sample size. Therefore, many tests may be necessary in order to arrive at a satisfactory decision concerning a better method or device, especially if it is desired to estimate how much better; and the degree of testing necessary increases as the variability of the material or process increases. In the past, the above situation has been responsible many times for the acceptance of devices or methods no better than those in current use and the rejection of those distinctly superior. It is also partly responsible for conflicting results when tests are duplicated at various places or times. The

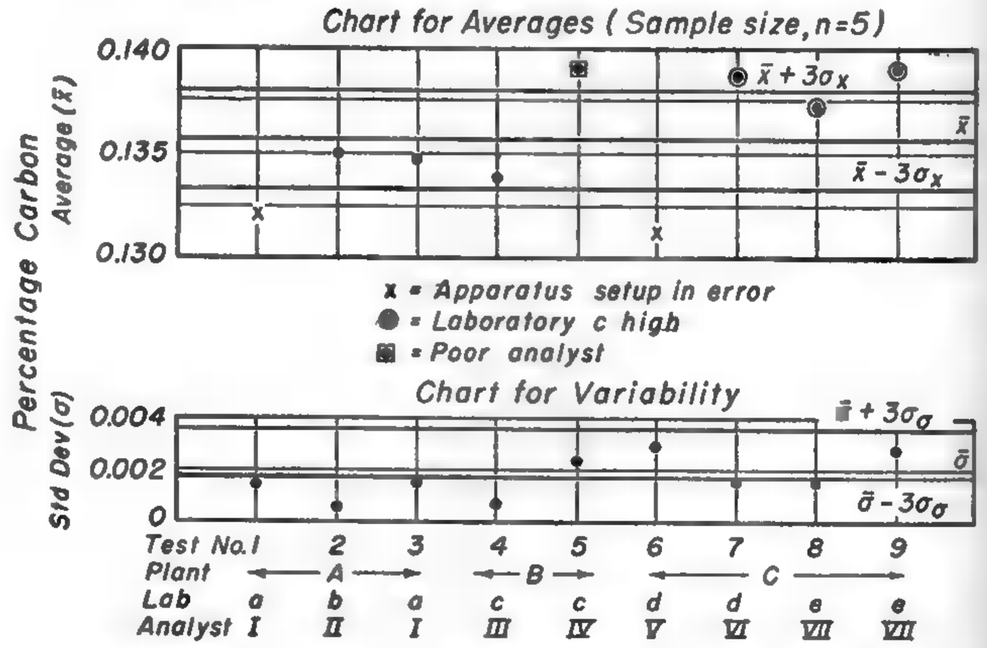

Fig. 4 Control chart for carbon content of five groups of identical drillings submitted to laboratories of three plants

same problem exists in acceptance or rejection of material when samples are tested for specified properties. Many statistical tools are available to solve such problems.[5,6,7]

In industrial processes, distributions that depend on the operation of a constant system of chance causes are the exception rather than the rule. Assignable causes usually enter and leave the system from time to time, and periods when such causes are operating can be located most effectively by employing techniques such as Shewhart control charts[1,2,8,9,10] or the analysis of runs.[11,12] A typical Shewhart control chart is shown in Fig. 4.

Such methods should be used when it is desired to interpret effectively industrial data on a quality characteristic or on factors important in the control of quality. Through the use of these methods needless investigations are avoided; trouble is expected only when the chart indi-

cates that an assignable cause is operating. The chart will not tell the cause of trouble; it merely signals that an assignable cause has entered, that something definite has gone wrong. Proper search should lead to the isolation of the trouble. The control chart method has proved to be an effective way of controlling quality during production.[9,13,14,15] It may be beneficial to shut down a machine when its product is out of control and to eliminate the assignable cause before producing more material.

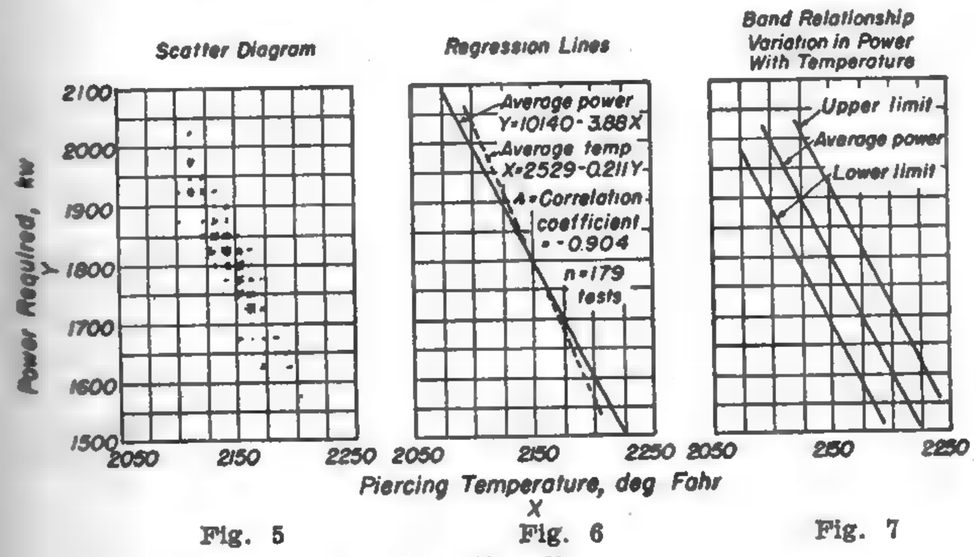

Fig. 5 Fig. 6 Fig. 7

Fig. 5 Scatter diagram
Fig. 6 Regression lines
Fig. 7 Band relationship. Variation in power with temperature

The inherent variability of materials and processes complicates the problem of determining relationships among variables. Functional relationships (where one value of Y and one only is obtained for a given X) do not exist; instead a *range* of Y's is found for a given value of X; yet average Y, or minimum and maximum Y, varies with varying X. Statistical relationships may be linear or curvilinear, just as are the ordinary functional relations. A typical statistical relation is shown in Fig. 5, 6 and 7.

Important problems arise here: Is the observed relation caused by chance? How does Y vary on the average with varying X? Within what limits can Y be predicted if X is known? An extension of this problem involves determining the simultaneous relation between a number of independent variables—Y_1, Y_2, Y_3, Y_4, ...Y_n—and X. Predicting equations may be developed, of the form $X = a + bY_1 + cY_2 + dY_3 + eY_4 + ...zY_n$, where b depicts the relation between X and Y for constant values of Y_2, Y_3, Y_4, and c, the relation between X and Y_2 for constant Y_1, Y_3, Y_4 and so on. Good descriptions of the necessary techniques[4,7,16,17,18] and examples of their industrial application will be found in technical publications.[19,20–25]

In spite of strong evidence in favor of the statistical approach, there is considerable skepticism as to the utility and results, probably because of the common interpretation of "statistical methods" as meaning a tabulation of averages or percentages. These may be misleading because of the small size of samples, and failure to classify the data properly. In the hands of a person familiar with the field and able to make proper hypotheses and classifications of data, the various statistical tools available have proved extremely helpful in the control of quality throughout industry. It must be remembered, however, that in the last analysis, statistical techniques are only a means of judging whether or not the observed data are fulfilling a hypothesis; if irrational hypotheses are contemplated, irrational results will probably be obtained.

The most useful statistical tools now available in quality control work are the following:

Frequency Curves. In addition to the uses of the frequency curve that have already been described, this device has had wide application in the isolation of factors influencing quality, particularly when large quantities of data must be considered.[23,26,27,28] Tabulating equipment and punch cards may be particularly valuable in performing an analysis of this type.

The analytical procedure here consists in sorting various factors and comparing frequency distributions of the quality variable, or comparing frequency distributions of the factors of possible influence for materials from the good and bad thirds or halves of the distribution of the quality variable. Other classifications of data may also be desirable. Examples of effective and ineffective factors determined in this manner are shown in Fig. 8.

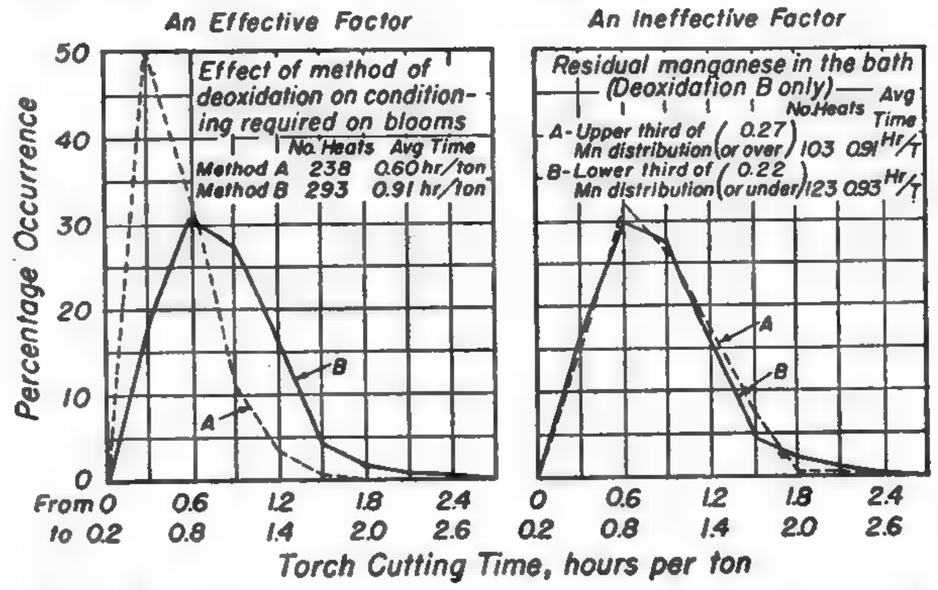

Fig. 8 Effective and ineffective factors determined by the use of frequency curves

Tests of Significance for various statistics of data, such as average, standard deviation, or chi-squared. These are important when relatively small samples are used to compare two conditions. [23] Table I illustrates the use of a test of this type for the difference between averages.

Table I. Significance Test for Differences in Averages of Two Conditions

Quality of Bloom Surface (as Measured by Time-to-Condition) for Two Methods of Deoxidation

Deoxidation A			Deoxidation B	
3.38	2.36	2:30	2.41	
3.84	2.41	3.38	2.53	
0.95	3.58	1.52	2.29	
2.37	3.61	3.36	3.29	
2.16	2.46	2.18	3.49	
1.73	3.39	0.88	4.03	
1.81	2.65	3.64	1.52	
2.18	3.10	0.49	0.86	Difference Between Methods A and B
2.38	3.21		2.03	
2.45	1.18			
Total Samples		28	9	
Average conditioning time		2.46	2.72	0.26
Maximum difference expected because of chance (2σ limits)*				0.67

The observed difference should be interpreted as attributable to chance, since it is less than the 2σ level, and method B should be considered as good as method A.

* See reference 3 or 7 for method of calculation. The limits depend both on the dispersion of individual observations under each condition and on the number of tests involved.

Tests of significance should also be used for comparing frequency distributions, discussed above, when the number of samples is relatively small.

Simple Regression and Correlation. When a large number of data are available, another method of isolating effective factors and determining their quantitative effect on an observed result, is to obtain average values of the quality characteristic in question for various small ranges of the factors being investigated. Because of the operation of the law of large numbers,[26] effects of other factors influencing individual observations will compensate, and the true relation between the factor under investigation and the quality characteristic will be developed. Averages for effective factors will vary in some systematic way with increasing values of the factors; those for ineffective factors will exhibit no trend and the averages will vary more or less at random. Examples of an effective and an ineffective factor and a description of the quantitative relationship in the effective factor are shown in Fig. 9.

It should be noted that the quantitative relations developed under operating conditions in the shop, can be expected to be maintained under these conditions and are therefore of more practical consequence than many relationships developed in the laboratory, where all variables are kept constant except the one being investigated. Calculations made in the laboratory may not hold under operating conditions because of countereffects not foreseen.

When few observations are available, least-squares methods must be resorted to and Pearsonian correlation coefficients must be calculated, in order to establish relationship and distinguish between true and chance association. At times association can be established with a surprisingly small number of samples.

Least-squares methods should also be utilized when it is desired to establish the quantitative method of variation of one dependent variable with another, based on relatively small samples; here tests of significance of regressions and accuracy of slopes should be calculated. When it is desired to develop the complete band type of relationship—linear or curved—least-squares methods should be used.

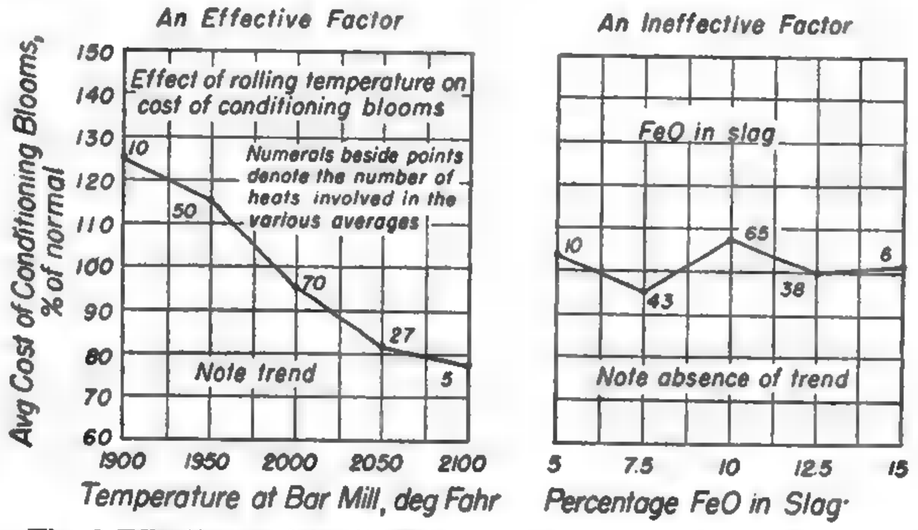

Fig. 9 Effective and ineffective factors determined by the use of simple regression and correlation

The determination of correlation by least-squares or regression using either averages or least-squares, can be greatly expedited by using tabulating equipment.[29,30]

Multiple Regression and Correlation. Probably the best method of isolating effective factors from routine data is that of the simultaneous consideration of their effect on the quality characteristic in question, by using least-squares methods of multiple correlation.[16,17,19–22,24] Effects of the various factors as developed, will differ from those of simple regression and correlation (*see* above) in that the results shown for any particular factor are the results for constant values of other factors of influence.

An equation may be developed in which all the effective factors are included, and the value of the dependent variable can be calculated in any given instance. An expression may be developed for the accuracy of the predicting equation. The total variation in the dependent variable, explained by all the effective factors, can be determined so that it can be seen at once whether or not it is worth while to search for effects of other factors not included in the study. The contribution of each effective factor to the total explained variation can also be determined roughly. It is emphasized, however, that factors for use in regression equations should be selected on the basis of some definite hypothesis, and that large quantities of data should be used if it is desired to develop regression equations for predicting future results. It may be desired to include some factors as reciprocals, some as squares, and so on, if the theoretical evaluation of the problem indicates that such should be done. Table II gives an example of the use of this technique. Many other examples are discussed in the literature.[19–22,24] Use of tabulating equipment will be found indispensable here.

Analysis of Variance and Design of Experiments. These techniques should be applied when special tests are conducted in either mill or laboratory to determine the effect of variables. The experiment should be designed and calculation sheets prepared before any testing is done. When designed so that the technique of analysis of variance can be applied to results, experiments have the following advantages:

1 Correct reproducible answers are obtained with a minimum of testing.
2 The effect of each factor and of combinations of the several factors included are determined as distinguished from chance. Factors and their combinations are classed as "effective" or "ineffective".
3 The reliability of experimental technique is evaluated.

Use of this device should eliminate reversals of test results during repetition. After effective factors have been isolated, they or their combinations can be expressed conveniently as a multiple regression equation, and a predicting equation can be evolved with little additional work. Books describing techniques and articles describing industrial applications are included in the references.[3,7,22,31–35] An example of such an analysis, taken from a laboratory investigation of the effects of nickel, manganese and vanadium on a property of a steel, is shown in Table III.

Control Charts. As mentioned previously, it is important to use control charts as a matter of routine in order to interpret variations in the quality characteristics of a part being produced on a rolling mill, drawbench or machine, so that no deliberate changes will be made as long as the process is under control, and so that operators will search for trouble immediately when an assignable cause results in an observation beyond control limits. It is also im-

Table II. Example of the Isolation of Effective Factors and Determination of Their Quantitative Effects Through the Use of Multiple Correlation

FeO in Metal. From the results on 65 tests on open hearth heats for C, Mn, and FeO in the bath, MnO, FeO, Fe_2O_3, R $\left(=\frac{CaO}{SiO_2 + 0.634\ P_2O_5}\right)$ and temperature, the following regression equations and evaluations of the effects of these factors on [FeO] were developed:

$$[FeO] = -0.322 + \frac{0.0092}{[C]} + 0.0798\,[Mn] + 0.0011\,(MnO) + 0.0019\,(FeO) + 0.0034\,(Fe_2O_3) - 0.0067\,(R) + 0.00013\,T \quad (1)$$

$$[FeO] = -0.299 + \frac{0.0092}{[C]} + 0.1188\,[Mn] + 0.0003\,(MnO) + 0.0035\,(Fe) - 0.0082\,(R) + 0.00012\,T \quad (2)$$

$$[FeO] = -0.296 + \frac{0.0092}{[C]} + 0.1280\,[Mn] + 0.0035\,(Fe) - 0.0082\,(R) + 0.0012\,T \quad (3)$$

Total variation in FeO unaccounted for after considering factors in: Equation 1=10.0%[a], Equation 2=10.8%[a], Equation 3=10.6%

Factor	Significance (Probability that the effect is caused by chance)	Independent Quantitative Effect on [FeO][d] (Most probable values from equation 3)
[C]	Less than 1 in 1 billion	From 0.05 to 0.06 C, FeO decreases 0.031% 0.10 0.11 0.008 0.30 0.31 0.001 0.60 0.61 0.0005
[Mn]	2 out of 5[e]	For 0.05% increase in [Mn], (FeO) increases 0.006%
(MnO)	9 out of 10[b]	
(Fe)	1 out of 50	For 1% increase in (Fe), (FeO) increases 0.0035%
(R)	1 out of 4[c]	For 0.05% increase in (R), (FeO) decreases 0.004%
T	1 out of 4[c]	For 100° F increase in T, (FeO) increases 0.012%

Standard deviation of error $\overline{(S)}$ considering all variables from Equation 3 = 0.025%; from duplicate tests = 0.018%.[e]

(a) Comparison of unaccounted-for variations from Equations 1 and 2 indicates that little is to be gained by considering iron oxide as FeO and Fe_2O_3. Total Fe tells the story as well.
(b) Ineffective factor.
(c) Effective, as a result of previous knowledge. Generally a level of 1 in 20 is taken as a lower limit for considering a factor effective.
(d) Quantitative effects of the factors.
(e) Use of equation 3 permits evaluation of [FeO] almost as precisely as chemical analysis.

Table III. Example of Analysis of Variance Applied to a Research Problem

Effect of 1 to 2% Mn, 0 to 3% Ni, and 0.0 to 0.1% V on a physical property of an aluminum-killed steel with 0.30% C, 0.30% Mo, 0.25% Si

1 *Data* consisted of 24 experimental melts with:
(a) 0 V, 1% Mn, and 0, 1, 2 and 3% Ni; same with 1.5% Mn; same with 2.0% Mn
(b) 0.10% V, 1% Mn, and 0, 1, 2 and 3% Ni; same with 1.5% Mn; same with 2.0% Mn
Tests run in triplicate (72 tests)

2 *Analysis of Variance.* Significance of test results:

Factor	Degrees of[a] Freedom	Sum of[b] Squares	Variance (Mean Sum of Squares)	F[c] Data	Limits of F[d] 5% Chance Level	Limits of F[d] 1% Chance Level	Remarks
Mn	2	30720.08	15360.04	44.65	5.14	10.92	Highly significant
Ni	3	9690.89	3230.30	9.39	4.76	9.78	Significant
V	1	6272.00	6272.00	18.23	5.99	13.74	Highly significant
Mn, Ni	6	4385.36	730.89	2.13	4.28	8.47	Not significant
Mn, V	2	735.59	367.80	1.07	5.14	10.92	Not significant
Ni, V	3	235.11	78.37	0.23	8.94	27.91	Not significant
Mn, Ni, V	6	2064.31					
Without group	48	58.67	344.05 = Estimate of error				
Total	71	54162.00	1.22 = Estimate of reliability of test[e]				

Notes:
(a) From the design of the experiment. *See* references 3, 5, 7, 31.
(b) Evaluated from the data. *See* references 3, 5, 7, 31.
(c) Variance for factor divided by estimate of error.
(d) Limits of chance variation for F. If the observed F exceeds the 5%-chance level, the factor is significant; if it exceeds the 1% level it is highly significant.
(e) If the variable here exceeds the estimate of error, the experiment has not been conducted in a reliable manner and other factors that may be very important are operating to affect the results.

3 *Quantitative Effects.* The regression equation.
Property = 18.258 + 45.83 (% Mn) + 10.49 (% Ni) + 234.84 (% V)
$R^2 = 0.85$; 85% of the variation in the property is explained by the manganese, nickel and vanadium contents in these steels, in these tests.

portant to use control charts for variables affecting final quality, such as open hearth variables affecting surface quality in conditioning or final working. Control charts are the usual criteria for statistical control, and when it is desired to take fullest advantage of various plans for sampling inspection, statistical control must be obtained first.

Analysis of Runs. This technique may be used likewise to distinguish between real and chance variation and probably represents some advance beyond the control chart in that it distinguishes between causes producing trends and those producing discontinuous and erratic effects. Observations are listed or plotted in order of time or position taken, and the sequence is examined for existence of runs up or down and those above or below the median. A "run down" is the interval between a maximal number and the next succeeding minimal one, and the length of run down is the number of numbers involved, including maximal and minimal numbers. Runs up and runs above or below the average are similarly defined. The exact mathematical formulation of this problem is somewhat complex,[21, 22] but for practical purposes it may be said that a run of seven or more, either up or down or above or below median, is significant evidence for entry of an assignable cause. This technique is illustrated in Fig. 10.

Sampling Inspection. Statistical sampling inspection plans may be applied whenever the purchaser is willing to take a slight risk of accepting a small proportion of product considered defective. Even with 100% inspection, however, it is usually found that a small proportion of defective product is shipped, as proved by reinspection of material that had been inspected 100% and accepted. Sampling inspection can never guarantee an accepted product that is entirely free from defects, such as might be required in parts used in critical positions; however, neither can 100% inspection. A product inspected 100% twice is required here. Sampling inspection has been found very useful in controlling the flow of good products from department to department within a plant, as well as for final inspection, and should be used where the cost of 100% inspection cannot be justified or where tests are destructive and 100% inspection is impossible.

Statistical sampling inspection will function most economically after statistical control has been attained, as indicated by the control chart. Consequently, installation of these procedures generally results not only in decreased cost of inspection but also in increased production and greatly decreased rejections. After the sample inspection procedure is in operation, the entrance of an unfavorable assignable cause results in reversion to 100% inspection in some types of plan or to the use of a more stringent plan with greater rejection of complete lots in other types of plan. In either instance, strong pressure is brought to bear on the operator, and diligent effort is expended to eliminate the assignable cause, resulting on the whole in greatly decreased rejections.

Plans for statistical sampling inspection are built on a detection feature and are designed to reject when the quality becomes unusually bad. If quality becomes unusually good, sampling can be further reduced. It is never possible to estimate the quality of the lot from a relatively small sample. The plans operate so as to give the customer reasonable assurance that he is receiving a product of satisfactory quality and to give him protection against the acceptance of inferior lots or the acceptance of a substandard product in the long run. The plans also operate so as to give the producer reasonable assurance that good material will not be rejected too frequently.

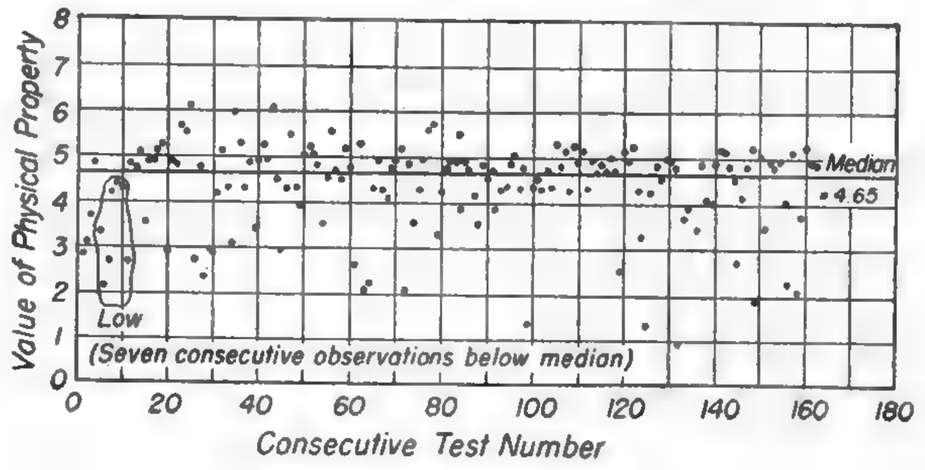

Fig. 10 Analysis of runs

When inspection with "go or no go" gages is carried out and material is classified as good or bad, a variety of plans is available, any of which will operate so as to guarantee that, independent of the quality of the material to be inspected, the material accepted or rejected will conform to the consumer's risk of accepting bad material and to the producer's risk of rejecting good material. Good and bad materials are defined by agreement as containing certain specified quantities of rejects. The following are the popular plans in use at present for this type of inspection.

The Dodge-Romig Plans.[36] These plans, of both single and double sampling types, are designed to guarantee either a maximum percentage defective in accepted lots,

or a maximum average outgoing quality limit. The consumer's risk is fixed at 10% and the producer's risk is about 5%. The plans assume that rejected lots will be inspected in detail 100%. When the size of lot and process average for defects is known, the plans list the size of sample to be taken, along with the number of rejections permissible in the sample for acceptance, reinspection (double-type plan), or rejection. The plans are designed to give a minimum of inspection if incoming material is at the process average. Examples of the application of these plans are discussed in reference 37. It should be noted that economies obtained in inspection are greater, the larger the lot size, but that lots must be homogeneous or misleading results may be obtained. Double sampling tables are used mainly for the psychology of a second choice; there is actually not much greater chance for acceptance, and these plans will not necessarily pass the greatest proportion of lots without inspection.

Army Ordnance Plans.[38] These plans are also of either the single or double sampling type and were designed mainly to keep the rejection of satisfactory goods at a minimum. After the acceptable quality limit for defects has been decided, the "normal" tables show the necessary samples to take and the defects permitted for various sizes of lots. Inspection results are also checked cumulatively. If the producer's quality becomes bad, inspection is automatically made more stringent; if the quality improves, the "reduced" inspection tables may be used with consequent greater savings in inspection costs.

Sequential Plans.[39] Based on assumed or negotiated values for good and bad quality, and the consumer's and producer's risks, limits for acceptance or rejection in samples ranging in number from one to as many as several hundred, are calculated from a simplified formula presented in reference 39. Successive samples are then taken until a decision is reached, and the material is either accepted or rejected. On material unquestionably good or bad, these plans give a decision quickly, but extensive testing may be required on borderline material.

Each of the foregoing types of plan has advantages and disadvantages, both practical and theoretical in nature. Single-sampling plans are simple to understand and it is not necessary to hold the lot for reinspection; but ordinarily somewhat more inspection is required than for double or sequential sampling. Double-sampling plans offer the second choice and are psychologically good. An effective reduced inspection plan is available in the double-sampling Army Ordnance Table. Sequential-sampling plans may not be convenient from a practical viewpoint because of the necessity of holding the lot until the samples are inspected piece by piece. As a rule, sequential plans will result in somewhat reduced inspection, but on certain lots a long time may be required for a decision.

Shewhart's control chart technique can also be applied to give a variety of plans for acceptance-rejection. However, this work requires a competent statistician, co-operating with the engineering staff.

When inspection involves actual measurements of the quality characteristic in question, the two most popular plans are Shewhart's control chart technique[10,12,23] and sequential-sampling plans for variables.[39] The previous remarks relating to these techniques, as applied to "go or no go" gage inspection, also apply here. When actual measurements are made, either of these techniques should be used and the actual measurements should be taken into account. This is a more reasonable way than to consider the material good or bad, if conforming or nonconforming to specified tolerance limits, since the degree of goodness or badness, as evident from the actual measurements, appreciably reduces the sampling required for making a decision concerning the lot.

The foregoing principles of statistical sampling inspection should eventually find wide application in the field of specifications, particularly when tests are destructive or expensive. After painstaking and expensive physical and chemical tests have been made on samples taken from the product, most present-day specifications are written so that it is still uncertain whether or not the material is suitable for the actual requirements of the user. There has been a decided lack of application of knowledge of the relationship of a sample to the whole. Today, most sampling inspection in specifications leads to acceptance or rejection on the basis of chance, and the customer usually gets a product that is precisely what the manufacturer offers for inspection. Technical publications[40,41,42] contain examples of the need and utility of modern statistical techniques in the development of satisfactory specifications.

The Crystal Structure of Metals and Alloys

By Kent R. Van Horn*

THE various elements crystallize according to a definite pattern or symmetrical arrangement of atoms that is repeated at regular intervals to form a section of any size. The three-dimensional latticework of imaginary lines connecting the atoms is called a space lattice. The smallest prism which possesses the full symmetry of the crystal is termed the unit cell. Each unit cell in a space lattice is identical in shape and orientation with every other. The type and dimensions* of the unit cells of most elements have been determined and tabulated in X-ray books[1,2,3,4,5] and are summarized on pages 20 and 21 of this Handbook.

Only 14 types of space lattice are possible (Fig. 1) and they fall into the seven crystal systems, each possessing certain characteristics as to equality of angles and lengths of the co-ordinate axes. The features that typify the seven crystal systems are:

1 *Cubic* (sometimes called isometric or regular). Three equal axes mutually perpendicular.
2 *Tetragonal.* Two equal axes perpendicular to each other and to a third (unequal) axis.
3 *Hexagonal.* Three equal axes inclined at an angle of 120 deg and a fourth (unequal) axis perpendicular to their plane.
4 *Rhombohedral.* Three equal axes mutually inclined at an angle not equal to 90 deg.
5 *Orthorhombic.* Three unequal axes mutually perpendicular.
6 *Monoclinic.* Three unequal axes, only one of which is perpendicular to the other two.
7 *Triclinic.* Three unequal axes, no two of which are perpendicular.

It is necessary to have a method for describing the faces of a crystal or the atomic planes within a crystal or a space lattice. The Miller indices are generally used to show the relationship of the planes with respect to the co-ordinate axes. These indices, *hkl,* are simply the reciprocals of the intercepts of a plane on the three crystal axes, *X Y Z* (edges of unit cell). The intercepts are measured in unit distances along the three axes, and not in centimeters. Thus, if a plane intersects the *X* axis at a positive unit distance and is parallel to the *Y* and *Z* axes, the intercepts are 1 ∞ ∞ and the indices (100). A plane cutting each of the three axes at unity on the positive side of the origin would be the (111) plane. If a plane cuts any axis on the negative side of the origin, the corresponding index would be negative and is designated by a minus sign above the number ($\bar{1}12$). A specific plane is enclosed by parentheses (100); a family of planes of similar form in curved brackets {100}, meaning (100) + (010) + (001) + ($\bar{1}$00) + (0$\bar{1}$0) + (00$\bar{1}$); and a direction or line in a crystal by a square bracket [100]. The indices of a direction are the smallest integers proportional to the co-ordinate differences, in terms of the parameters, between equivalent points lying on a crystal line. Therefore, reciprocals are not used in determining the indices of a direction. A full

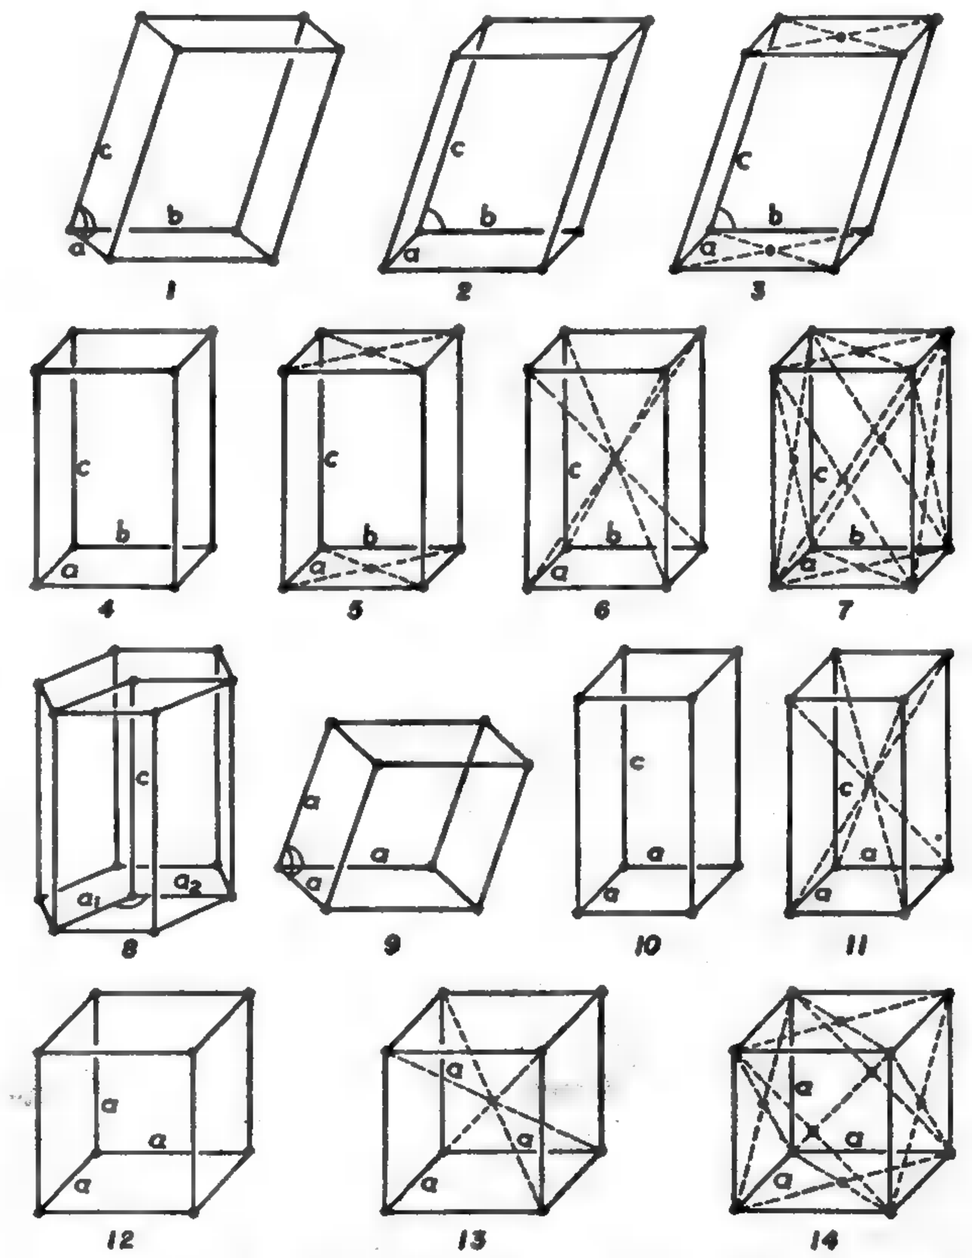

Fig. 1 The 14 space lattices illustrated by a unit cell of each: (1) triclinic, simple; (2) monoclinic, simple; (3) monoclinic, base-centered; (4) orthorhombic, simple; (5) orthorhombic, base-centered; (6) orthorhombic, body-centered; (7) orthorhombic, face-centered; (8) hexagonal; (9) rhombohedral; (10) tetragonal, simple; (11) tetragonal, body-centered; (12) cubic, simple; (13) cubic, body-centered; (14) cubic, face-centered. (C. S. Barrett[4])

set of equivalent directions (similar form) are indicated by carets <100>, representing [100] + [010] + [001] + [$\bar{1}$00] + [0$\bar{1}$0] + [00$\bar{1}$]. The cubic system is the only one

* Chief, Cleveland Research Division, Aluminum Research Laboratories, Aluminum Company of America

* The characteristic magnitude for defining the unit cell or a point in the cell is called the parameter. The edges of the unit cube *a, b, c* and the angles α (between *b* and *c*), β (between *c* and *a*) and γ between *a* and *b*) are its parameters.

in which each direction is perpendicular to a plane of the same indices.

Two methods are in common use for identifying planes and directions in the hexagonal system: one with indices consisting of three and the other, of four numbers. Only three axes a_1, a_2, and c are considered in the first method while four axes a_1, a_2, a_3, and c are in the other method (Fig. 1). The reciprocals of the intercepts of a plane on the axes are reduced to the smallest integers in the same manner as for other crystal systems.

A periodic table of the elements is reproduced in Fig. 2, with the inert gases and the metals beryllium and magnesium appearing twice to complete the symmetry of the arrangement. The number in the periodic system is indicated above each member of Group I and above the last element occurring on any horizontal line. The large majority of the metals crystallize according to three of the fourteen space lattices—the face-centered and body-centered of the cubic, and the close-packed type of the hexagonal system—and are enclosed by characteristic designations. All polymorphic modifications having any of these three atomic arrangements are represented by additional outlines (Fe, Co, Tl, and others). The complex lattices are not indicated. The majority of the metals, which generally have one (or more when there are polymorphic modifications) of the three lattices of high symmetry, appear at the left and the central part of the table. The nonmetallic elements, excepting the inert gases of Group VIII, are located at the extreme right of the table and have more complicated unit cells.

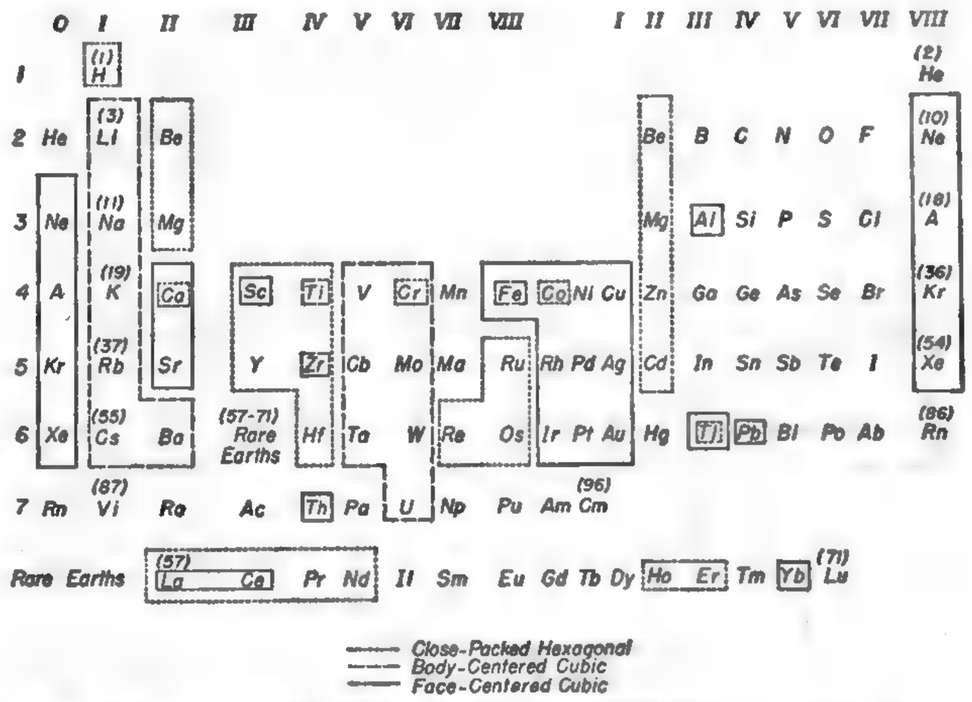

Fig. 2 Periodic table showing the chemical elements that have crystal structures of high symmetry

Since a high degree of crystalline symmetry (for example, face-centered cubic, body-centered cubic, and close-packed hexagonal arrangements) is responsible for many of the important properties of metals, these types of lattice will be described briefly. The plasticity of metals is generally attributed to movements along specific crystallographic planes in certain directions, all the atoms in one series of planes moving as a block relative to a similar series of parallel planes. The planes of easiest slip generally have the greatest atomic concentration and the associated characteristic of a large distance between the intervening planes (interplanar distance). The latter feature implies that the restraining forces acting between consecutive planes will be a minimum. Also, slip within the favorite planes proceeds most easily along the atomic rows of highest density. It is the flowing or gliding movement along these planes of atoms which permits a solid metal to alter its external form. The three lattices of high atomic symmetry have more densely populated planes and lines of atoms than the complex structures. The three simple atomic arrangements also exhibit different degrees of plasticity; for example, metals crystallizing in the close-packed hexagonal lattice are generally less ductile than those of the face-centered cubic type.

Face-Centered Cubic Lattice. A more concrete picture of the common metal crystal structures can be obtained from Fig. 3, 4 and 5, which were reproduced from Hume-Rothery's treatise on alloys.[6] Figure 3a shows the face-centered cubic unit cell with an atom located in each corner and center of each face of the cube. Figure 3b illustrates the same configuration repeated for a number of cells, but the atoms are represented by spheres in contact. This type of lattice is termed "close-packed" because the most intimate possible association of the spheres results. Although

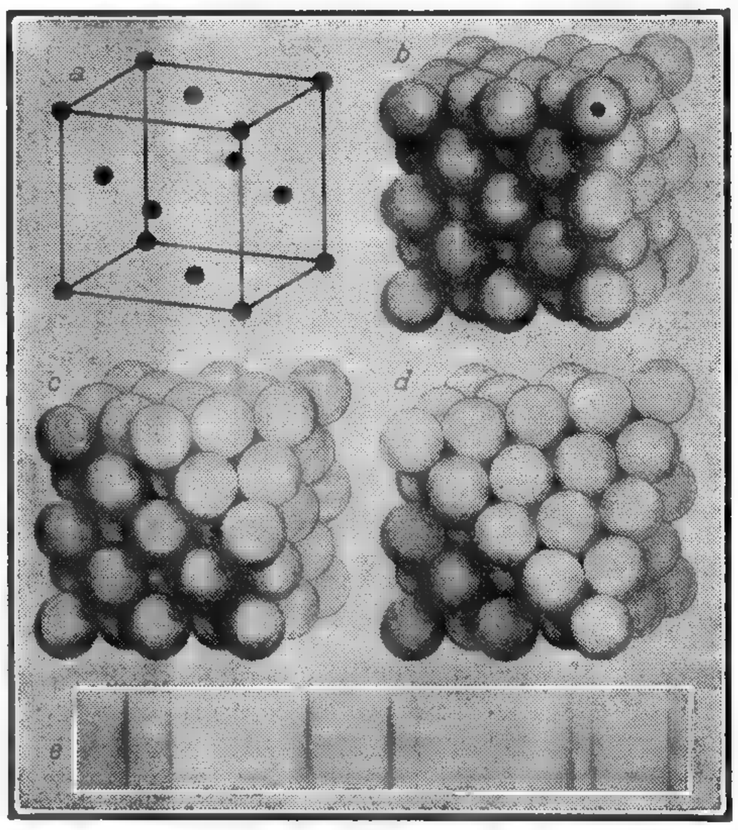

Fig. 3 Face-centered cubic structure. (*a*) Face-centered cubic unit cell. (*b*), (*c*), (*d*) Face-centered cubic packing of spheres in contact.[6] (*e*) X-ray photogram of face-centered cubic copper. Mo-K*a* radiation.

Fig. 3b typifies the manner in which the atoms exist in metals more nearly than do the voids suggested by Fig. 3a, it should not be inferred that an atom is a hard ball of specific dimensions. If the sphere marked with a dot is removed from a corner of a cube Fig. 3b, the arrangement of Fig. 3c is obtained, exposing a plane of six spheres (appearing lighter in the illustration). Lines through the centers of the spheres form an equilateral triangle. Figure 3d shows the arrangement on this plane more clearly after these six spheres are extracted. The same operation could be initiated from any of the corners of a cube, thereby uncovering eight similar close-packed planes, in which each atom is at the center of a hexagon formed by lines through the centers of its six equidistant neighbors. Because the eight planes, if extended, would form the faces of an octahedron, they are called the octahedral or {111} planes. There are only four series of {111} planes, since the opposite faces of the octahedron are parallel. The three rows of close atom packing on the {111} planes are the sides of the equilateral triangles or <110> directions, which are the normals to the faces of the regular dodecahedron. The face-centered cubic lattice has, therefore, four close-packed planes {111} and twelve close-packed directions <110>, amounting to the highest degree of atomic concentration and symmetry encountered in any lattice. Consequently, the metals of this type (such as aluminum, copper and silver) are ductile, easily deformed, and good as conductors of heat or electricity. The X-ray pattern characteristic of this space lattice is included as Fig. 3e.

Body-Centered Cubic Lattice. The body-centered cubic unit cell has an atom at each corner and one in the center of the cube, as illustrated in Fig. 4a and represented by spheres in contact in Fig. 4b.[6] If the two dot-marked spheres of the nearest cube edge of Fig. 4b are removed, the result is shown in Fig. 4c. The plane exposed is that containing the most atoms for this space lattice, namely, the face diagonal or dodecahedral (110) of which there are six sets. The large voids or interstices between the atoms suggest that this plane is not one of close packing compared with the face-centered cubic {111} planes. Therefore, the body-centered cubic metals do not have a well-defined slip plane, but deform by movement along various planes {110}, {112}, {123}, depending on the relations of

stress and the important directions <111>. Figure 4c exhibits close-packed lines of atoms, the diagonal <111> rows, which are normal to the four sets of octahedral {111} planes. With no close-packed planes and only four close-packed directions, this condition does not permit a high degree of plasticity and the metals of this type (such as *a* iron, molybdenum, or tungsten) have great strength and medium ductility. The X-ray pattern characteristic of this lattice is illustrated in Fig. 4d.

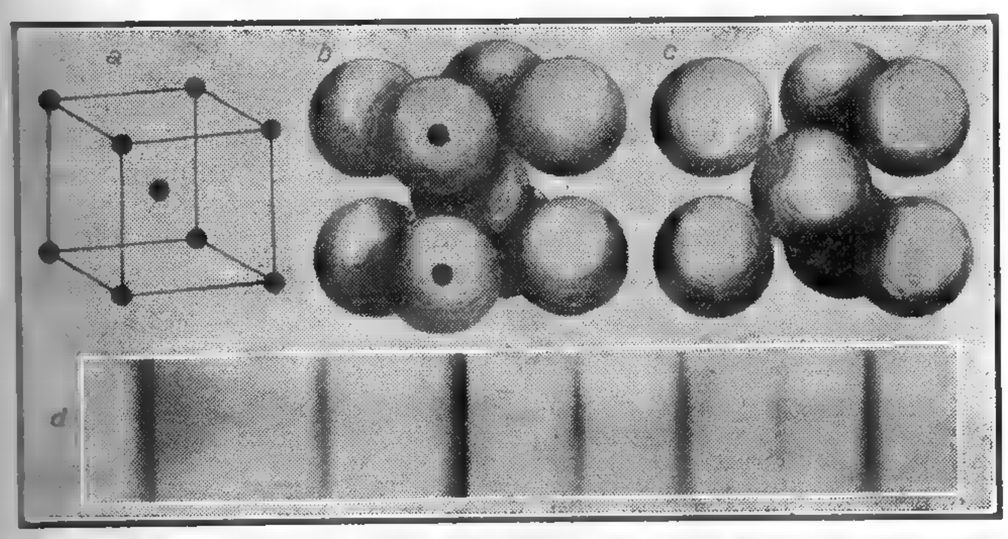

Fig. 4 Body-centered cubic structure. (*a*) Body-centered cubic unit cell. (*b*), (*c*) Body-centered cubic packing of spheres in contact.[6] (*d*) X-ray photogram of body-centered cubic iron. Mo-K*a* radiation

Close-Packed Hexagonal Lattice. The close-packed hexagonal unit cell is represented in Fig. 5a and is also illustrated by spheres in contact in Fig. 5b. The close packing of spheres approaches that of Fig. 3b. The upper and lower horizontal planes of spheres exhibit the hexagonal grouping of one atom intimately surrounded by six neighbors. These planes of high atomic concentration are the basal faces {001} or {0001}, *see* Fig. 5, and the lines of close-packing on these planes are parallel to the edges of the first-order prism faces <210>. Since the opposite faces of the hexagon are parallel, there is one close-packed series of planes {001} and three important rows <210>. Consequently, it is to be expected that slip may proceed along specific planes in certain directions in this structure, but not with the freedom of the face-centered cubic lattice (four planes, twelve directions). The hexagonal elements (such as cadmium, magnesium and zinc) can accommodate their structure to stresses by another mechanism, twinning, which alteration generates new additional slip planes {001}, thereby approximating the plasticity possessed by the face-centered cubic metals and surpassing that of the body-centered cubic metals. The X-ray pattern characteristic of the close-packed hexagonal cells is reproduced in Fig. 5c. Metals crystallizing with lower symmetry than the face-centered cubic, body-centered cubic and close-packed hexagonal arrangements, such as orthorhombic, monoclinic, or triclinic, do not have the close-packed planes and directions for slip or deformation. They are, therefore, relatively brittle and are used less extensively than the more plastic metals.

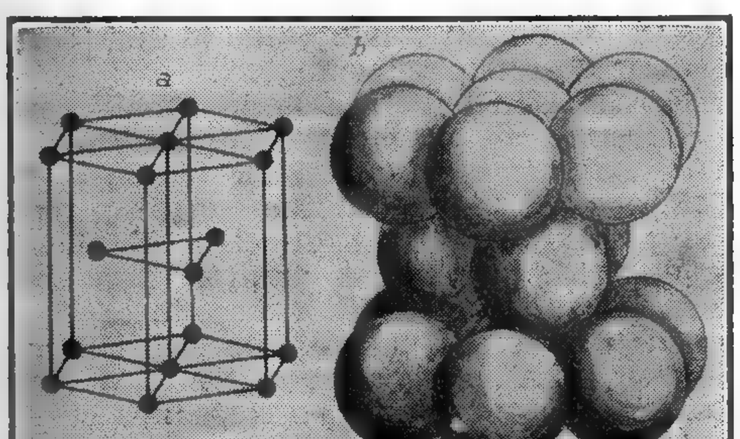

Fig. 5 Close-packed hexagonal structure. (*a*), (*b*) Close-packed hexagonal unit cell and packing of spheres in contact.[6] (*c*) X-ray photogram of close-packed hexagonal zinc. Mo-K*a* radiation

Polymorphic Modifications of Metals. When a mineral crystallizes in two or more different forms, it is termed polymorphic. The prefixes "di" or "tri" are employed to denote the number of modifications, if there are two or three. Metals that occur in two or more forms, characterized by either different crystal structures or marked differences in energy content, or both, are generally called "allotropic". The terminology has been the source of confusion, because allotropy has been interpreted by some to represent a reversible change of a physical property, while others consider allotropy to be equivalent to polymorphism, involving only an alteration in the crystallinity. The disturbing effects of impurities frequently cause a variation in some physical property, which has been erroneously interpreted as a significant allotropic change. Although allotropy may be considered by some to denote a crystal structure transformation, it seems advisable to use the term "polymorphism", so that there will be no doubt as to the nature implied.

Precision X-ray investigations of the elements have disclosed that at least fifteen metals (calcium, cerium, chromium, cobalt, iron, lanthanum, manganese, rhodium, scandium, thallium, tin, titanium, tungsten, uranium and zirconium) exist in two or more different crystal forms. The names of the polymorphs, the types of crystal structure and the temperature ranges of stability have been tabulated.[4,5,6,7] In addition to the metals, carbon, nitrogen, oxygen, phosphorus, selenium and sulfur have polymorphic modifications. The elements arsenic, barium, beryllium, erbium, hafnium, neodymium, praseodymium, ruthenium and strontium may possibly be polymorphic.

The classic example of polymorphism is the transition, at 13 C, of metallic white tin to the gray powder frequently called "tin pest". White tin is tetragonal and the gray variety, diamond cubic.

The much discussed phase change from α to γ iron, on heating, is the basis of heat treating steel. For a considerable period of time there were supposed to be four crystalline forms, namely, α, β, γ and δ iron. However, the nature of the transformations was established by the X-ray analysis of pure electrolytic iron at elevated temperatures.[8] The so-called "β" iron was found not to be a polymorphic modification and pure iron exists in only two different crystalline forms corresponding to the two transformations, $\alpha \rightleftarrows \gamma$ at A_3, and $\gamma \rightleftarrows \delta$ at A_4. Both α and δ iron are body-centered cubic; the γ form is face-centered cubic.

Alloy Structures. When two metals are melted together and then solidified, a number of different structures may result. The various types are derived from the degree of mutual solubility of the component metals, their ability to combine or form intermediate phases, and the effect of temperature on these tendencies. The structural types which the elements may assume in the solid are represented by phase diagrams, and are characterized by (1) elements, (2) solid solutions and (3) intermediate phases.

There is at least some solid solubility of any two metals. However, the solid solubility of one metal in another may be indeterminately small. In this instance, the metal is considered to exist in the binary system and if the metal is not polymorphic, the same crystal lattice will exist up to the melting point.

A solid solution of two or more elements is defined as a phase in which the crystal lattice of only one component is retained. This includes complete solid solubility and restricted solubility, such as the end (terminal) phases of systems exhibiting immiscible regions (eutectic and peritectic) and intermediate phases. Solid solutions, representing either complete or restricted solubility, may be divided into two types—the substitutional class, and the interstitial group. When the solute atoms replace or are substituted for some of the atoms of the solvent lattice, the solution is termed "substitutional". Substitutional solutions contract or expand the dimensions of the solvent metal cell, depending on the size of the replacing solute atoms. In the second, or interstitial type, the solute atoms are dispersed in the vacant spaces between the solvent atoms; that is, they are introduced into the lattice in addition to the solvent atoms. An interstitial solute always enlarges the solvent lattice. The interstitial solutions occur infrequently and are confined to systems where the diame-

ter of the solute atom is appreciably smaller than that of the solvent atom. Boron, carbon, and nitrogen are prone to form interstitial solutions with the transition elements—for example, carbon in γ iron (austenite). The crystal structures of continuous or extended terminal solid solutions are generally of high symmetry (Fig. 3 to 5).

Intermediate phases are frequently referred to as intermetallic compounds or solid solutions, depending on certain phenomena and preferences of definitions. With the older methods of determining phase diagrams, it has been difficult to define the limits where a solid solution begins or a compound terminates. No satisfactory classification of intermediate phases was evolved until the advent of X-ray analysis. The term "intermediate phase" is used in this Handbook to denote those reaction products of two or more elements having a crystal structure different from that of any of the components.* An intermediate phase may have a restricted or extended range of homogeneity. A variable composition is obtained by a change in the numerical atomic ratios of the elements composing the phase, effected generally by atomic substitutions and infrequently by interstitial additions. In several instances, two atoms or a chain of atoms replace a single atom in a substitutional region of an intermediate phase. The crystal structures of some intermediate phases are of high symmetry (Fig. 3 to 5) but most are complex arrangements.

A substitutional solid solution ordinarily exhibits a random or disordered distribution of the solute and solvent atoms in the solvent cells. However, some solid solutions, when slowly cooled or annealed at low temperatures, possess definite ordered positions of both types of atom in the solvent space lattice (superstructure). This re-sorting of atoms may occur in a solid solution when two elements, A and B, exist in concentrations approximately represented by the formulas AB and A_3B, such as AuCu, $AuCu_3$, $PdCu_3$. Also intermediate phases, having a variable composition in the range of the same atomic proportions as above, may experience an order-disorder change, as the β phase, CuZn.

It would appear that the ordered distribution is the stable condition at low temperatures in the susceptible composition. At high temperatures, where the alloy is less rigid, thermal movements tend to shuffle the atoms into random positions. The transition is not so abrupt as transformations involving a lattice change, but is gradual, so that many intermediate stages may be encountered. X-ray methods can follow the process accurately in either direction, since the ordered atoms give diffraction effects in addition to the reflections from the parent lattice.

* In a few systems, intermediate phases have the same type of structure as a component but appreciably different parameters.

The Interconversion of Atomic and Weight Percentages

By Cyril Stanley Smith*

THOUGH alloys are compounded and analyzed by weight, the research metallurgist frequently needs to know the relative proportion of atoms in an alloy. The conversion for binary alloys is done by means of the following formulas:

$$y = \frac{100\,\frac{x}{A}}{\frac{x}{A} + \frac{100 - x}{B}}; \qquad x = \frac{100\,yA}{yA + (100 - y)B}, \qquad (1)$$

where x and y are the percentages by weight and by atoms, respectively, of the element that has atomic weight A in a binary alloy with another element that has atomic weight B. The following rearrangement of these equations is easier to use:

$$y = \frac{100x}{x + \frac{A}{B}(100 - x)}; \qquad x = \frac{100y}{y + \frac{B}{A}(100 - y)}. \qquad (2)$$

The relation can be expressed also as a function of the ratio of the amounts of the two elements, because the ratio by weight is merely the ratio by atoms multiplied by the ratio of atomic weights, that is

$$\frac{x}{100 - x} = \frac{A}{B}\left(\frac{y}{100 - y}\right). \qquad (3)$$

By the use of a table of $f(x) = \log\left(\frac{x}{100 - x}\right) + 10$ and a table of log (A/B), the multiplication becomes simple addition just as in the use of ordinary logarithm tables. Such tables are given herewith.*

Use of the Tables.

1 First look up in Table I the value of log $\frac{\text{at. wt } A}{\text{at. wt } B}$ for the two components concerned. A is the element whose percentage is to be converted; B is the other, usually major, component. If the system is not represented in Table I, compute the figure from known atomic weights.

2 Find from Table II or III the value of $f(x)$ corresponding to the percentage figure (either atomic or weight per cent) that it is desired to convert.

3 If conversion is from *atomic* to weight per cent, *add* the two values. The resulting value of $f(x)$ corresponds to the desired weight percentage, which is found by consulting Table II or III again.

4 If conversion is from *weight* to atomic per cent, *subtract* log (A/B) to obtain a new value of $f(x)$ corresponding to the desired atomic percentage.

Conversion of Small Percentages. Small percentages may be converted by using the approximate formula $y = (B/A)x$. Sometimes it is simpler to use a correction factor $x[(B/A) - 1]$ to add to the weight percentage to obtain the atomic equivalent directly. Neither method should be used for percentages greater than about 0.3% except when the value of (A/B) is close to 1.

Conversions When Components Do Not Differ Greatly in Atomic Weight. A simple method due to Marsh [Metals and Alloys, 5, 48 (1934)] employs a correction curve to give a number to be added to the weight percentage to obtain the atomic percentage directly without multiplication. This is useful when the elements concerned do not differ much in atomic weight, systems such as Fe-V, Fe-Cr, Fe-Mn, Fe-Co, Fe-Ni, Cu-Zn, Ag-Cd, Pt-Au, Pt-Ir or Pb-Bi.

Conversions in Ternary Systems. Tables I, II and III cannot be used for ternary systems. Where great accuracy

* Director, Institute for the Study of Metals, The University of Chicago, Chicago

* Tables I and II and Fig. 1 are reprinted by permission of the American Institute of Mining and Metallurgical Engineers. Table III was prepared by the Computation Section of the Los Alamos Laboratory, Manhattan District. Further discussion of the principles involved in the conversions, will be found in AIME Contribution 60 (1933).

is not required, the graphical method described below may be used. On the triangle representing the composition of the system in the usual way, draw two lines from the corner representing the element of highest atomic weight (point C, Fig. 1) to two points (B', A') on the opposite side, located accurately so that, in Fig. 1, $\frac{AB'}{AB} = \frac{\text{at. wt } B}{\text{at. wt } C}$ and $\frac{BA'}{BA} = \frac{\text{at. wt } A}{\text{at. wt } C}$.

A line from point A then divides CB and CB' each into parts the ratio of which differs in the ratio of the distance of the intercepts from point A, and hence represents graphically equation 3 above.* This is true regardless of the relation among points C, B and A, but it is convenient to select these as the corners of the equilateral composition triangle.

A line $Apde$ (Fig. 1) passing through point p on the weight percentage scale, represents all binary alloys whose ratio of B to C is the same as at point p, and is given by point e on the binary side, BC. Point d represents the atomic ratio corresponding to this (more correctly, Cd/dB' is the desired ratio but the co-ordinates of the point d are exactly proportional to this). This is transferred to the

* This construction is useful in binary systems, but the accuracy obtainable is far less than by the use of the tables.

*A is the element whose percentage, either weight or atomic, is being converted; B is the other component, usually the major one.

*Editor's Note: Since the proof of this article was read, the Committee on Atomic Weights of the International Union of Chemistry has accepted 63.54 as the atomic weight of copper [J Am Chem Soc, 69, 731 (1947)]. The values in this table are based on the previously accepted atomic weight of 63.57 for copper. This can be corrected for by adding 0.0003 to all values in the copper column of the table.

Table II. Values of Log $\frac{x}{100-x} + 10$

x	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
See Table III for $x = 0.01$ to 4.99.

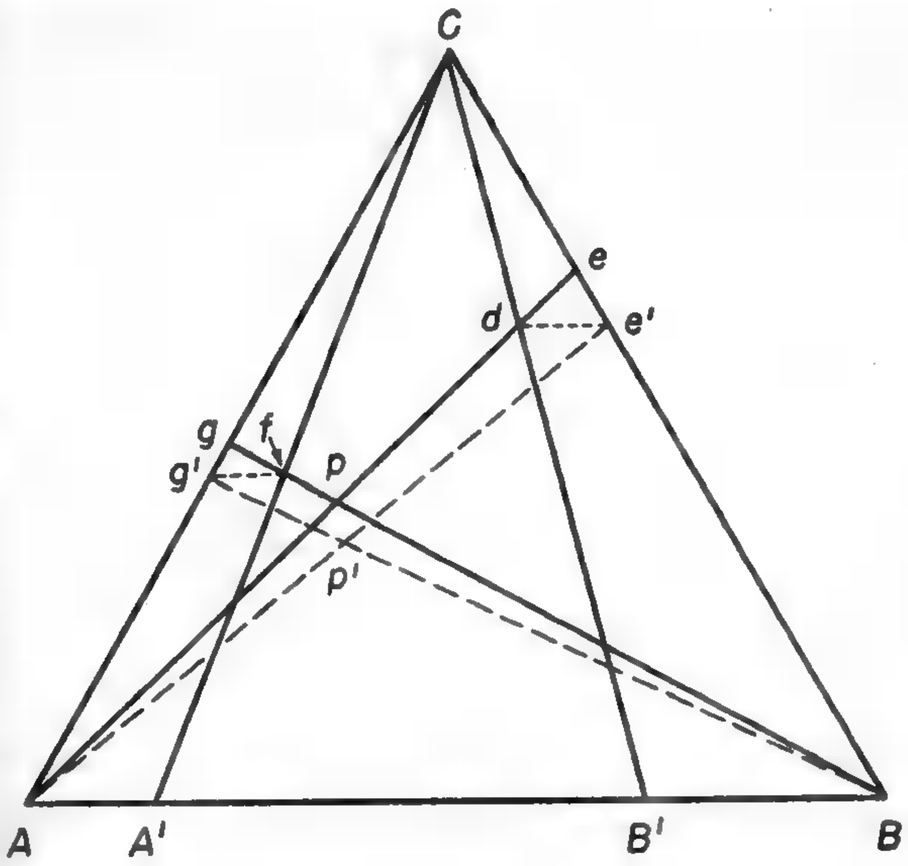
side of the standard equilateral triangle as point e' by drawing a line parallel to the triangle base. A new line joining e' to A then represents all alloys of the correct ratio of atoms B and C. A similar construction on the opposite side, using CA and CA', converts the line $Bpfg$ to the corresponding line $Bp'g'$ representing the atomic ratio, and the intersection, p', is the desired point corresponding to p, but in atomic instead of weight percentage.

In practice, using triangular co-ordinate paper, the lines CB' and CA' are established and drawn once and for all, while point d is found by a straight edge and transferred by eye to e', where a point is marked. Enough of the line $ap'e'$ is drawn to ensure an intersection. Similarly point g'



is found and marked; then p' is found and finally marked.

Though Fig. 1 shows the conversion in an equilateral triangle, and operation with an element common to both ratio lines, it is equally satisfactory to have points A' and B' *outside* the triangle, to use point A or B in place of C for one or both of the ratio lines, and to use an isosceles triangle where a larger scale is needed for one component. Just the base of such a triangle may be used and only the requisite portion of the lines CA' and CB' need be drawn.

Conversions of Volume Percentages. All the above methods are applicable for conversion from or to volume percentage of any elements or phases whose density is known. This is most useful in two-phase mixtures where the weight and densities of the component phases, not the elements, are used. In binary mixtures, compute the value of $\log \frac{\text{density } A}{\text{density } B}$ and use it in conjunction with Table II in exactly the same manner as the value of log (A/B) when converting between atomic and weight percentages—*subtracting* from the appropriate value of $f(x)$ if converting from weight to volume percentage, and *adding* if converting from volume to weight percentage.

Fig. 1 Conventional equilateral triangle of composition for a ternary system, showing constructions necessary for the graphical interconversion of atomic and weight percentages. See text for explanation.

Fluidity of Metals

By Charles W. Briggs*

THE term "fluidity" refers to the property of a metal which allows it to flow freely and evenly into a mold and fill it before such freezing occurs as would offer an obstruction to its further flow. This property is sometimes referred to as "castability", "runnability", "flowing power" or "fluid life". In the past, "fluidity", the word often preferred, had a specific physical meaning; namely, the reciprocal of the coefficient of viscosity. However, in recent literature the term "coefficient of liquidity" is preferred for this constant, thus allowing the broader field to be covered by "fluidity". Many have not yet accepted the term in its new sense, believing that old associations stand in the way of its adoption; hence the terms given above are often preferred.

When fluidity is considered in its broader aspects, it should not in any sense be identified with viscosity. The viscosity of a fluid in the physical sense is concerned with movements in the interior of the liquid; thus, at a given temperature it is a definite physical constant. The viscosity test, which is rather simple and accurate at relatively low temperatures, is exceedingly difficult to perform at the higher temperatures required by molten iron and steel. Therefore it has been necessary for foundrymen to devise a simpler method for the study of fluidity. In general, this test consists of pouring molten metal into sand molds that contain a cavity in the form of a channel. The test is concerned primarily with the fluid life of the metal, and measurements refer both to the metal and to the mold.

The fluidity of metal depends on two major factors: (1) properties of the metal and (2) variables of testing. The factors relating to the metal are those of viscosity, surface tension, surface films, gas content, suspended inclusions, and the mode of solidification and crystallization. The second set of factors includes the form of the test piece, the casting head, the properties of the mold, the rate of pouring and the degree of superheat.

Properties of the Metal. *Viscosity.* There is a general belief that molten metals differ widely in viscosity and that metals that flow poorly have high viscosity. In reality the viscosity of metals is very low; the kinematic viscosity is less than that of water in all metals investigated.[2] Also, since viscosity changes only slightly with change of temperature, it is really a negligible factor in casting. Two main methods are employed in measuring viscosity. In one method liquid metal is allowed to flow under a constant head through a capillary tube; in the other, some form of torsional pendulum is used. The first method can be applied only to metals of low melting point, since the capillary tube is constructed from glass or quartz. The second method may be used at relatively high temperatures with a fair degree of success, since the apparatus consists essentially of refractory cylinders or disks suspended in the molten metal and operating in torsional oscillations. Studies of tin and lead,[3] various brasses, bronzes, copper,[4] and cast iron[5] have been undertaken by the torsional pendulum method.

A critical review of the published data on viscosity was prepared by Andrade.[6] In this he developed a new theory of the inner mechanism of the viscosity of liquids, which has enabled him to calculate η with close approximation of the experimental values for a number of metals. These are listed in Table I.

Table I. Viscosity of Certain Liquids[6]

Substance	η, poise
At atmospheric temperature	
Water	0.0105
Just above the melting point	
Mercury	0.021
Lead	0.028
Tin	0.020
Copper	0.038
Iron	0.040

It may be concluded, therefore, that the viscosity of metals is only a small multiple of that of water; and that the kinematic viscosity (or viscosity divided by density), on the basis of which may be compared the effects of stresses resulting from viscosity in modifying the existing motion of a fluid, is considerably lower than that of water. Evidently the viscosity of metals is not closely related with casting behavior, and the effects that have been attributed to viscosity are mainly from other causes.

Surface Tension. When molten metals are poured into a sand mold, the mold surface is not wetted.[7,8] The rise of steel in a narrow channel is impeded by the surface tension of the liquid metal. This effect becomes less marked as the diameter of the passage is increased.

Bircumshaw[9] has tabulated values of the surface tensions

* Technical and Research Director, Steel Founders' Society, Cleveland

of some of the common metals, at temperatures not much higher than their melting points (Table II).

Table II. Surface Tension of Some Common Metals[9]

Metal	Temperature, deg Cent	Surface Tension, dynes per cm
Antimony	640	350
Bismuth	269	378
Lead	327	452
Mercury	20	465
Tin	232	526
Cadmium	320	630
Zinc	419	758
Silver	998	923
Copper	1131	1103
Gold	1120	1128
Iron (2.2% C)	1420	1500
Iron (3.9% C)	1300	1150

The deductions that may be drawn from the table above are these: (1) the surface tension of metals increases as the melting point increases; (2) from the figures for the two alloys of iron and carbon, steel has a higher surface tension than cast iron; and (3) since the surface tension of water at 20 C is only 81, the values for metals are relatively high. It has also been determined that surface tension generally diminishes as temperature increases.

A high value of surface tension has the effect of increasing the pressure required to cause the metal to enter and flow along a narrow channel, but the direct effect of the true surface tension of many metals is almost overshadowed by the effect of surface films which exert an influence equivalent to that of greatly increased surface tension.

Surface Oxide Films. It has been found that surface films affect the flowing power, especially of nonferrous alloys. In a study made on brass ingots, Genders and Bailey[10] showed that the oxidation of a stream of molten brass by contact with air creates a surface film of zinc oxide which raises the apparent surface tension of the metal, restricts the flow, and is an inevitable cause of defects in ingots.

Determinations of the apparent surface tension of oxidized and clean molten aluminum have been described by Portevin and Bastien.[11] They show that the effect of the oxide film is to increase the value nearly three times. This surface film property of aluminum also affects alloys in which it is present. According to Desch,[2] the difficulty of casting aluminum bronze is caused by the formation of a skin so tough that it hinders pouring and, when broken into fragments, is entangled in the metal, making a dirty casting. When the oxide is soluble in the molten metal, no film is formed, so copper, cast iron and nickel pour in a clean stream.

According to Greaves[12] there is evidence that strongly suggests the existence of films in an overoxidized steel killed with aluminum. Such a surface film would reduce the fluidity. A chromium-rich oxide skin is also thought to have a marked effect on the fluidity of steels.

Gas Content. In the application of data relating to the effect of surface tension in a metal flowing in a channel, one difficulty arises from the fact that the metal is often not in actual contact with the mold, but is separated from it by a thin layer of gas, either issuing from the metal or arising from the material of the mold. Gases that are given off from metal during its flow through a casting, probably increase the resistance to flow. It is also probable, however, that gas issuing from the metal tends to break up oxide films or prevent the formation of them, thus improving fluidity.

Suspended Inclusions. Solid matter in suspension causes a rapid rise in the apparent viscosity of a liquid, since suspended particles hinder flow. A liquid in which more than a small portion of particles is suspended will give a higher value than the same liquid free from particles.

Many steel foundrymen have attributed fluidity to the effect of dissolved oxides. There is no evidence to suggest that oxide in solution would in itself improve the fluidity of cast steel. It may, however, alter the surface tension or produce some effect on surface oxide films.

Solidification and Form of Crystallization. Tests on binary alloys led Portevin and Bastien[13] to formulate two laws: (1) Fluidity varies inversely with the interval of solidification. It will be greatest when the melt is homogeneous (as in pure metals, or eutectics) and least for the saturated solid solutions. (2) Fluidity depends on the crystal form of solidification and is relatively much greater when the liquid forms crystals with convex faces than when it forms dendrites. The above principles have been confirmed by other investigators.

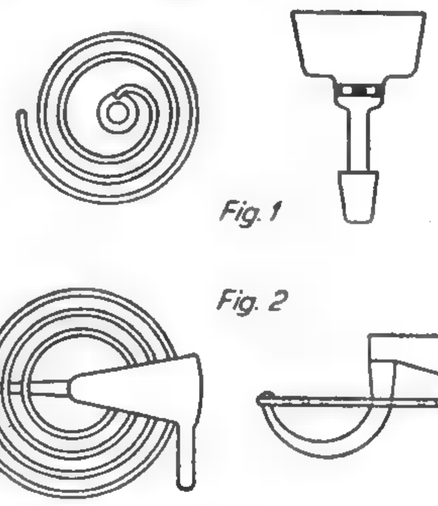


Fig. 1 European type of fluidity mold (Cury)
Fig. 2 Bureau of Standards type of fluidity mold (Saeger and Krynitsky)

Variables of Testing. *Form of the Test Specimen.* Various types of test specimens have been used to measure fluidity in the past. Unfortunately many of the investigators have adopted totally new specimens or have so altered specimens previously used that it is not possible to compare data. It appears desirable that a standard test specimen and testing procedure be devised, so that fluidity values will be more comparable.

In nearly all the tests that have been used to evaluate fluidity of molten metals, a channel of small cross-sectional area is provided, through which the molten metal is caused to flow. The channel is long enough to extract sufficient heat to cause solidification of the metal and to stop movement of the stream. The length of flow is regarded as the measure of fluidity. If a test specimen is to develop good sensitivity, it must be designed with a definite relationship among (1) the factors of force acting to drive the metal through the flow-channel, (2) the dimensions of the flow-channel, and (3) the thermal characteristics of the mold material. The flow-channel of most of the test specimens

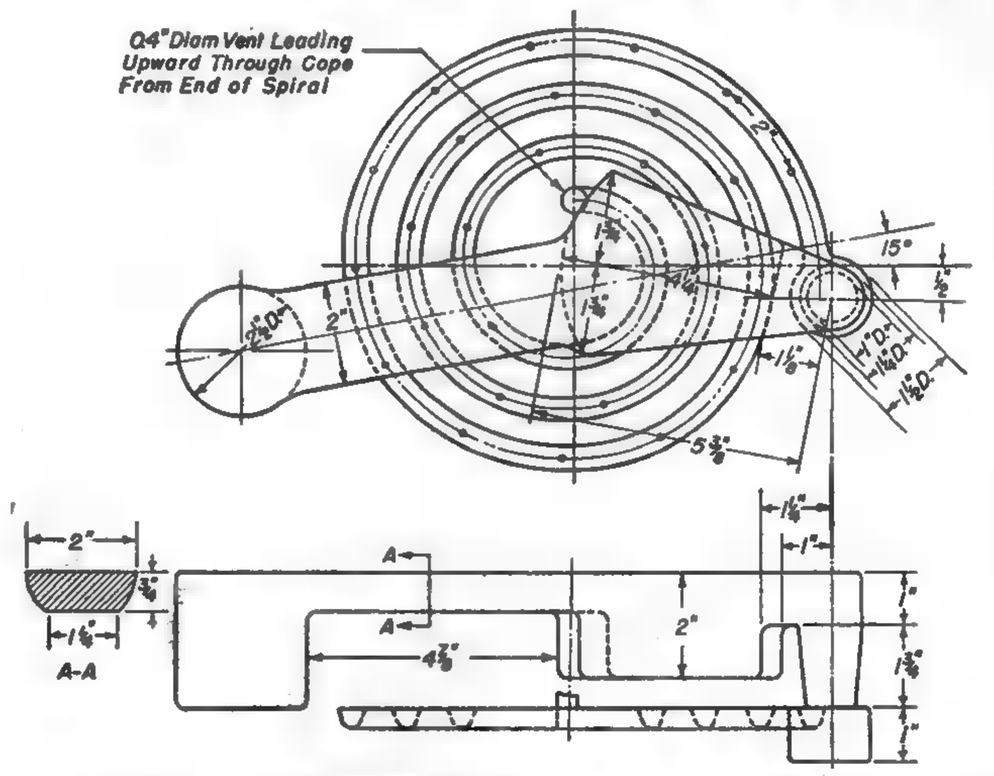

Fig. 3 Spiral piece for testing fluidity, used in U. S. Naval Research Laboratory (Taylor, Rominski and Briggs)

has been constructed in the form of a spiral (Fig. 1, 2 and 3). A straight flow-channel of short length (Ruff type,[21] Fig. 4) is also used. Studies concerning the shape and dimensions of the flow-channel indicate that the circular or half-circular and trapezoidal sections are the preferred types, since in these types a minimum surface of contact exists between the metal and mold. The cross-sectional area of the flow-channel is usually from 1/12 to 1/7 sq in.[20]

Gating Methods. The system of gating should be designed so that metal is available at the entry of the flow-channel under a constant pressure-head and without

appreciable inertia. These ideal conditions are virtually unattainable, but they must be approached as nearly as possible. Although a horngate has been used successfully in testing the fluidity of cast iron, a straight down gate is prescribed for steel and magnesium. The cross-sectional area of the sprue must be considerably larger than that of the flow-channel. A six-to-one ratio is recommended. The sprue should be short and must be filled as rapidly as possible after pouring is started.

Casting Head. One of the essential parts of the mold is the casting head and the metal reservoir. The height of these above the flow-channel affects the length of the spirals run. A reservoir must be provided to break the fall of the metal from the ladle and to supply an even flow of metal to the down gate of the mold.

Properties of the Mold. Important data have been recorded, especially for alloys melting at a low temperature; in these investigations permanent molds have been used. However, in the last few years sand molds have been used almost entirely, since for reasons of sensitivity, a mold should have the least possible tendency to chill.

Slight variations in the temperature of the mold and the state of dryness of the mold do not affect the length of the spiral obtained. The permeability of the sand should be sufficient to insure an easy escape for the gas produced by the contact of the liquid metal with the mold. The molding sand should be so bonded that the permeability is not less than 75 by the AFA permeability test.

To insure an easy escape of gas or air from the mold, the end of the spiral should be well vented. The bond strength of the sand should be sufficient to avoid erosion of the sand by the liquid metal. Mold surfaces may cause variations in the length of spiral obtained. Factors that influence the character of the results are (1) grain size of the sand, (2) mold washes and (3) surface coatings.

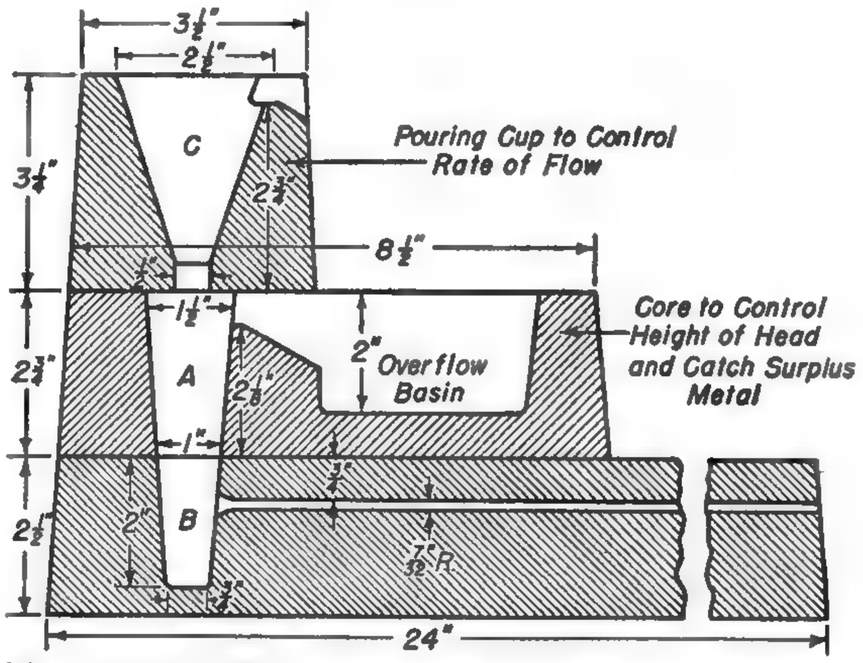

Fig. 4 Ruff's fluidity test mold having a straight flow-channel

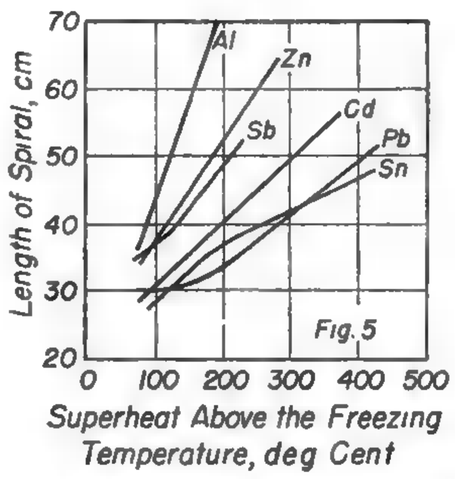
Rate of Pouring. The length of the test specimen depends also on the speed of running the metal in the flow-channel. This speed depends, in turn, on the rate at which the mold is poured. If the pouring rate varies between one test and another, the length will vary in the same way. Therefore, exceptional care must be taken to pour all molds at the same rate (preferably a fast rate) and to insure that the pouring height above the mold is always the same.

Degree of Superheat. As the temperature of the molten metal is raised, the length of the resulting cast flow-channel is increased. An increased length of flow-channel with increase of casting temperature does not necessarily imply that the metal is more fluid at the higher temperatures, since the additional spiral length may result entirely from the increased ranges of temperature, through which the metal cools while it is flowing in the flow-channel. It should also be emphasized, however, that the degree of superheat may alter the composition of the metal or increase surface oxide films or gas content so much that the channel length is affected.

There is some tentative evidence[22] which indicates that many alloys have approximately equal fluidity when heated an equal amount above their liquidus temperatures.

Accuracy of Test Methods. Before proceeding to the results that have been obtained by testing methods, it is necessary to emphasize that it is difficult to establish a correlation between these tests and actual foundry experience unless numerous tests are made under foundry conditions. In fact, little correlation has been established to date. The probable reason for not establishing better correlation is that the test methods are inadequate, involving so many factors that it is impossible to avoid erratic and meaningless results unless extreme care is used. Also there is no one standard test method.



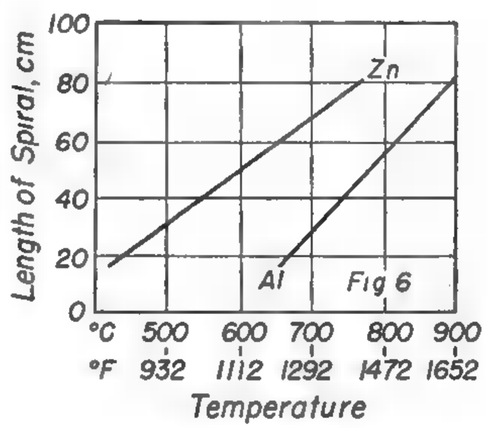


Fig. 5 Fluidity of metals that have low melting points; cast in permanent molds; spiral cross-section area, 0.170 sq in. (Portevin and Bastien)
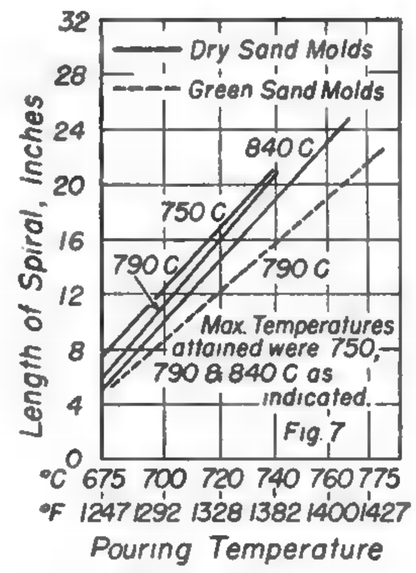
Fig. 6 Fluidity of zinc and aluminum cast in permanent molds (Portevin)

Fluidity of Metals With Low Melting Temperature. Most of the experimental work on the fluidity of metals with low melting temperature has been carried on by Portevin and Bastien,[13] using a permanent mold. The data, as set forth in Fig. 5, are complete and are plotted so that fluidity values can be correctly evaluated. In Fig. 6 the curves for zinc and aluminum are plotted directly against the temperature and offer conditions comparable with those set forth in Fig. 5.

A few studies have been carried on, using aluminum in sand molds. The results of Saeger and Krynitsky[14] (Fig. 7) are typical of what may be expected of commercial aluminum. These authors studied the effect of various maximum temperatures on the fluidity and explain the decrease in fluidity, accompanying increase in heating temperature, as caused by absorbed gas.



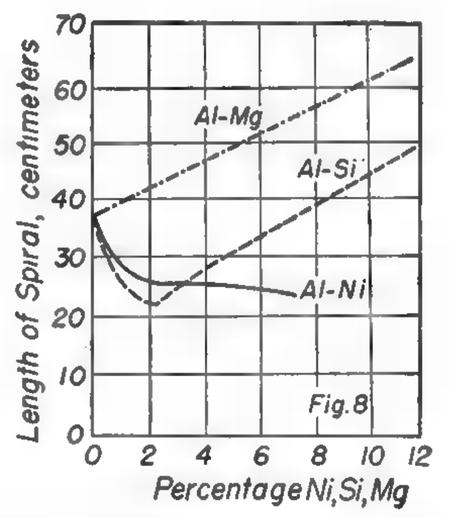


Fig. 7 Fluidity of commercial aluminum cast in a sand mold—spiral cross section, 0.066 sq in. (Saeger and Krynitsky)
Fig. 8 Effect of alloying elements on the fluidity of aluminum cast in permanent mold (Portevin)

The effect that alloy additions have on the fluidity of aluminum is shown in Fig. 8. It may be noted from this

Table III. Relative Fluidity of Some Aluminum Alloys[23]

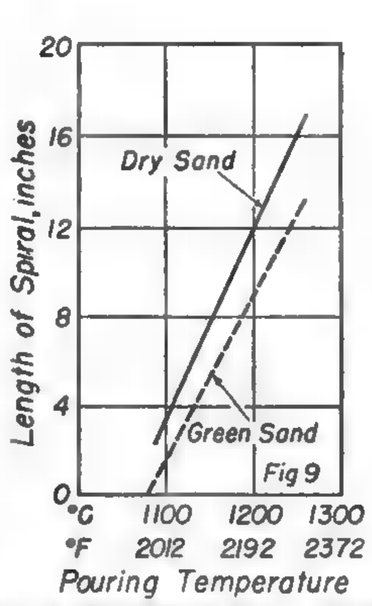
Alloying Element, percentage		Relative Fluidity[a] At 1350 F	At 1450 F
5	Si	100	100
10	Cu	103	103
3.75	Mg	77	92
3.75	Mg, 1.0 Si	93	99
4.3	Cu	87	92
6	Mg, 1 Mn, 1.5 Ni	103	110

(a) The 5% Si alloy is generally recognized as a fluid alloy and its fluidity was taken as 100. Cross section of spiral flow-channel, 0.11 sq in.

figure that the addition of some metals—for instance, nickel—brings about a drop in the fluidity; others may act as magnesium does to increase fluidity; and still others, such as silicon, may first decrease and then increase the fluidity.

Other information on the effect of alloying elements on the fluidity of aluminum is shown in Table III.

The Fluidity of Brass and Bronze. Using the Bureau of Standards mold that they had devised, with a spiral cross section of 0.066 sq in., Saeger and Krynitsky[14] studied the fluidity of brass, Fig. 9. They obtained a straight-line



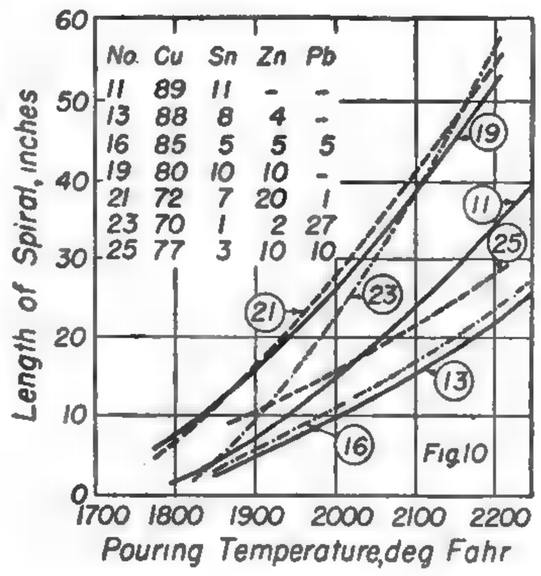


Fig. 9 Fluidity of brass, virgin metal containing 85% Cu, 5% Zn, 5% Sn, 5% Pb. Spiral cross section 0.066 sq in. (Saeger and Krynitsky)

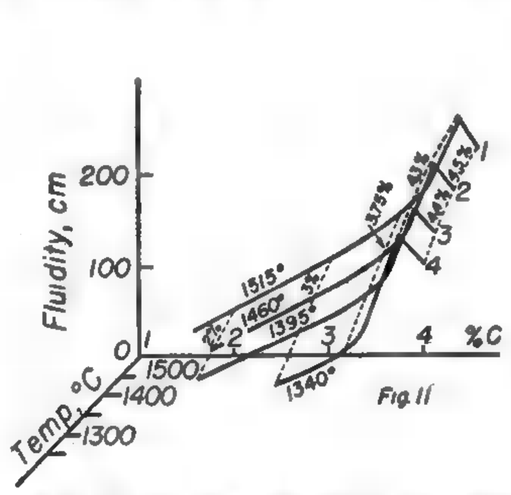
Fig. 10 Fluidity of bronzes cast in green sand mold; spiral cross section 0.098 sq in. (Pilling and Kihlgren)

relation, whereas Pilling and Kihlgren,[15] using a modification of the Bureau of Standards mold with a spiral cross section of 0.098 sq in., obtained a slight curve for a comparable alloy, Fig. 10. The effect of aluminum and of antimony on the fluidity of cast red brass (85-5-5-5) was studied[24] in green sand molds. Aluminum was added in increments up to 0.1%. It was observed that quantities of 0.025% Al increased the fluidity the most at 1065 C (1949 F) and 1150 C (2102 F), whereas at 1230 C (2246 F) an addition of 0.05% Al produced the longest flows. Antimony additions up to 0.25% indicated that adding from 0.15 to 0.20% Sb increased the fluidity of red brass considerably at all testing temperatures.

The Fluidity of Cast Iron. Studies concerning the fluidity of cast iron have been carried on by various investigators,[1] using permanent molds and sand molds. The most nearly complete set of data, however, has been prepared by Perin and Berger.[16] In Fig. 11, the relations among



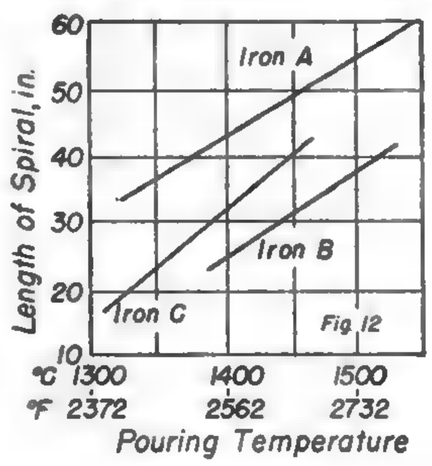


Fig. 11 Diagram showing the relations among temperature °C, fluidity and carbon content; cast in sand mold; spiral cross section, 0.078 sq in. (R. Berger)

Fig. 12 Fluidity of cast iron; sand mold, spiral cross section 0.066 sq in. (Saeger and Ash)

	TC	GC	CC	Si	■	Mn	P	Liquidus °C
Iron A	3.56	2.85	0.71	2.62	0.016	0.21	0.85	1170
Iron B	2.91	2.05	0.91	2.07	0.023	0.17	0.68	1240
Iron C	3.71	2.81	0.90	1.16	0.054	0.58	0.10	1200

temperature, fluidity, and carbon content are indicated. It may be seen from this diagram that if the casting temperature is kept constant, the fluidity increases with the carbon content until the eutectic concentration (4.3% C) is reached, and then decreases at higher carbon contents. Also, in the hypoeutectic region, there is a sudden increase in fluidity around 4.0% C.

Of course there are several elements in cast iron other than iron and carbon. Berger has investigated the influence of these elements, also, on the fluidity of cast iron. Because the additions of phosphorus and silicon influence the temperature of the liquidus, the fluidity comparisons are rather complicated, and for exact information the reader should turn to Berger's original work. However, for those interested in the study of irons, a general law may be formulated as follows: the eutectic mixtures are those which possess the greatest fluidity. The hypoeutectic alloys are the only ones of practical importance. In these the element regulating fluidity is carbon, next is phosphorus, and in a certain measure (under 1%) silicon. As for manganese, its influence on fluidity is of little importance. The amount and direction of its influence are essentially a function of the composition of the metal considered. Since, however, the modern commercial trend is toward the low-carbon metals, the fluidity of cast iron would depend more on the increment in temperature above the liquidus than on the other recognized controllable factors.

Three commercial cast irons investigated by Saeger and Ash[17] are shown in Fig. 12. These authors state that the running qualities of the irons depended on the liquidus temperature and apparently were not influenced by any previous maximum heating temperature prior to the pouring of the fluidity test at a lower temperature. For a chosen pouring temperature, the heats of iron having the lower liquidus temperature have superior running qualities.

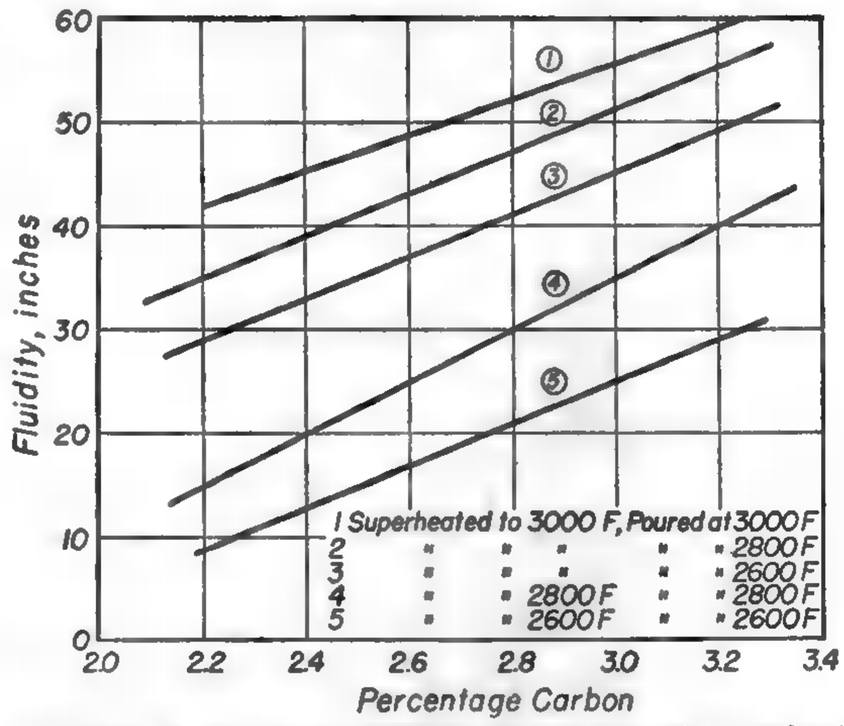

Fig. 13 Fluidity of cast iron of different carbon contents superheated at various temperatures (Zeigler and Northrup)

These results are not entirely substantiated by the work of Zeigler and Northrup.[25] Their studies of standard gray irons indicate, as shown by Fig. 13, that the influence of carbon content on fluidity is a straight-line relationship and that fluidity is affected not only by the pouring temperature but also by the degree of superheat. Thus fluidity of cast iron is increased by increasing the carbon content, the pouring temperature and the temperature of superheat.

It has been pointed out previously that the surface characteristics influence the fluidity. This has been demonstrated in a practical way by Courty.[18] He found that when cast iron was poured into a steel spiral mold, the length of the spiral could be increased from 51 to 81 cm by varying the mold coatings. The order of progressive increase was (1) linseed oil, (2) iron oxide, (3) graphite, (4) black lead and (5) a thin layer of soot from an acetylene flame.

The Fluidity of Steel. A number of studies concerning the fluidity of steel have been made in recent years. For steel, Ruff[26] devised the fluidity test specimen having a straight flow-channel. Andrews and co-workers,[19,27] using a special specimen, found that variations in carbon content up to 0.90% increased the fluidity of cast steel only slightly. Additions of silicon, manganese, copper, chromium, nickel and phosphorus were found to improve fluidity in proportion to the amount added. Walker[28] compiled results from practical foundry trials, using the straight flow-channel.

His results were inconclusive, chiefly because of the lack of adequate means for measuring steel temperatures. Sarjant and Middleham,[29] using a test specimen having a straight channel, indicated that the method has the necessary simplicity and convenience for use in plants. Their studies showed that carbon contents of 0.15, 0.43 and 0.83% progressively increase fluidity; that small additions of aluminum up to 0.30% increase fluidity of low-carbon steels; that copper up to 2% improves the fluidity of cast steel; and that high-manganese steels do not possess good fluidity at high temperatures.

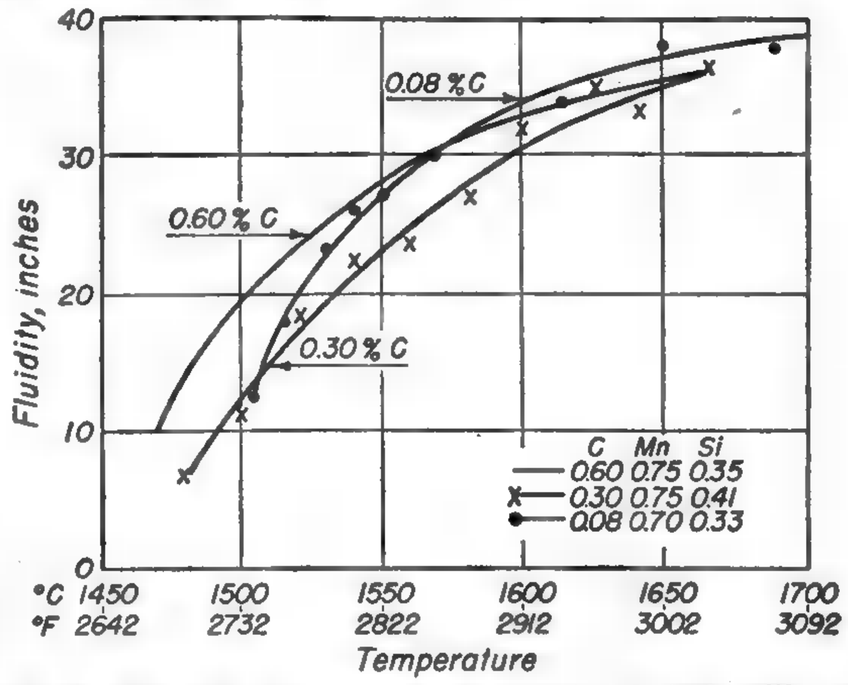

Fig. 14 The influence of carbon on the fluidity of steels with average manganese and silicon contents (Taylor, Rominski and Briggs)

Kron and Lorig[30] studied relationships among fluidity, temperature and composition in cast steels of several compositions, using the straight flow-channel. Their studies indicated that the flowing qualities of carbon steel were improved moderately by increased amounts of manganese, silicon and copper.

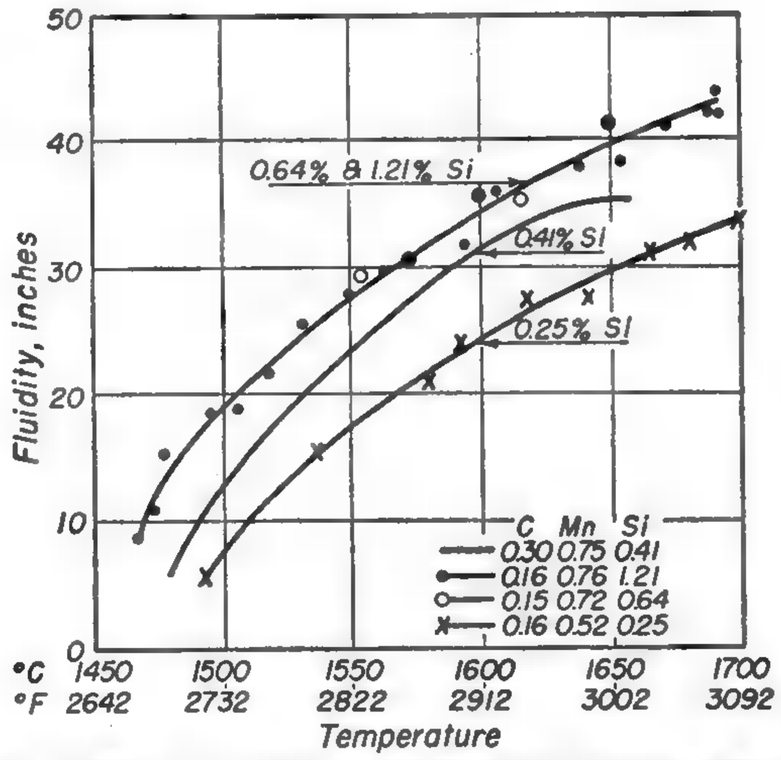

Fig. 15 The influence of silicon on the fluidity of steels having commercial compositions (Taylor, Rominski and Briggs)

The most nearly complete studies of the fluidity of steel have been made by Taylor, Rominski and Briggs.[31] Figure 14 shows that carbon has only a slight influence on fluidity of steel, whereas silicon has a marked effect on fluidity, as shown in Fig. 15. A notable change toward greater fluidity is found in the medium-carbon steels when silicon is increased from 0.25 to 0.45%. Presumably this change is not an effect of silicon addition as such, but rather of the state of deoxidation of the steel. Nickel improves the fluidity of steel progressively up to 3.25% as shown in Fig. 16. Higher concentrations as great as 5% Ni result in a decrease in fluidity.

An increase of manganese to 2% has virtually no greater effect on the fluidity of the alloy than that found in a regular grade carbon steel of about 0.75% Mn. Steels containing more maganese (approximately 2 to 14%) will exhibit improved fluidity at low temperatures (2650 to 2800 F) as the manganese content increases, whereas at temperatures 2900 F and above, the manganese-rich steels are inferior to plain carbon steels in fluidity.

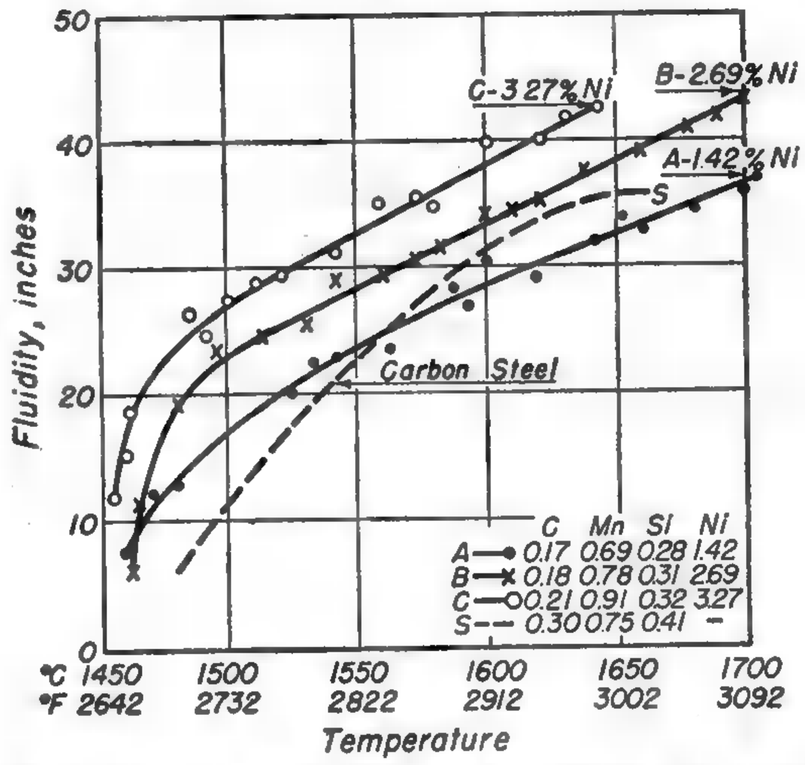

Fig. 16 The influence of nickel on the fluidity of cast steel (Taylor, Rominski and Briggs)

Additions of copper to plain carbon steel increase fluidity progressively as the concentration increases to about 4% Cu. Substantial additions of chromium to steel decrease the fluidity as compared with plain carbon steel. Small additions, less than 1.5% Cr, have no effect on the fluidity characteristics. Molybdenum and vanadium, when added to a normal plain carbon steel in amounts between 0.25 and 1%, cause a reduction in fluidity from that ordinarily obtained with no molybdenum or vanadium.

Aluminum is more effective than silicon in promoting fluidity, especially at the lower temperatures and when small quantities of aluminum are used. As aluminum is added beyond 0.2%, or that amount required for deoxidation control, fluidity is progressively decreased to low values at 1.2% Al. This indicates that the amount of aluminum for maximum fluidity is somewhat critical. The threshold value depends on the state of oxidation of the bath prior to the addition of the element. In order to have good fluidity, steel must be well made and thoroughly deoxidized. Rimming steels have fluidity inferior to that of dead-killed steels. Also, dead-killed steels that are excessively high in deoxidizers, such as aluminum and silicon, have fluidity inferior to that of steels killed with just sufficient silicon and aluminum.

Properties of Metals at Low Temperature

By Russell Franks*

IT is well known in the field of metallurgy that temperature has a marked influence on the properties of the metals—both cast and wrought—that are widely utilized for constructional purposes. The data presented here deal with the effects of temperature on metals, in the range from room temperature (70 to 75 F) to minus 300 F and lower.

All the common metals are considered here, such as steels of both high and low alloy content, nickel and nickel alloys, copper and copper alloys, aluminum and aluminum alloys, magnesium and magnesium alloys. The mechanical properties that are considered include toughness, strength, ductility and hardness. Other data are presented concerning thermal conductivity, thermal expansion, and the modulus of elasticity, showing the extent to which these properties are influenced by exposure to low temperature.

Caution must be used in selecting the proper metal for a particular service at low temperature, in order to assure satisfactory performance; otherwise the equipment may fail because of inadequate toughness and ductility, and both time, money and life may be lost. In the selection of the metal, attention should be given to the specified composition as well as the manner in which the metal part or parts are to be fabricated into the finished article. For example, the influence of heat treatment may be so important that it determines whether the fabricated metal has or has not the properties necessary to insure successful application at low temperature. Usually a frank discussion between producer and consumer will clarify the problems to be encountered, and will provide a practicable plan for solving them.

Fields of Application. The use of metals at subatmospheric temperature has spread to virtually all the basic industries producing commodities for general consumption. During the past few years the tonnage of metals required to withstand the effects of exposure to low temperature has increased appreciably. The field of application for metals at low temperature is broad, involving conditions that vary widely in regard both to temperature and to the properties required in a metal article to meet the needs of its particular service. In the chemical industry, the temperatures most frequently encountered are as low as minus 150 F, and the equipment involved may be a large gas-fractionating column or a retort with extremely heavy wall. Refrigeration has provided important applications for metal construction in which liquid compounds are employed at temperatures as low as minus 75 F. This application will be increasingly important when such low temperatures are commonly used in homes to preserve fruits, vegetables, meats and other foods. The petroleum industry requires large quantities of metal equipment for the refining of oil and oil products, as in the dewaxing process. The equipment used in these three well-known fields may consist of relatively small articles produced from thin sheets, thin-wall tubes, small bars and such; on the other hand, the equipment may be large pressure vessels with heavy walls fabricated either by welding or by bolting. The aircraft, automotive and marine industries as well as the railroads are concerned with subatmospheric temperature from the standpoints of refrigeration and of direct exposure during the winter months. Military requirements for metals at low temperature are varied and widespread, including almost all the normal civilian low-temperature applications, and many others.

Probably one of the most important applications for metals at low temperature is in the production of the indispensable gas, oxygen. Virtually all the equipment employed in the production, transportation and use of this gas is built from a metal of some kind. At one time the transportation of liquid oxygen from one part of the country to another was a problem. It is common practice now to use a large metal container so satisfactory that the early accidents arising from the handling of liquid oxygen have been reduced to a negligible number. This problem has been solved solely by the selection of the proper metal—an example given merely to emphasize the importance of selecting the right metal, after applying the necessary tests to determine the adequacy of the metals in question.

General Behavior of Metals at Low Temperature. The ferrous metals, such as ordinary carbon and low-alloy constructional steels, exhibit a characteristic loss of toughness suddenly when a certain low temperature is reached. This "transition temperature" may occur near the freezing temperature of water or at a much lower temperature. Most of the nonferrous metals, such as copper, nickel and alloys of these metals, are relatively free from this behavior, particularly if the alloys represent a comparatively stable solid solution. On the contrary, the unstable precipitation-hardening alloys of these and other nonferrous metals should be suspected of brittle behavior at temperatures below normal. The austenitic type of stainless steel, categorically referred to as 18-8 steel, is virtually free from the embrittling effect at low temperature. Although this alloy is predominantly iron, it has no transition temperature in any of the ranges extending as low as minus 300 F. Some of the iron-nickel alloys do not have the transition

* Electro Metallurgical Company, Pittsburgh

Prepared for the Subcommittee on Properties of Metals at Low Temperature, with membership as follows: Russell Franks, *Chairman;* A. J. Herzig (Climax Molybdenum Company); E. R. Johnson (Republic Steel Corporation); G. C. Riegel (Caterpillar Tractor Co.); H. W. Russell (Battelle Memorial Institute); J. W. Sands (The International Nickel Company, Inc.) and E. C. Wright (National Tube Company).

point at low temperatures even though they contain more iron than nickel. These remarks apply particularly to the comparatively stable austenitic solid-solution type of alloys, because when these ferrous alloys are made subject to precipitation hardening, they too should be suspected of brittle behavior at low temperature.

As indicated above, under the conditions of stress imposed by a notch, at some temperature below normal, referred to as the "transition temperature", steel may be expected to change from a tough to a rather brittle behavior, generally accompanied by a coarse-grained fracture. The brittle behavior of a given steel can be evaluated best at present by the notched-bar impact test. Standard bend or tensile tests do not reveal such behavior, as data accompanying this article indicate.

For a discussion of notch sensitivity versus velocity sensitivity, the reader may refer to the article entitled "Notched-Bar Impact Tests" on page 112.

When constraint is increased by the sharpness of the notch, by the shape and size of the sample, by the reduction of temperature or by other factors of stress concentration, the notched-bar impact values approach zero.

Notches produced by thermal and corrosion cracks are serious when the temperature is reduced. Large masses of steel sometimes undergo brittle failures because of residual stresses augmented by decreasing temperature. Contraction stress, effect of plasticity, and thermal gradients are all emphasized by reduction of temperature.

Various investigators have obtained data indicating how exposure to low temperature affects certain physical properties of metals—thermal expansion, thermal conductivity and the modulus of elasticity. The data of the accompanying Tables I to VI inclusive indicate clearly that the coefficient of thermal expansion decreases with a decrease in temperature; that the thermal conductivity increases with a decrease in temperature; and that the modulus of elasticity increases with a decrease in temperature. There may be exceptions, but these broad generalizations apply to most metals exposed to subatmospheric temperatures.

The changes occurring in some of the physical and mechanical properties of metals are undoubtedly connected with metallurgical changes brought about by exposure at low temperature. It is known that steels of low carbon content retain their toughness to a lower transition temperature than do steels of relatively high carbon content. Presumably steels decrease in toughness when the ferritic solid solution becomes at least partially decomposed, forming a precipitate of carbide. The changes occurring in the microstructure of ferrite in low-carbon steels have not been well identified, but when the carbon content is high,

the changes in microstructure are associated with carbide precipitation. Copper, nickel, chromium and molybdenum are added to steels of relatively low carbon and alloy content to prevent the occurrence of harmful transformations. It is generally conceded that if the carbon content is much more than 0.30%, great difficulty is encountered in preventing loss of toughness, even though the metal has been thoroughly deoxidized by additions of aluminum.

The more highly alloyed ferrous metals that contain nickel and chromium in such proportions as to give a relatively stable austenitic structure, retain their toughness at the lowest temperatures because the metal is free from decomposition products that decrease toughness. The same is true when the face-centered cubic type of structure is relatively stable in copper-base or aluminum-base alloys but, even in these alloys, the toughness will be reduced if the solid solution is made unstable by the introduction of some element that induces precipitation.

Properties of Ferrous Materials at Low Temperature. *Ferritic Steels.* Data relating to the toughness and strength of carbon steels are given in Tables VII and VIII. These data, selected from the work of various investigators, make it clear that the impact toughness of ordinary carbon steel in the as-rolled condition, decreases to a low value at minus 40 F, unless the steel is properly deoxidized. When the as-rolled steel is properly deoxidized, the toughness remains high in the as-rolled condition down to minus 40 F, but is reduced to a low value at a temperature of minus 80 F. When low-carbon steel is deoxidized by means of aluminum and is then normalized, good toughness is retained as low as minus 100 F and somewhat lower. The strength and ductility of these carbon steels are not affected in the same manner. The data of Table VIII show that the strength of the carbon steels is increased greatly with little or no change in ductility, as measured by elongation and reduction of area, when temperatures as low as about minus 150 F are reached; whereas, under the same conditions, the impact toughness of the steel is at a low value. The tensile characteristics, therefore, are less indicative of what happens when low-carbon steel is subjected to low temperature than are the data obtained through the impact test. However, the tensile test data indicate that, as the carbon content of steel is increased, the exposure to the low temperature causes a decided decrease in ductility, even though the steel has been heat treated. These data illustrate the beneficial effect of deoxidation and heat treatment in obtaining fine-grained steels that are superior to the coarse-grained steels in toughness at low temperature.

The data of Tables IX and X, concerning the low-temperature characteristics of the alloy constructional steels, indicate that in general the fine-grained steels are superior to the coarse-grained steels in toughness at low temperature. These steels contain relatively small percentages of nickel, chromium, molybdenum or vanadium or combinations of these metals, in addition to the usual

percentages of manganese and silicon. It is unnecessary to discuss in detail the properties of the various SAE and AISI steels except to state that their best low-temperature toughness is generally obtained as a result of cooling rapidly from temperatures in the vicinity of 1500 to 1600 F and then tempering in the range from 1000 to 1200 F. After this type of heat treatment many of the steels exhibit excellent toughness at temperatures approaching minus 200 F, particularly those steels that have a martensitic structure after rapid cooling. The strength increases without serious loss of ductility during exposure to low temperature, a fact leading to the question of whether this marked increase in strength can be utilized in low-temperature application of the steels that have adequate toughness, permitting the production of lighter structural parts in order to save weight.

The low-alloy, high-strength structural steels are being widely utilized and their toughness at low temperatures has received a great deal of consideration. Data obtained from studies of low-temperature toughness of these steels are presented in Table XI, where it is seen that most low-alloy, high-strength structural steels are superior to the ordinary carbon steels in low-temperature toughness. This should be expected because these low-alloy, high-strength steels are relatively low in carbon content and are thoroughly deoxidized. Although data are not available, it is probable that, as in other steels, the strength of these steels is greatly increased at low temperature. Thus these materials also might be utilized to greater advantage at low temperature if the increase in strength is considered and if their toughness is adequate. It should be noted that normalizing improves toughness at low temperature.

A good deal of information has been obtained concerning cast steels that vary widely in composition. This information, presented in Tables XII and XIII, indicates that, in general, at low temperature, cast steels are less tough than wrought steels. However, good toughness can be obtained in cast steels of relatively low alloy content if they are properly heat treated and are not exposed to temperatures lower than about minus 100 F. The data of the tables reveal that a number of cast steels have adequate toughness, provided they are conditioned properly for service at low temperature.

A considerable amount of work has been done to develop special steels for service in which the temperature is reduced to minus 300 F. The steels in one series are low in carbon content and contain as much as 8½% Ni. The data indicate that when the carbon content is low, no great advantage is obtained by increasing the nickel content to much more than 3% if the service does not

involve temperatures below minus 180 F. But if the temperature in question approaches minus 300 F, it appears that as much as about 8½% Ni is required to give high toughness, which can be retained in the steel if it is normalized. The strength and ductility of a 3½% Ni steel at low temperature are given in Table XIV. At temperatures as low as minus 185 F, satisfactory low-temperature toughness is obtained also in the chromium-copper steels when they have been normalized and properly deoxidized, as shown in Table XV.

Austenitic Alloys. The austenitic chromium-nickel and chromium-manganese-nickel types of stainless steels are especially adapted for service at low temperatures because of their high degree of stability at minus 300 F and lower. The austenitic chromium-nickel steels are somewhat tougher than the chromium-manganese-nickel steels, and the addition of molybdenum, titanium and columbium to the well-known 18% Cr—8% Ni steel does not affect toughness greatly at low temperature. Moreover, only the simplest solution heat treatment is required in fabricating these alloys, regardless of the size of section. As shown in Tables XVI and XVII, the toughness of 18-8 steel is not reduced when the temperature is decreased to minus 300 F, and the yield strength and tensile strength of the metal are greatly increased without appreciable loss of ductility. This combination of properties is considered unique in the field of ferrous metallurgy because the 18-8 steel is the only steel that retains its toughness unimpaired at such a low temperature. Furthermore, welds of the 18-8 steels have high toughness at low temperature, and much welded equipment has been used successfully under such conditions.

It has been known for a long time that nickel and nickel alloys retain their toughness to a remarkable extent at low temperature. The toughness of iron-nickel alloys reaches a maximum when the nickel content is approximately 40%. At this point the iron-nickel alloy is as tough and ductile at minus 300 F as at room temperature. Evidently the structural stability is at a maximum when this percentage of nickel is present. Data are given in Tables XVIII and XIX concerning the toughness, strength and ductility of iron-nickel alloys at low temperature.

The use of manganese for imparting low-temperature

toughness to iron has been thoroughly considered and, as indicated in Tables XX and XXI, the addition of as much as 50% Mn to iron fails to produce a material as tough at minus 300 F as at room temperature. However, the addition, for example, of 5% Cr to iron containing about 25% Mn produces a material that is fully austenitic in character, and that does retain full toughness when exposed to temperature as low as minus 300 F. The manganese content of iron can be reduced further to about 16% with low carbon content when small amounts of nickel, chromium and copper are added, without sacrificing toughness at about minus 300 F. The reason for this is apparently that the manganese austenite is fully stabilized in the presence of low carbon content, by the small percentages of nickel, chromium and copper. When the carbon content is increased to about 1% in steels that contain about 12 to 14% Mn, the resulting metal has excellent toughness at minus 100 F, but does suffer a loss in toughness when the temperature is decreased further to minus 300 F. These latter steels represent the well-known Hadfield's manganese steels that have been used successfully at moderately low temperatures down to about minus 100 F.

Properties of Nonferrous Alloys at Low Temperature. The available data concerning aluminum and aluminum alloys show that the wrought commercial aluminum designated as 2 S-O retains its toughness in the annealed condition down to temperatures in the vicinity of minus 300 F. The Al-Cu-Ni-Mg alloy designated as 18 S-T has relatively low toughness and does not change noticeably when it is exposed to similar low temperature. The 24 S-T aluminum alloy, containing copper and magnesium, also retains its toughness when exposed to temperatures as low as minus 105 F. The same is true of the 52 S alloy and the cast aluminum alloy designated as 195T. In Tables XXII and XXIII, concerning the toughness and tensile strength of the different aluminum alloys, the data indicate that neither the strength nor the ductility of the various aluminum alloys changes greatly when subjected

to temperatures as low as minus 112 F. In fact the indications are that the ductility of the aluminum is increased slightly as a result of exposure to low temperature. It is apparent that cold rolling the aluminum alloys does not affect the ductility at low temperature, which means that aluminum and aluminum alloys have a high degree of structural stability when exposed under such conditions.

As shown in Tables XXIV and XXV, copper and most copper alloys possess remarkable toughness when exposed to extremely low temperature. The only exceptions are the copper-beryllium and the cast Cu-Zn-Pb-Sn alloys. The copper-beryllium alloys have good low-temperature toughness in the annealed condition but, when these alloys are aged to obtain high strength, their toughness reaches a low point and remains low when exposed to low temperature. The same is true of the Cu-Zn-Pb-Sn alloys, particularly in the cast condition, in which their toughness is low and remains so at low temperature. Copper and copper alloys increase greatly in tensile strength when they are exposed to low temperature, and the increase in tensile strength is not generally accompanied by a decrease in ductility. The wrought silicon bronzes containing 1½ to 4% Si have been used to a wide extent, as well as the copper-nickel alloys for low-temperature service involved in the handling of liquid oxygen. Experience has indicated that welds made in silicon bronze have excellent toughness at low temperature. Copper and copper alloys

tensile strength when wrought magnesium alloys are cooled to subnormal temperatures. The cast magnesium alloys designated as A10 and AZ63 undergo neither a decrease nor an increase in tensile strength during exposure at low temperature, which indicates that in the cast condition the magnesium alloys are considerably more stable structurally than they are in the wrought condition. In this respect the magnesium alloys are similar to the aluminum-base alloys; however magnesium alloys are not so tough at room temperature as aluminum alloys.

The nickel-base alloys known as Monel and Inconel have excellent toughness at low temperature. Even in "K" Monel, which has less toughness at room temperature than standard Monel, no change occurs at low temperature. Also these nickel alloys increase greatly in tensile strength at low temperature without a serious sacrifice of ductility. The information in Tables XXVIII and XXIX indicates that the nickel alloys are structurally stable at low temperature, and it can be assumed that welds of the alloys will be tough at subatmospheric temperature as low as minus 300 F and even lower.

Factors Involved in Fabrication of Metals for Low-Temperature Service. Welding has become so important a process for fabrication of equipment operating at low temperature that it deserves special mention. The two methods of welding generally practiced are gas welding and electric welding. Ordinarily an electrical method is employed for welding the ferrous metals. The only exception is that atomic hydrogen welding is sometimes used for joining ferrous alloys such as 18-8 steels. The nonferrous metals are commonly welded by a gas process, usually oxyacetylene.

When fabrication includes welding, it is necessary first to select the parent metal that has ample toughness for the service under consideration, and then to join the sections of parent metal with a weld metal of similar composition that has been proved by testing to be substantially as tough as the parent metal. Welded joints are generally considered to include three zones, which merge into one another. These zones are the base or parent metal, the weld metal and the heat-affected zone between the weld metal and the base metal. Great emphasis should be placed on the quality of weld metal, since usually the adjacent zone and the parent metal will have sufficient toughness if the proper metal is selected. If the weld metal is of poor quality or if harmful notches exist between the weld and the parent metal, difficulty may result from low toughness in the weld or from a notch effect in the metal immediately adjacent to the weld.

Residual stresses exist in welded structures and, in instances where it is possible to do so, the equipment should be stress relieved before installation, in order to avoid difficulties that might result from concentration of stresses. One of the important locations in which stress concentration can occur is in the heat-affected zone, which may be stronger and less ductile than either the base metal or the welded metal. In air-hardenable steels, for example, a stress-relieving treatment will serve a useful purpose in avoiding stress concentration. Welds are essentially cast metal, and the use of heat treatment should be considered as with steel castings.

The thickness of section is important in building equipment for service at low temperature. Where heavy sections are involved, it is necessary to deposit several beads successively during the welding operation. In this process, the metal adjacent to the weld is heated and cooled several times, during which structural changes occur in the metal. These changes are controlled to a large extent by the type of heat treatment to which the parent metal has been subjected previously, and thorough investigation should be made concerning the properties of the metal next to the weld. Samples should be tested to determine the final heat treating procedure that should be applied to the finished equipment. If these precautions are observed and if the material for the particular service has been selected judiciously, the weldment should have adequate toughness at low temperature.

Wear of Metals

BY THE SUBCOMMITTEE ON WEAR OF METALS*

WEAR is one of the most destructive influences to which metals are subjected. Nearly everything that moves causes and is exposed to wear, simultaneously bringing about and undergoing progressive destruction. The problem of wear is thus of vital concern to metallurgists and engineers. The purpose of this article is to discuss the variables connected with the wear of metals and to suggest means for minimizing the undesirable effects of wear.

Wear resistance is not an inherent property of a metal, which may be considered by itself. It is complicated by many factors and cannot be determined apart from the specific conditions of service. Wear is the resultant of the material itself, of the mating material, and of the operating conditions of service. In combination, these varying factors serve to cause different types of wear. Since there is no universal type of wear, there is no universal method or machine for testing wear.

Definition. For the purpose of this article wear may be considered essentially a surface phenomenon, and consists of the gradual mechanical deterioration of contacting surfaces, as by tearing off particles through friction. Wear may be modified by the simultaneous effect of corrosion or other chemical attack.

Theory and Mechanism of Wear. *Types and Classifica-*

* The members of this subcommittee are S. J. Rosenberg, *Chairman* (National Bureau of Standards); Tracy Jarrett (Koppers Company, Inc.); H. S. Avery (American Brake Shoe Company); and Oscar Maag (Timken Roller Bearing Company).

tions. Wear occurs by the displacement and detachment of metallic particles from a metallic surface. This process may be caused by contact with another metal (metallic wear), by contact with either a metallic or a nonmetallic abrasive (abrasion), or by contact with flowing liquids or gases (erosion). This last type is frequently combined with some form of corrosion, whereas metallic wear and abrasion may or may not be.

A logical method of classifying wear depends on the nature of the contacting surfaces, as follows:

I Metal against metal
  A Sliding friction
    1 Lubricated (engine crosshead, shaft in bearing)
    2 Nonlubricated (brake shoe against wheel)
  B Rolling friction
    1 Lubricated (roller bearings, gears)
    2 Nonlubricated (wheel on track)
II Metal against nonmetal or abrasive
  A Sliding friction
    1 Wet (conveyer screws for wet sand)
    2 Dry (plowshares)
  B Rolling friction
    1 Wet (ball and rod mills)
    2 Dry (jaw crushers, crushing rolls)
  C Impact of loose abrasive
    1 Wet (impellers)
    2 Dry (sand blast)
III Metal against liquids or vapors
  A Wet steam (turbines)
  B Combustion gases (gas turbines)

Frequently these conditions of service are combined so that an application which was originally metal against metal may evolve into metal against nonmetal or abrasive by the introduction of nonmetallic abrasive particles or of the abraded particles of the original surfaces; rolling and sliding friction are frequently combined, and too often lubrication fails.

The usual conception of metal-to-metal wear involves the mechanical interference of tiny projections or asperities. These produce friction when they interfere with the relative motion of contacting surfaces. When two rather smooth surfaces are in contact, the first step in producing wear—penetration or displacement of small particles—is more difficult than when the contacting surfaces are rough. When two surfaces are moving in contact, some of the projections of the one will find the depressions in the other and will increase the resistance to further movement. If the driving force is sufficient to maintain movement, the interlocked projections are deformed and, if made of sufficiently brittle material, may break or be torn off.

A consideration of this idea leads to the belief that hardness, toughness and surface smoothness are necessary for wear resistance—hardness to resist initial indentation, toughness to resist the dislodgment of metallic particles, and surface smoothness to eliminate the projections.

In abrasive wear it is probable that the abrading particles first penetrate the metal and then cause the tearing off of the metallic particles. Since the ease with which the abrading particles may dig in depends on the hardness of the metal, and since the ease with which the deformed metal may be torn off depends on the toughness, it is apparent that the properties necessary for resistance to abrasive wear are the same as those necessary for resistance to metallic wear. However, of the two factors, hardness and toughness, hardness is probably more important, a fact that accounts for the frequent use of surface-hardened metals primarily to minimize wear.

When two surfaces move one across the other, as in Fig. 1a, it is apparent that the peaks of the irregularities must either shift position or break. If the local stresses, which may be quite complex, are sufficiently great, failure occurs as in Fig. 1b. Such failure may also be caused by fatigue resulting from the local stresses. Wear of this type may occur regardless of whether the contact is by sliding, rolling or impact; it is particularly severe in the case of abrasive wear (Fig. 1c).

Wear of metal against metal may be minimized by increased smoothness of the rubbing faces and by lubrication that separates the surfaces. If the film of lubricant is sufficiently thick, metallic contact may be completely eliminated; friction then depends on viscosity of the oil film, and metallic wear is reduced to a negligible amount. This condition, known as "thick or fluid film" or "complete lubrication", can be controlled chiefly by means of design.

Complete lubrication is not always attainable. More frequently partial failure of the oil film occurs and "boundary lubrication" results. Friction and removal of metal occur as described above; the amount depends on speed, pressure, nature of the surfaces, and efficiency of the residual oil film. The extreme example is dry wear with no lubricant.

Dry wear permits friction to generate considerable heat. As temperatures rise, the strength and hardness of metallic materials decrease, rendering them more susceptible to wear. Oxidation or other chemical attack is facilitated on the faces subjected to friction and this may cause further loss of metal. The temperatures involved are much higher than might be suspected. Intrinsic hardness or hardness resulting from massive or very stable structural compounds, may be useful in combatting dry wear. The hardness of heat treated structures is often less valuable, perhaps because it is readily reduced by the heat of friction.

Abrasive wear is most frequently caused by nonmetallic materials, usually as a result of scratching. In general, a substance is seriously scratched only by materials harder than itself. Most protection against abrasion is based on this principle. However, the principle is not always true, perhaps because even nominally pure substances may contain harder foreign particles, or because there are additional factors that are unknown or insufficiently understood. Rubber provides an interesting exception where toughness or elasticity appears much more important than hardness in many applications.

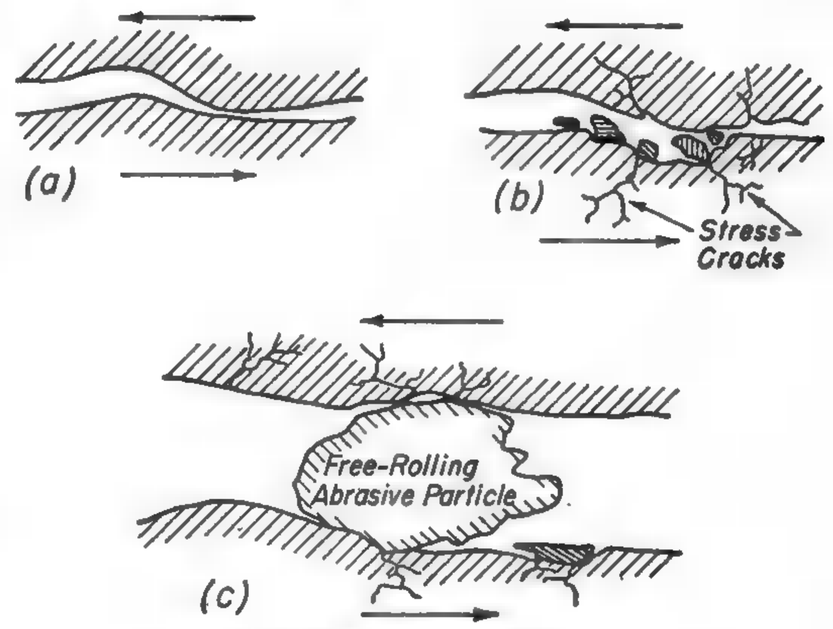

Fig. 1 Schematic illustration of wear

Cold work and plastic flow may accompany the wear of metals. During cold work the dimensions of the wearing objects change slightly to accommodate plastic compression of the metal. Such work hardening is especially important in wear resulting from impact, since appreciable hardening of the surface increases the strength and endurance limit. The operation of this factor is important in the wear resistance of the bronzes and austenitic manganese steels.

Some forms of abrasion involve little or no impact, but in other forms the kinetic energy of a blow is an important factor. Although wear, in the ordinary sense, does not result from stresses sufficient to cause fracture, in actual applications a brittle material may have its useful life terminated by a sudden blow. Impact may cause failure on a smaller scale also. The shear stresses under a point or an edge that has been applied with a blow are quite large. These stresses can easily exceed the elastic strength of the material struck; if the material is brittle, it then shatters readily. Extreme brittleness, as of glass that contains high residual stresses, or a perfect cleavage coupled with high hardness, is favorable to this type of failure, which may simulate erosion rather than fracture if it occurs on a microscopic scale. Shot or sand blasting may be accompanied by this type of wear as well as by the scratching of abrasive particles. Yielding of the surface by either elastic deformation or plastic flow tends to relieve these stresses and prevent fracture. A fine-grained structure

may also minimize failure and consequent wear by localizing cleavage cracks in microscopic crystals, rather than by permitting them to be propagated across a large grain. The greater resistance to impact abrasive wear of flint in comparison with quartz, or of molded versus massive crystalline boron carbide, may tentatively be attributed to such a mechanism.

Metallic substances and intermetallic compounds, even when they are brittle by engineering standards, probably owe their superior wear resistance to some ductility which, in combination with great strength, provides toughness considerably greater than that of most minerals and ceramic substances. The qualitative difference between such materials can be demonstrated easily by an attempt to measure the penetration hardness of a brittle mineral, such as quartz, by means of the Brale diamond cone (the Rockwell hardness test). The mineral will fracture while a piece of the most brittle cast iron (if reasonably large in size) will yield, permitting the hardness determination. This hypothesis explains partially why hardness alone is not a reliable index to wear resistance.

Resistance to wear that involves heat checking, as in brake shoes, is also influenced by brittleness. Here the stresses are the result of temperature gradients rather than of the kinetic energy of impact, but the capacity to absorb the stresses is similarly aided by plasticity. A metal with a low modulus of elasticity, such as gray cast iron, is generally considered more resistant to thermal cracking than a hard white iron, though it may be less able to withstand frictional wear. The low modulus is associated with lower stresses for a given amount of thermal expansion. The greater plasticity of gray irons, along with their lower moduli, may explain their popularity in brake service, particularly as brake drums.

Seizing and galling, wear phenomena quite different from those above, are attributed to the forces of atomic attraction. Atoms of the same or very similar metals cling to one another powerfully. The forces of cohesion decrease as the sixth power of the distance and when the separation is greater than a millionth of an inch they are probably negligible.

If two clean surfaces of the same metal actually touch each other they will weld together, giving evidence of this atomic attraction. Even with apparently smooth surfaces, however, the actual contact points are few under ordinary circumstances, and the effect is obvious. The thinnest films of oil, dirt or absorbed moisture may cause separation beyond the critical distance. When conditions include carefully smoothed faces, removal of films and dirt by friction, pressure sufficient to break through any residual separating material and to facilitate intimate contact by elastic or plastic deformation, and favorable combinations of adjacent metals, the power of atomic attraction becomes apparent and seizing or welding takes place. High temperatures are not necessary, but they facilitate this welding since they soften materials and make plastic flow easier.

If small areas "seize" but operation of the machine is not arrested, pieces of the opposite face may be pulled out. The resultant projection will then cause scoring or excessive local wear, and serious damage may result. This tearing and scoring, as well as complete stoppage by seizure, are the most serious occurrences that may follow the failure of lubrication.

Seizure is combatted by lubrication, by provision of contacting metals that have little tendency to weld together (such as steel and silver), and by design or surface finish that favors the retention of some lubricant even if the main supply fails. Thus, a slightly rough surface may require a thicker, more viscous oil film for complete lubrication, but will retain traces of oil under pressure, and will consequently discourage seizure more effectively than a very smooth surface—superfinished, for example.

An important practical consideration conforming with this hypothesis is the selection of a contacting metal that will provide a film-forming material (such as lead oxide from leaded bronze and babbitt, or graphite from gray cast iron) to supplement failing lubrication.

Corrosion may be considered a type of wear, since it causes material loss that may be expressed in the same units as mechanical attrition. Here, however, corrosion should be considered a complicating or contributing factor. It may cause direct metal loss, pitting, or the formation of films. The pitting may invite fatigue failure or may supply minute oil reservoirs. The films may be brittle, easily removed, abrasive or otherwise undesirable; but if tough and tenacious, they may be invaluable, as experience with the corrosion products of extreme-pressure lubricants has demonstrated.

Thus, the product of a single mechanism is very difficult to predict without careful analysis and study of the contributing factors. This is perhaps the major problem in wear; the several chief sources of deterioration may combine in such a way that they obscure or greatly complicate what might otherwise be a reasonably clear problem. To identify and weigh these factors for practical purposes requires engineering skill, experience, and good judgment.

The hypotheses presented here are based on many observations, and will be found useful in the analysis of wear problems. They are not all firmly grounded on many rigorous experiments, however, and observations at variance with them should not be rejected as unreliable without further scrutiny, but should be carefully examined for clarification of the complex phenomenon of wear.

Factors Influencing Wear. The chief factors that influence wear may be listed as follows:

I Variables connected with metallurgy
- *A* Hardness
- *B* Toughness
- *C* Constitution and structure
- *D* Chemical composition

II Variables connected with service
- *A* Contacting materials
- *B* Pressure
- *C* Speed
- *D* Temperature
- *E* Surface finish

III Other contributing factors
- *A* Lubrication
- *B* Corrosion

The complexity of the problem of the wear of metals is emphasized by a consideration of the many factors involved. Even a general appraisal of each of these factors is difficult, for a more or less rigid but still unclarified interrelationship exists among many of them. Thus, to say that a certain composition is the most wear resistant is obviously impossible without considering many of the other factors associated with the metal, as well as the conditions of service. Two materials, one of which is definitely superior to the other in a particular service, may suffer a reversal in wear resistance by a slight change in the conditions of service.

No one property can always be associated with high resistance to wear. The mechanical properties known to be of importance are strength, indentation hardness, and ductility or toughness. In general, resistance to wear does not increase directly with the tensile strength or with the hardness, important as they may be. High hardness tends to decrease wear by making the metal resistant to penetration, scratching and deformation. Toughness tends to decrease wear by making it difficult to tear off small particles of deformed metal. When the normal pressure is high, the hardness and toughness of the deformed material are important, since the actual wear occurs on material which has been work hardened by the pressure. The relative importance of hardness and ductility may be expected to vary with the conditions under which the wear occurs.

Methods of Testing. There can never be a "universal" wear test, because there are many different types of wear and a material that is advantageous in one application may be disadvantageous in another. Equipment for wear testing must be designed to simulate actual service conditions. Results from any type of wear test cannot be accepted until it has been proved that those results actually check service data. The rating of materials obtained by any one test ordinarily cannot be applied to a different type of wear.

Many wear-testing machines have been placed on the market from time to time. Others have been designed and built in individual laboratories, for specific applications.

In the descriptions which follow, the symbols indicate the types of wear (*see* the first outline above) for which the machines are normally used. Often it is possible to modify the equipment, adapting it to other types of wear.

Class 1. Metal Against Metal. One of the oldest and most widely used commercial machines is that manufactured by Alfred J. Amsler & Company, Schaffhouse, Switzerland.[8] The essential features of this machine are (1) a gear train so constructed as to subject the test specimens to either sliding or rolling friction or to a combination of both, (2) a calibrated spring for adjusting the contact pressures between the test specimens, (3) a cam device that may be used to produce a lateral sliding motion between the test specimens, and also to produce a pounding action between them if desired, and (4) a friction dynamometer and torque indicator and recorder for determining the frictional work done on the test specimens and the frictional torque developed during the test. For rolling friction, the specimens used are 2 in. in diam by 0.4 in. thick; for sliding friction, the upper specimen is usually modified so that the test is of the brake shoe type. This machine is designed primarily for metal-to-metal wear under relatively heavy pressure. While it has been used most generally for dry metal-to-metal tests, it has also been adapted for use with lubricants. Further adaptations have been made for testing at elevated temperatures.[8] (Types IA1, IA2, IB1, IB2.)

The Skoda-Savin machine,[9] manufactured by the Limited Company (formerly the Skodaworks), Praha, Czechoslovakia, consists essentially of a thin tungsten carbide disk which is rotated under load against a preferably flat specimen. The machine is equipped with a pump for supplying a coolant to the specimen (Type IA1, IA2). The Spindel machine[10] uses a somewhat similar principle; a flat test specimen is pressed against the edge of a disk 1 mm thick, rotating at a peripheral speed of 25 mm per min under a pressure of 5 kg for soft materials and 10 kg for hard materials. The disk acts as a blunt circular saw and the surface of the segment ground away is used as a measure of wear. For some purposes, the amount of wear of the steel disk is also measured (Type IA2).

For testing lubricants and wear, the Timken Roller Bearing Company, Canton, Ohio, manufactures a machine in which a steel ring is rotated against a stationary test piece. Two lever systems are provided, one for loading and one for measuring friction of the stationary test block. If lubricants are used, provision is made for heating the oil. Wear is measured by a loss in weight of the test specimen or by the width of the scar on the test block or stationary test piece. (Type IA1, IA2). A somewhat similar test, in which a flat specimen is held against a steel cylinder rotating at constant speed, was developed by Jannin[11] (Type IA1, IA2).

The Saniter test[12] consists of a revolving horizontal cylindrical specimen that drives, by friction, the inner race of a loaded ball bearing, the inner diameter of which is considerably larger than the diameter of the specimen. The Saniter wear number is based on the reduction in diameter of the specimen measured in ten-thousandths of an inch and compared with the loss from a standard bar under similar conditions (Types IA1, IA2).

A machine for the rapid determination of frictional wear is described by Coberly and Arnold.[13] The machine reciprocates test samples, prepared by lapping them optically flat, under load in an oil bath. The small amount of wear which occurs in a few hours is measured by the refraction pattern produced between the worn surface and an optical test plane. An electrical gage and the profilograph are used as supplementary methods of measuring wear. In this machine various materials are tested in pairs and the best combinations of mating materials under the specific test conditions imposed may thus be determined (Type IA1).

The evaluation of material by the use of a machine designed specifically to simulate a certain type of wear is the most practical method of approach, although usually not the easiest. This principle of design was used by Frencn and Herschman,[14,15] in their machine for testing the wear of plug gages. In this machine a cylindrical test specimen (the gage) was moved vertically in a split ring (the material being gaged) by means of a connecting rod working from a crank. The split ring was rotated to simulate the wringing action of gaging. Pressure between ring and gage was adjusted by means of springs. Means were also provided for flooding the specimens with coolants or lubricants, in which abrasives could be incorporated. Test data secured by using this machine were found to check service results, (Types IA1, IA2, IIA1, IIA2).

Another example of an apparatus designed for a specific type of wear is the machine for testing brake shoes, built by the American Brake Shoe Company, Mahwah, N.J. This machine duplicates in the laboratory, on full size wheels, the actual operating conditions of braking a train with any predetermined wheel load and from any desired speed (Type IA2).

Class 2. Metal Against Nonmetal or Abrasive. The Brinell machine,[20] manufactured by Aktiebolaget Alpha, Stockholm, Sweden, is an apparatus for testing the resistance of metal to abrasion by dry sand, which abrading medium must be carefully standardized. The circumference of a slowly rotating soft iron disk, 100 mm in diam and 4 mm thick, is held against the flat surface of a specimen under load while a stream of sand is fed in between from a hopper (Type IIA2).

Blake[21] describes a machine developed for testing materials under conditions of wet grinding. In principle, this device is an accurately controlled grinding machine in which all conditions concerning abrasive, pressure, speed, time, and moisture or other liquid content are under the control of the operator. Test specimens are rotated circumferentially on an annular copper ring, placed in a trough containing the abrasive medium (Type IIA1).

A sandblasting machine for making impact abrasive tests under controlled conditions has been manufactured by Carl Zeiss, Switzerland[24] (Type IIC2). A simple apparatus using the sandblast principle, and easily built in the laboratory, is described by Rosenberg[20] (Type IIC2).

The Taber Abraser, manufactured by the Taber Instrument Company, North Tonawanda, N.Y., consists of a pair of small abrasive wheels which wear a circular path on a rotating test specimen. It is designed for measuring the abrasion resistance of metal finishes (Type IIA2).

In the literature may be found references to various types of tests—metals against abrasive papers, against grinding wheels, against sand or other abrasive on a lap; metal in loose sand, either dry or wet; metal balls or cylinders tumbled in sand in a ball mill; sand blast on metal; rotating thin steel disk or tungsten carbide disk gouging into a flat specimen; brake shoe type of test (rotating metal member against stationary metal member); moving endless steel belt rubbing against steel; reciprocating, metal-to-metal, either flat or curved plates; cylinder or rod between three rolls; rotating disks; rotating the flat end of a rod against metal; rotating the hollow end of a cylinder against a flat block; scratching tests and others. Conditions of these various types of tests can be and have been varied almost without limit—pressure, temperature, speed, surface finish, lubrication, different abrasives, and such. Schematic descriptions of various types of apparatus for testing wear are given by Tichvinsky.[7]

Such a variety of tests and test conditions is bewildering. The selection of a wear test is logically based on the type of service and conditions involved; the test should simulate these as closely as possible.

Precautions in Interpreting Results of Wear Tests. Data from wear tests must be interpreted with caution. Neglecting even one factor may lead to erroneous conclusions.

Obviously the first precaution to take is the adoption of a test which simulates service conditions. The use of an arbitrary test will rarely yield data of value. When the proper type of test has been selected, test conditions must be adjusted so as to correspond to service conditions. This is not always easy. The temptation to exaggerate service conditions in order to shorten the period of testing will frequently cause an unbalance in other conditions—for example, higher operating temperatures because of increased friction; excessive work hardening or deformation of contacting surfaces because of increased pressure.

In metal-to-metal wear, the condition of the contacting surfaces is important. Rates of wear after the mating surfaces are "worn in" are usually different from the previous rates. Data based on the wearing-in portion of an

individual test should not be used. A better understanding of the rate of wear will be gained by plotting the cumulative wear, as determined by a series of consecutive tests, against some factor such as time or total travel. During the wearing-in period the slope of the resultant curve is frequently different from the later slope and will depend somewhat on the type of surface finish.

Many investigators have expressed wear resistance as the ratio of the loss in weight of test materials as compared with that of an arbitrarily selected "standard" material tested under similar conditions. Such procedure permits some variation of test conditions, but the standard must be uniform and reproducibility must be established, or the results obtained can easily complicate the interpretation of the data. This method is valuable when test conditions cannot be strictly controlled and the "standard" specimen can be tested simultaneously with the test specimen, thus assuring that both are subjected to whatever variations may occur during the course of the test. Where test conditions can be kept under strict control, and uniformity is thus established, the method described in the preceding paragraph is more direct than comparison with a selected "standard".

In evaluating the wear resistance of metals for a specific application, the test method used *must* rank different materials in the same order of merit as that established by service experience. Only then can that test procedure be trustworthy for evaluation of new or untried materials.

Strict control of test conditions is absolutely essential. The literature is replete with cases where slight changes in test conditions have reversed the order of merit of test materials. Ellis[22] for instance, testing materials in a ball mill, found that a change from one type of abrasive to another reversed the wear resistance of many of his test materials, as did a change in the pH value of the grinding mixture, or a change of atmosphere within the ball mill.

The influence of oxides that frequently form on the wearing surfaces during test should not be overlooked. It has been shown that the formation of certain oxide films frequently acts as a protection against wear.[16]

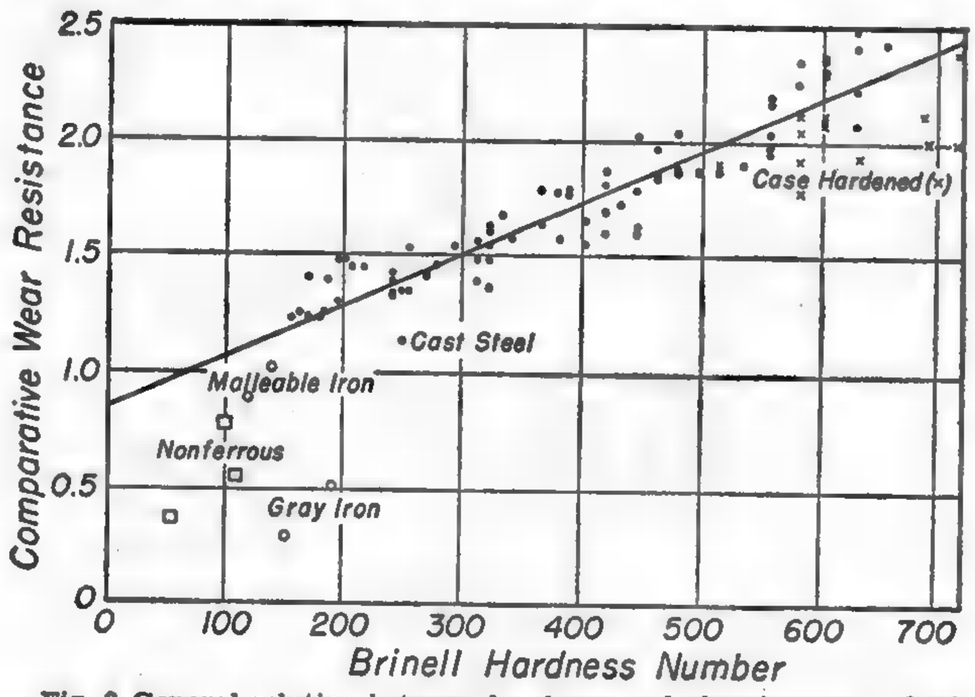

Fig. 2 General relation between hardness and abrasive wear of miscellaneous materials. Wet 80-mesh Crystolon abrasive on cast-iron lap. (Wear type IIA1.) Comparative wear resistance is the ratio of weight loss of specimen to weight loss of SAE 1010 steel (treatment not given). Unit pressures also not given. (From data by Weiss[23])

Test Results and Correlation with Service Data. It is not possible in an article of this type to review the enormous amount of work that has been done in this field. Attention will be directed, however, to selected data, both published and unpublished. A concise, yet extensive, review of the literature up to 1937 was written by Gillett.[1]

In steels, a fair correlation between hardness and wear resistance has been noted by many investigators, even though numerous exceptions to this statement may be found. In the absence of any other data, the selection of a steel hardened to as high a degree as is practicable for the application at hand is usually acceptable engineering. Thus, using a lapping type of wear test employing silicon carbide abrasive and a cast iron lap on both carbon and alloy structural steels subjected to a variety of heat treatments, Weiss[23] gives results that, when plotted, show a fairly linear relation between hardness and wear resistance in this particular type of test (Fig. 2). (Wear type IIA1). The application involved was the selection of materials and heat treatments for power transmission chains, and a private communication from the author indicates that the rating of steels as determined in this test has been found to check service results.

Unpublished data from the American Brake Shoe Company (Table I) show the relative abrasion resistance of various structures (Wear type IIA1). The apparatus used was quite similar to that described by Blake.[21] Conditions of test were as follows:

Abrasive, 40 lb of quartz sand, grain fineness No. 50, mixed with 30 liters of water

Specimen travel, 119 fpm for 1.35 miles (7130 ft)

Bearing surface pressure, 38.5 psi

A 2½ to 1 life ratio has been reported for Ni-Hard as compared with ordinary chilled white cast-iron balls.[25] This ratio agrees well with the ratio implied in Table I.

Table I

Typical Wet Sand Abrasion Factors (Wear type IIA1)[a]

Material	Bhn	Abrasion Factor
Ferrite (ingot iron)	90	1.40
Gray cast irons	200±	1.00 to 1.50
SAE 1020, annealed	107	1.00 (Standard)
White cast irons	400±	0.90 to 1.00
Pearlite	220 to 350	0.75 to 0.85
Austenite (12% Mn)	200	0.75 to 0.85
Bainite	512	0.75±
Martensite	715	0.60±
Martensitic cast irons (Ni-Hard)	550 to 750	0.25 to 0.60

(a) The abrasion factor is the ratio of weight lost by specimen during test to the weight lost by a "standard" specimen. This arbitrarily selected standard was annealed SAE 1020 steel, Bhn = 105 to 110.

Results obtained by this test showed excellent correlation with field results from milling siliceous ore (Table II). It is significant that a substitution of calcite, fluorite, feldspar, or other minerals for quartz, may alter considerably the behavior in tests of this type.

Table II. Correlation of Laboratory and Field Tests

Material	Abrasion Factor — Laboratory Test[a]	Abrasion Factor — Field Test[b]
Air-hardening steel liners	0.69	0.70
Air-hardening steel liners	0.65	0.68
Air-hardening steel liners	0.73	0.69
Air-hardening steel liners	0.68	0.69
Air-hardening steel liners	0.65	0.64
Air-hardening steel liners	0.70	0.68
Air-hardening steel liners	0.69	0.70
Water-quenched steel balls—outside	0.54	...
center	0.65	...
volumetric average	0.56	0.56
White cast-iron balls	0.92	0.93
SAE 1020 steel, annealed	1.00	1.08

Rosenberg[20,17] used the Brinell sand abrasion and the Amsler wear-testing machines in studying the wear of carbon steels. He found that in these two particular types of test the harder steels were more resistant to wear or abrasion (Fig. 3 to 7) (Wear types IIA2 and IA2 plus IB2). This same trend for alloy steels has been observed with the Timken machine (unpublished data from Timken Roller Bearing Company). Thus, a graphitic steel (0.50% C; 0.45% Mn; 0.75% Si; 0.25% Mo) tested in the presence of an extreme pressure oil under a unit load of approximately 20,000 psi, gave the following results:

Hardness, Rockwell C	Loss in Weight of Test Piece (Wear type IA1) after 2-hr run, grams
40	0.0770
45	0.0117
59	0.0093
58	0.0067

A study of various test results indicates that resistance to wear generally increases with carbon content. Exceptions to this may usually be explained by microstructural

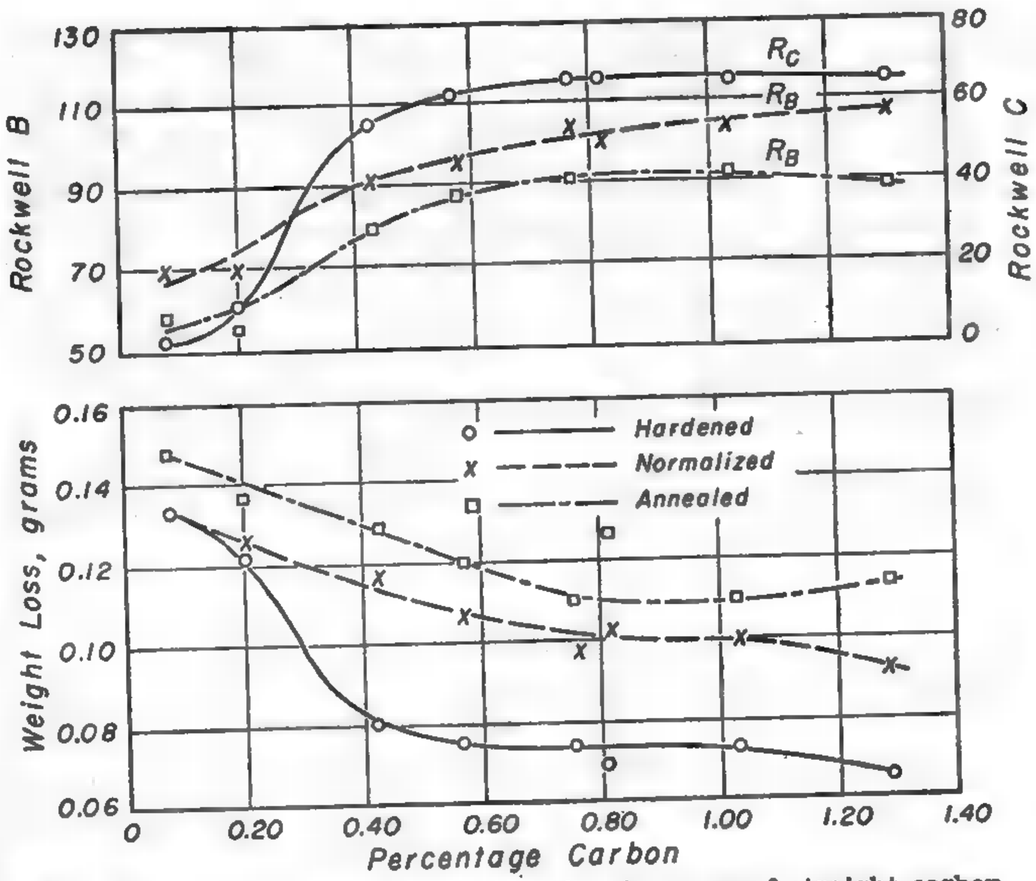

Fig. 3 Effect of carbon content on abrasive wear of straight carbon steels. Brinell sand abrasion (Wear type IIA2). Illinois glass sand passed through sieve of 0.297-mm opening. Pressure of rotating disk, 10 kg. Length of test, 60 meters travel of disk (Rosenberg[20])

features. In normalized steels the presence of free ferrite is deleterious to the wear resistance; increasing the carbon content until a pearlitic structure is obtained is usually beneficial. Hypereutectoid carbon steels may show a slightly improved resistance to wear if the carbides are small and well distributed. Although the presence of a network of excess cementite in hypereutectoid steels is undesirable for many applications, such a structure is more resistant to abrasion than one where the excess cementite is globular.

The wear resistance of carbon steels is markedly improved by heat treatment. Unfortunately, however, the brittleness of such structures renders them unsuitable for many purposes; in such metals some resistance to wear must be sacrificed by tempering to improve toughness.

The technical literature is not always in agreement concerning the effect of alloying elements on wear. In unhardened steels alloying elements appear to affect wear resistance only insofar as they cause the formation of more pearlite and of finer pearlite. The effect of alloying elements in hardened steels is generally less noticeable, except as they cause the formation of hard excess carbides, or serve to decrease the rate of softening under the influence of frictional heat.

Fig. 4 Effect of tempering temperature on abrasive wear of 0.81% C steel. Brinell sand abrasion (Wear type IIA2). Illinois glass sand passed through sieve of 0.297-mm opening. Pressure of rotating disk, 10 kg. Length of test, 60 meters travel of disk (Rosenberg[20])

graphite flakes is superior to one having small coarse flakes. Figure 8 shows the effect of combined carbon on the wear of cast iron, as determined by Boegehold in the brake shoe type of test[18] (Wear type IA2). Hardening cast iron to produce a martensitic structure causes a marked improvement in wear resistance, and the resistance of chilled iron to certain types of wear is well known. Gray cast iron is remarkably free from any tendency to gall and seize and is very effective for use with materials as hard or harder than the iron itself.

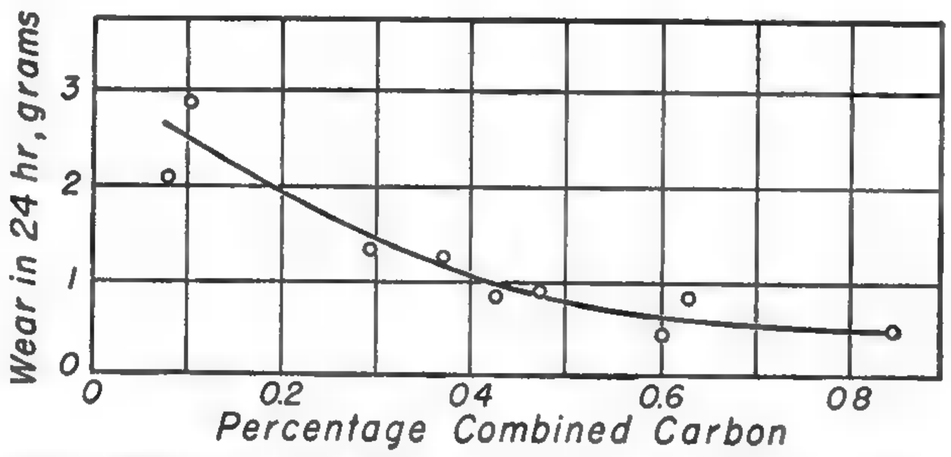

Fig. 8 Effect of combined carbon on wear of cast iron. Brake shoe type test. (Wear type IA2). Standard material (the drum) was cast iron of 180 Bhn and 0.46% combined carbon. Sliding speed, 1600 ft per min. Pressure, 12 psi (Boegehold[18].)

As with steels, disagreement exists concerning the specific effects of other elements on the wear resistance of cast iron. These differences are probably more apparent than real, since they are very likely the result of the specific test conditions used. Boegehold[6] writes: "Certain conclusions to the contrary, the general picture obtained from all this work is that increased hardness, or the addition of elements which form hard constituents in the iron, either by going into solution or by combining chemically, results in decreased wear."

Solid solution alloys, either ferrous or nonferrous, generally lack wear-resisting qualities, perhaps because of their relative softness as well as their homogeneous structures, and such alloys should not be used when wear is an important consideration. Such materials also tend to gall and seize. Austenitic manganese steel is a notable exception, but its best performance depends on service conditions that cause work hardening. The wear resistance of most of these materials, such as the austenitic and ferritic stainless steels, can be improved markedly by nitriding.

Herschman and Basil[19] have shown that in their investigations the wear resistance of tin-base bearing alloys was greater than that of lead-base alloys. (Wear type IA1 plus IB1). Service tests corroborated their laboratory results.

Protection Against Wear. Adequate lubrication, smoothness and soundness of the metal surfaces, and the prevention of corrosive conditions are the most effective methods of eliminating wear. If lubrication is impossible, low specific pressures should be employed and recourse may be made to the most efficient materials.

Surface hardness, usually beneficial in protecting against wear, may be secured in ferrous alloys by heat treatment. Induction hardening, flame hardening, case hardening, cyaniding, nitriding, Ihrigizing (siliconizing), chromium plating, and hard surfacing have all been found useful. Surfaces that are too hard and brittle may spall if the application involves impact as well as wear. For such applications, hard surfacing with the cobalt-chromium-tungsten alloys, with air-hardening steels, or with austenitic manganese steel is probably best. Sintered carbides have a high degree of wear resistance.

Platings of soft metals (such as tin on piston rings) have been used, but their primary function is to assist in the wearing-in operation. Applications of "Granosealing" (a phosphate treatment)[26] and the "Sulfide process" (a caustic-sulfur treatment)[27] have been reported as reducing wear and scuffing, particularly between piston rings and cylinders. Porous chromium platings on piston rings have proved very efficient in preventing wear.[28]

Wear of lead bearings has been reduced by plating with indium. The indium also protects against corrosion.

Galling and seizure may be minimized by the use of dissimilar metals and by avoiding the use of solid solution alloys. The use of at least one metal that forms some sort of lubricating film, or of a thin, tightly adherent oxide coating, or of a sulfide, chloride or phosphide coating, is frequently helpful. Plastic deformation may permit almost perfect contact of mating surfaces under pressure, thus facilitating seizure. This may be prevented by using materials with higher elastic limits. For parts that operate under such extreme pressures that elastic deformation permits intimate contact, as in certain gears, the best preventive measure is a lubricant that combines with the metal surface to form a tenacious "corrosion" product of sufficient strength to keep the parts separated.

The Resistance of Metals to Oxidation at Elevated Temperature

By Benjamin Lustman*

THE NATURE and extent of the attack on metals and alloys, when heated in oxidizing environments, are determined largely by the properties of the scale that is formed—its structure, chemical composition, melting point and boiling point. The metal base and gas environment are usually important only as they affect the scale. From numerous investigations, it has been found that at high temperatures the oxidation of many metals proceeds according to a parabolic relation:

$$x^2 = kt \qquad (1)$$

where x is weight or thickness of metal consumed or formed into scale, t is time and k the rate constant. Theoretically such an equation is to be expected if oxidation proceeds by the diffusion of metal or oxygen through the scale.

The essential condition for the validity of equation (1) was shown by Pilling and Bedworth[1] to be the formation of a dense and adherent scale, a condition that obtains when the specific volume of the oxide is equal to or greater than the specific volume of the metal; that is, when

$$\frac{M \cdot d}{m \cdot D} \geqq 1 \qquad (2)$$

where M and D are the molecular weight and density of the oxide, and m and d those of the metal. Values of this ratio for the oxides formed on various metals are shown in Fig. 1. The metals that are underlined in this diagram have been found by experiment to form adherent protective scales, increasing in weight or thickness with time according to equation (1). The almost general validity of the Pilling and Bedworth rule may be appreciated by examining this diagram.

Li 0.57	Be 1.59								
Na 0.57	Mg 0.79	Al 1.28	Si 2.27						
K 0.45	Ca 0.65		Ti 1.95	V 3.18	Cr 1.99	Mn 1.79	Fe 1.77	Co 1.99	Ni 1.52
Cu 1.68	Zn 1.62		Ge 1.64	As 2.15					
Rb 0.45	Sr 0.65		Zr 1.51	Cb 2.61	Mo 3.4				Pd 1.60
Ag 1.59	Cd 1.21	In 1.23	Sn 1.32	Sb 2.35					
Cs 0.46	Ba 0.74	La 1.11	Ce 1.16		W 3.4				
			Hf 1.48	Ta 2.33					
	Hg 1.31	Tl 1.38	Pb 1.40	Bi 2.27					
			Th 1.32		U 3.05				

Fig. 1. Ratios of specific volumes of oxides and metals, arranged in the periodic sequence. The underlined metals have been found by experiment to form adherent protective seals in hot oxidizing environments.

As in other diffusional processes, the variation of the rate of oxidation with temperature, or the rate constant k of equation (1), may be expressed by an Arrhenius equation:

$$k = Ae^{-\frac{Q}{RT}} \qquad (3)$$

where A and Q are constants, R is the gas constant, T is absolute temperature, and e is the base of natural logarithms. Thus, when the logarithm of oxidation rate is plotted against the reciprocal of absolute temperature, the graph will be a straight line.

The weight of scale formed on those metals having oxides of specific volume smaller than that of the metal, increases linearly with time. The resultant scale is porous and crumbly, and the rate of attack is controlled only by the specific reactivity of the metal, and the composition of the gas atmosphere. Exceptions to the Pilling and Bedworth rule have thus far been noted only for tungsten and molybdenum, which, in spite of a much higher specific volume of oxide than of metal, as shown in Fig. 1, form nonprotective oxides that increase in weight proportionally to reaction time.[2] The oxidation of molybdenum is complicated further by the high vapor pressure and relatively low melting point of the predominant oxide, MoO_3.

A third class of metals, the noble metals, have oxides with higher dissociation pressures than the partial pressure of oxygen in air at the oxidation temperature; therefore the noble metals form no superficial oxide. Thus, at low temperatures, silver forms a superficial oxide that decomposes on heating to 375 F (190 C), at which temperature the decomposition pressure of Ag_2O equals the partial pressure of oxygen in air. Palladium and rhodium behave similarly; their oxides decompose at about 800 C and 1100 C, respectively. Cladding of base metals with such noble metals has been proposed as a means of protection, but such cladding is useful only at moderate temperatures. Because of the appreciable solubility and high rate of diffusion of oxygen in such metals at elevated temperatures, oxygen penetrates to the base metal and forms a layer of oxide at the interface.

The theory of the scaling of metals that form protective oxides has been advanced greatly in recent years by the researches of Wagner.[3] On the basis of various experimental facts, Pfeil[4] concluded that, during the oxidation of iron, iron ions diffuse from the metal through the oxide to the oxide-gas interface and there react with oxygen. Wagner showed that in addition to negatively charged oxygen ions, both electrons and positively charged metal ions migrate through the oxide layer. The scale may be considered an electrolytic cell with its metal-base cathode and gas-atmosphere anode short-circuited by an external resistance (analogous to electron conduction through the oxide). The electromotive force of such a cell is given by the free energy of formation of the oxide. From a knowledge of the conductivity of the oxide and the relative mobilities of positive and negative ions, it is possible to calculate values of the constant k in equation (1), and these calculated values are in good agreement with experimental determinations.

It follows from this work that the lower the electrical conductivity of the oxide, the lower the rate of scaling. Since, in general, the more refractory oxides have lower electrical conductivity, those metals forming oxides of high melting point are most useful as alloying additions to confer resistance to oxidation.

When the temperature and duration of oxidation yield oxide films thinner than 2000 A (0.0002 mm), the composition, the structure, and the rate equations governing the growth of the films (as well as the methods for measuring film weight and thickness), may be quite different from the corresponding relations of the thicker films or scales discussed here. Such thin films are of interest mainly in connection with studies of corrosion.

Structure of Scales. Scales generally consist of a layer-like structure, each layer comprising an oxide phase that is stable at the reaction temperature. Thus, when iron is heated in air or oxygen at atmospheric pressure and temperatures above 1000 F (550 C) an outside layer of Fe_2O_3, an intermediate layer of Fe_3O_4, and an inner layer of FeO appear in succession on the iron base. The surface of the iron itself is also saturated with the quantity of oxygen soluble at the oxidation temperature. The relative thickness of each layer is governed by the relative diffusivities of iron ions in each phase. Thus, since the FeO layer has the highest conductivity, it constitutes 85 to 90% of the total scale thickness; the Fe_3O_4 layer 10 to 15%; and the Fe_2O_3 layer 0.5 to 2%. When removed mechanically from the base metal, the scale separates into three sections. The

* Research Laboratories, Westinghouse Electric Corporation, East Pittsburgh, Pa.

outer section consists of the layers of the Fe_2O_3 and Fe_3O_4 phases; the middle section consists of the FeO phase bounded on one side by the Fe_3O_4 layer and on the other by a plane representing the original surface of the specimen; and the inner section consists of the FeO phase bounded by the original surface of the iron specimen and the surface of the still unoxidized metal.

In alloys, the added element may occur in the scale in several forms, depending on its relative oxidizability with respect to the base metal. Thus, when small amounts of the additions (alloying elements) form refractory oxides—for example, aluminum, silicon and chromium when added to iron—the added element may occur in the inner (FeO) scale layer adjacent to the steel base, either as its own oxide or as a double oxide with FeO. The concentration of such elements in the inner layer of scale may be as high as four times the concentration of the element in the alloy. In the two outer layers of scale, the added element may decrease to 10% of its concentration in the base metal.

In richer alloys, when such elements are increased in content, the concentration in the inner scale layer rises continuously until the layer consists almost entirely of the refractory oxide with a correspondingly low rate of diffusion. Marked decrease in the rate of oxidation is to be expected only when the scale adjacent to the metal consists entirely of such ■ refractory oxide. Thus, by using a slightly oxidizing atmosphere for preheating copper that contained an amount of aluminum insufficient to retard oxidation appreciably during heating in air, Price and Thomas[5] were able to form on the copper a layer of refractory aluminum oxide that effectively stopped further scaling when the metal was reheated in air.

When metals are added that are less reactive with oxygen than the base metal, the added metal is also enriched in the layer of scale adjacent to the metal surface; however, in this instance the added metal occurs as fine metallic particles embedded in the scale. Thus, on an iron-nickel alloy containing 5% Ni, metallic particles containing 30% Ni or more are found in the scale.[6] Similar precipitates occur when cobalt and copper have been added to iron. The structure of the scale is otherwise altered only slightly. Since refractory oxides do not result from such additions, little improvement can be expected in the resistance of the alloy to oxidation.

The action of hot air on metals causes not only the formation of external scales, but oxygen also diffuses into the metal base, resulting in "internal oxidation", metallographically visible as a layer that contains particles of oxide of the alloying element embedded in the essentially pure solvent metal. Steels that contain chromium, aluminum or silicon form internal oxides of these elements (or their double oxides with FeO) embedded in the surface of the metal, often at grain boundaries. One important result is that subsequent pickling for the complete removal of scale is difficult.[7] In steels that contain copper, the diffusion of oxygen into the surface, and the formation of oxides with iron, leads to the precipitation of metallic copper at the grain boundaries; in the presence of excessive amounts of sulfur in the steel, such liberation of copper may cause surface defects during hot working.[8]

It has been shown quantitatively[8,9] that the depth of the subscale and the distribution of oxides or of precipitated noble elements in the internally oxidized zone, may be calculated from a knowledge of the rate of diffusion of oxygen and of the alloying element in the base metal, and the solubility of any reaction product formed.

Determination of Resistance to Oxidation. A number of methods are available for measuring the resistance of metals to attack by oxidizing atmospheres; the choice of method will depend on the particular application of the metal and on its physical form. Methods that have been used are:

1 Determination of the Increase in Weight of Specimens After ■ Given Duration of Exposure. Such a method is particularly applicable for the continuous measurement of the course of oxidation, and enables the experimenter to compare materials that are to be subjected to attack at a constant temperature. Spalling of the oxide at temperature or during cooling, and vaporization of the oxide at elevated temperature lead to inaccuracies in this method. However, difficulties caused by spalling during cooling, may be overcome by collecting the spalled-off oxide in ■ boat surrounding the specimen.

2 Determination of the Decrease in Weight After Removing the External Scale. This method is particularly useful in evaluating the effect of various furnace atmospheres on the rate of loss of metal, or damage to surface finish, and on the ease of pickling. This method suffers the disadvantage that complete removal of the oxide without affecting the base metal is often difficult and practically impossible when the oxide penetrates the metal and no sharp division exists between oxide and metal phases.

3 Measurement of the Amount of Gas Consumed in the Oxidation Reaction. This, like method 1, is particularly applicable to the continuous determination of the rate of attack. Such a method would be limited to closed systems and to simple atmospheres.

4 Determination of the Time Necessary for the Destruction of a Given Size of Material. This method has been used extensively in the testing of wire to be used in electric heating devices. Bash and Harsch[10] devised a method of testing that, with slight modification, has been adopted in ASTM Standard Method B 76-39 as a life test for electrical heating alloys. A 12-in. length of No. 20 or No. 22 gage wire is suspended between a fixed upper clamp and a mercury cup. Current through the wire is adjusted so as to yield a temperature of 2050 to 2150 F (depending on the alloy), as measured by an optical pyrometer. The time required to burn out the wire with the current alternately on 2 min and off 2 min, is accepted as the life of the material. The life of wire is comparatively unaffected by variation in size for diameters larger than No. 24 American wire gage. However, the actual and relative durations of heating and cooling have considerable effect. A time cycle of 2 min on, ▮ min off, was found to be most injurious. This method is standard for evaluating the life of electrical resistance alloys but is applicable only to alloys that can be fabricated to wire.

5 Metallographic Examination of the Oxidized Material. Such examination will reveal not only the depth but also the distribution of oxidizing attack, as well as certain changes in composition or structure within the metal, such as decarburization and internal oxidation. Metallographic examination of the oxidized specimens should be an essential step in determining resistance to oxidation.

Each of the above methods reveals different oxidation characteristics, and the relative as well as absolute oxidation behavior of alloys will vary with the method of test.

Rate of Oxidation of Alloys. The principal criterion for an oxidation-resistant alloy is the ability of the alloy to form an oxide scale of low electrical conductivity, which indicates a low rate of diffusion of metal ions, as outlined above. Equally important for resistance at high temperature is the melting point of the oxide. In general, the higher the melting point of an oxide, the lower its conductivity. Presence of alloying elements that form low-melting eutectics or compounds with other constituents of the scale must be avoided, since molten scales give no protection. Thus the presence of 0.04% B in a 30% Cr steel completely destroys resistance to scaling at 2200 F (1200 C).[11] Likewise, steels that contain more than 5% Si are useless above 2200 F because of the $FeO\text{-}SiO_2$ eutectic, which melts at 2250 F (1240 C). In the following paragraphs it may therefore be noted that those alloys which form refractory oxides are most resistant to oxidation.

Iron-Chromium Alloys. The most important component of heat-resistant alloys is chromium, both because it forms a highly refractory oxide and because its alloys with nickel and iron, or both, are workable even when the percentage content of chromium is high. The effect of increasing chromium content in a 0.15% C, 0.7 to 0.9% Si steel, heated in air for 120 hr at various temperatures, is shown in Fig. 2. It may be noted that, at each temperature, with increasing chromium content the amount of scale decreases continuously to a low value. After this low value has been reached, further additions of chromium cause little improvement. The chromium content at which a low rate of scaling is obtained denotes the composition at which the scale consists entirely of refractory Cr_2O_3; it may be noted that the proportion of chromium required increases with increasing temperature.

Curves of the type shown in Fig. 2 are general for all alloy additions that confer resistance to oxidation. For temperatures higher than 1800 F (1000 C), alloys that contain 26% Cr or more, may be necessary. Oxidation characteristics of iron-chromium alloys may be improved still further by additions of aluminum or silicon in amounts greater than 2%.[13]

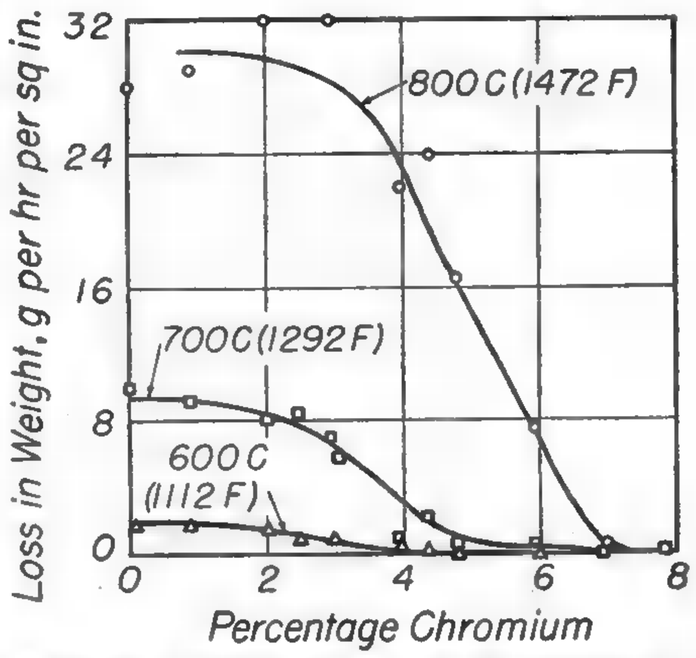

Fig. 2 Effect of chromium content on the scaling of a steel containing 0.15% C and 0.7 to 0.9% Si (Houdremont[12])

Nickel-Chromium Alloys. It may be noted from Fig. 3, in which the logarithm of oxidation rate is plotted against chromium content, that improvement in the resistance of nickel to oxidation, is concurrent with chromium additions up to its solubility limit. Since the widely used chromium-nickel alloys nearly always contain manganese and silicon, which decrease the solubility of chromium in nickel, such alloys are limited to a maximum of 25% Cr. It has been shown by Horn[14] that the oxidation of nickel-chromium alloys of relatively high chromium content cannot be described by a simple equation of the form of equation (1); for long durations of exposure to oxidation, such alloys oxidize much more slowly than would be expected from a parabolic relation between increase in weight and time, so that the decrease in oxidation attack of nickel by chromium additions (Fig. 3) would be much more pronounced had the changes in weight been observed over a longer period of time. In tests similar to the Bash and Harsch test, it has been found that 20% Cr alloys withstand 1200 intermittent heatings to 1050 C as compared with 150 for a 6% alloy.[15] A chromium content of 20% appears to be optimum in the absence of iron.

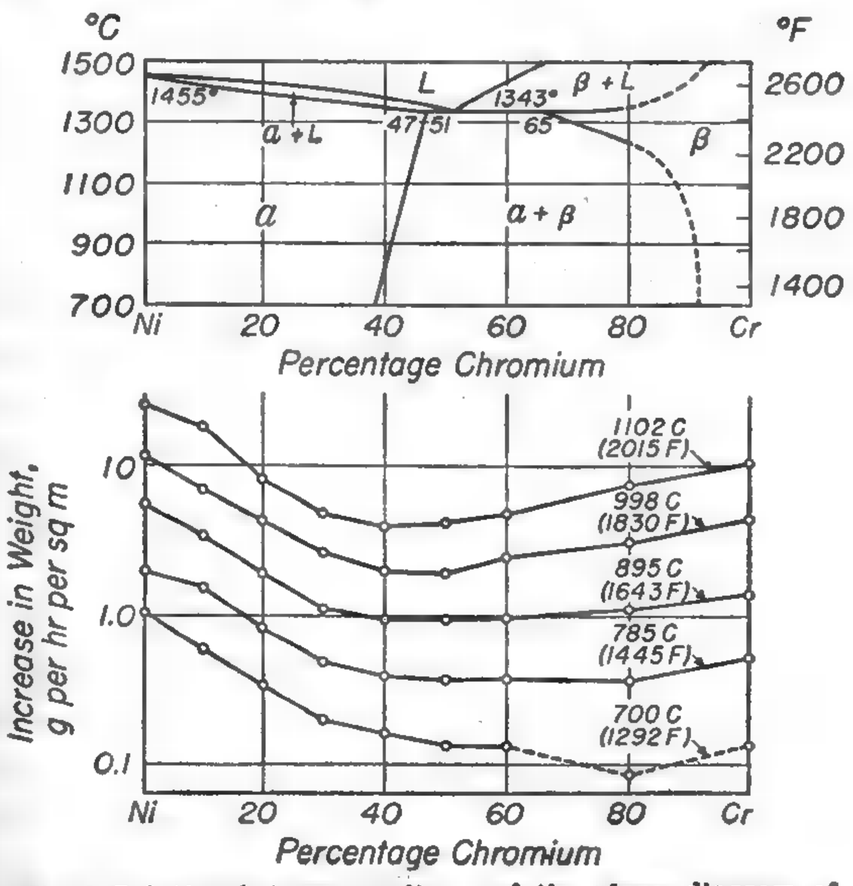

Fig. 3 Relation between scaling and the phase diagram of chromium-nickel alloys (Matsunaga[18])

It has been noted that small additions of chromium (2 to 3%) decrease the resistance of nickel to oxidation. An addition of about 0.25% Cr induces free spalling of the oxide, a fact not disclosed by Fig. 3 because no opportunity was afforded for spalling by cooling. This behavior is explicable to some extent by the type of scale formed on these alloys. On the nickel-chromium axis of Fig. 4 are plotted the structures of the oxides formed on binary nickel-chromium alloys at 1000 C (1830 F). Up to about 10% Cr the oxide formed is NiO. With higher chromium contents the resulting oxide has the crystal structure of Cr_2O_3, which is more refractory than NiO and affords greater protection. The good resistance to oxidation of nickel-chromium alloys has been attributed to the presence of the spinel $NiO \cdot Cr_2O_3$, which has been reported in alloys containing 15 to 20% Cr.

Carbon, by combining with chromium to form insoluble carbides, decreases the resistance of nickel-chromium alloys to scaling; the life of an 80% Ni, 20% Cr alloy is reduced one-half by the presence of 0.30% C.[15] Manganese also causes a slight increase in the rate of scaling, while silicon and aluminum, even in amounts insufficient to reduce the workability appreciably, improve resistance to oxidation. Tungsten and molybdenum, which may be added to improve the strength at high temperatures, have little effect on the resistance to scaling.[16]

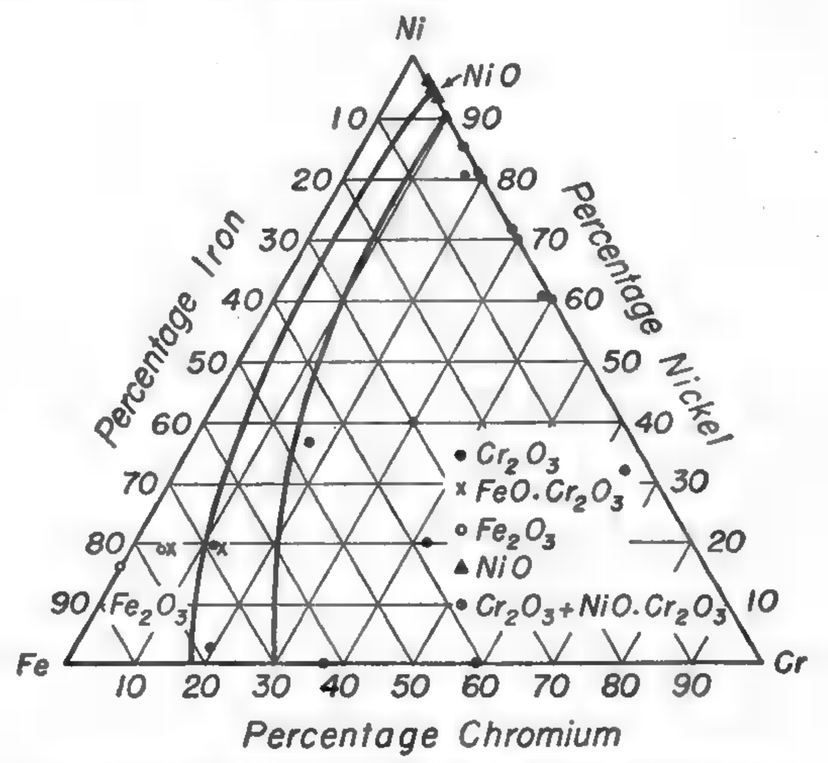

Fig. 4 Constituents of scale layers on Fe-Ni-Cr alloys[7,14,16]

*Iron-Nickel-Chromium Alloys.** Still more important than the iron-chromium alloys as heat-resistant materials are the iron-chromium-nickel alloys. Nickel is added to such alloys principally to render the alloy austenitic at room temperature; nickel also improves the mechanical properties of the alloys. The improvement in oxidation resistance conferred by additions of nickel, is minor in comparison with the effect of chromium. This is shown in Fig. 4, in which are plotted the principal constituents of the scale formed on various alloys at 1830 F (1000 C). The lines divide the composition range into three regions; the one at the right (high chromium contents) denotes alloys that, when oxidized, have an increase in weight of less than 0.001 g per sq cm in 7.5 hr at 1000 C; the increase in weight at low chromium contents is more than 0.01 g per sq cm; and the increase in weight in the intermediate region is less than 0.01 g per sq cm. In the region of low increase in weight the scales that form are predominantly Cr_2O_3, and the scales containing NiO or Fe_2O_3 form in the region of high increase in weight. It is evident from this diagram that chromium is mainly responsible for decreasing the scaling attack. Similar results were obtained by Brasunas, Gow, and Harder[17] in 100-hr continuous tests in air. It was found that the beneficial influence of increased additions of nickel was most prominent at low chromium contents. As the chromium content of the alloys increases, the influence of nickel becomes less pronounced. This is shown in Table I, in which are listed

* *See also* STAINLESS STEELS AND HEAT RESISTING ALLOYS.

the minimum nickel contents required with various chromium contents to render Fe-Ni-Cr alloys resistant to oxidation. A loss in weight of 0.04 g per sq in. per day (0.1 in. penetration per year) was considered satisfactory resistance. Carbon was found to have little effect on the resistance to oxidation; additions of silicon improved the oxidation behavior appreciably.

Table I. Minimum Nickel Contents Required With Various Chromium Contents to Render Iron-Nickel-Chromium Alloys Resistant to Oxidation in Air[17]

(A loss in weight of 0.04 g per sq in. per day was considered satisfactory resistance.)

Iron-Aluminum Alloys. Aluminum is the most effective addition for suppressing the scaling of iron. Ziegler[19] showed that during a two-hour testing period an 8% Al alloy has the same oxidation resistance as an 80% Ni, 20% Cr alloy. If the scaling rate of iron-aluminum alloys is plotted against aluminum content, curves will be obtained similar to those shown in Fig. 2 for chromium steels;* similarly also, larger concentrations of aluminum are required as the reaction temperature increases. Low rates of oxidation are obtained only when a white Al_2O_3 scale forms over the surface of the alloy. Internal oxidation is severe in such alloys, causing an impoverishment of the alloy in aluminum. Thus after long periods of oxidation, severe local attack may occur at damaged places in the oxide coating; by internal oxidation of the aluminum, the material will have lost the ability to repair the protective coating. These alloys are difficult to fabricate.

Iron-Aluminum-Chromium Alloys. These alloys are resistant to oxidation even at very high temperatures, but in sensitivity to damage of the oxide film and difficulty in fabrication, suffer the disadvantages of the iron-aluminum alloys, although to a lesser extent. Even in such alloys, aluminum is the most effective agent for restraining oxidation; minimum attack is noted when the principal scale constituent is Al_2O_3.[6] The optimum composition of such alloys appears to be from 20 to 30% Cr and 3 to 8% Al.

Iron-Silicon and Iron-Silicon-Chromium Alloys. Silicon behaves like aluminum in decreasing the scaling of iron, although silicon is somewhat less effective than aluminum. Because of the low melting point of the FeO-SiO_2 eutectic, these alloys are not considered heat-resistant. Alloys containing 12 to 30% Cr and 5 to 10% Si are quite resistant to scaling but, like the Fe-Al-Cr alloys, are hard to work.

Table II. Minimum Nickel Contents for Satisfactory Resistance to Corrosion of Iron-Nickel-Chromium Alloys at 1800 F in Air and in Oxidizing and Reducing Atmospheres; 0.1-In. Penetration per Year[27]

% Cr	% Ni necessary for oxidation resistance in

Copper Alloys. Oxidation-resistant copper alloys are obtainable only when the low-melting, highly conductive copper oxide scale is replaced by a refractory oxide scale. Thus, Dunn[20] showed that copper-zinc alloys are appreciably more resistant than copper only with zinc contents greater than 25%, when a ZnO scale forms. Frohlich[21] found that additions of aluminum, beryllium, magnesium and silicon afford real protection to copper; zinc and tin provide somewhat less; while iron, nickel, manganese, calcium, chromium and other elements give no protection. The addition of several per cent of beryllium, silicon (or both) to constantan (55% Cu, 45% Ni) increases the maximum temperature for use of the alloy from 1100 to 1475 F (600 to 800 C).[22]

Effect of Minor Additions on Oxidation Resistance. Smithells, Williams and Grimwood[23] found that the purity of the initial materials had an appreciable effect on the life of nickel-chromium alloys. Alloys made of electrolytic chromium failed much more quickly than did those made of chromium reduced by the thermit reaction ($Cr_2O_3 + 2\ Al = 2\ Cr + Al_2O_3$). This effect was further investigated by Hessenbruch[24] who found that, by suitable additions, the life of various heat-resistant alloys could be prolonged as much as 10 times. Additions of calcium, thorium and, notably, cerium in amounts less than 0.5% improved the resistance to scaling to a degree out of all proportion to the amounts of added element. Such improvement was found to be general with additions of the alkaline earths and rare earth elements. The service life of nickel-chromium alloys in American practice is greatly extended by the addition of 0.01 to 0.2% Cu, 0.01 to 0.5% Zr, and 0.01 to 1.0% Al.[25]

Hessenbruch offered a tentative explanation of these results, based on the observation that those elements which, when present in small amounts, prolong the life of nickel-base alloys, have atomic volumes greater than that of nickel oxide, whereas those elements which have smaller atomic volumes have no effect. Presumably such minor impurities are to be considered as obstacles to the passage of nickel ions through the scale.

Influence of Gas Atmosphere. In any discussion of the oxidation resistance of metals, the effect of gas atmosphere must be considered, since the composition, pressure, and

Table III. Maximum Temperature for Stability of Various Alloys in Air[20]

(Temperature for stability chosen as that below which losses caused by scaling are less than 0.0002 to 0.0004 ■ per sq cm per hr.)

Material	Composition (Remainder Fe)	Maximum Temperature for Stability, deg Cent

* See Fig. 1 in the article on iron-aluminum alloys, page 606.

rate of flow of the atmosphere may affect the structure, composition and adherence of the oxide scale. Thus, steel is oxidized at an increasing rate by atmospheres of carbon dioxide, dry air, oxygen and steam, respectively. To be stable in steam at 925 F (500 C) a steel must be resistant in air at 1200 F (650 C), and to withstand steam at 1750 F (950 C) a steel must withstand air at 2200 F (1200 C).

The oxidation of mild steel in air was shown by Hatfield[26] to be trebled by the addition of 5% SO_2 and 5% H_2O. Likewise the rate of oxidation of 18-8 Cr-Ni steel in air is increased ten times by the addition of 5% CO_2 + 5% H_2O, eight times in the presence of 5% SO_2 + 5% H_2O, and seven times by 5% H_2O. Nickel and alloys that contain nickel are seriously attacked by reducing atmospheres that contain sulfur. This effect is shown in Table II.

Griffiths[28] found that the adherence of scale to steel is markedly affected by gas composition and rates of heating and cooling. The factors that control the adherence of scales to metal surfaces have been investigated only sparingly. The oxidation stability of alloys is affected not only by oxidizing constituents in the atmosphere but also by carburizing and nitriding constituents that decrease the resistance to oxidation through reacting with alloying elements in the steel, such as chromium and aluminum.

Oxidation Stability of Alloys. Because of the marked effect of small amounts of impurities in the gas atmosphere and in the base metal, and because of the sensitivity of scaling rate to factors such as heating cycles and rate of heating, it is impossible to state with certainty the range of stability of metals in oxidizing atmospheres. Any listing of alloys in their order of merit with respect to scaling, must therefore be considered as comparative only for given atmospheres, heating and cooling cycles and other test conditions. The temperature of stability in Table III is chosen as that temperature below which losses caused by scaling are less than 0.0002 to 0.0004 g per sq cm per hr (0.03 to 0.06 g per sq in. per day).

The Stress Corrosion of Metals

BY THE SUBCOMMITTEE ON STRESS CORROSION*

THE STUDY of stress corrosion concerns the behavior of metal under the combined action of corrosive environment and enduring high tensile stresses. Corrosion fatigue, which results from frequently repeated stresses of lower magnitude combined with a corrosive environment, is not considered as coming within the above definition; neither is failure that is produced by penetration of a liquid metal into a solid metal.

"Stress corrosion" is a general term that may be considered to include acceleration of corrosion by stress as well as the limiting situation, stress-corrosion cracking.[1] Both terms may be defined more easily after the diagrams of Fig. 1 and 2 have been considered. Three identical test specimens may be assumed as examples. Specimen *A* is the unexposed, unstressed blank; its breaking load is

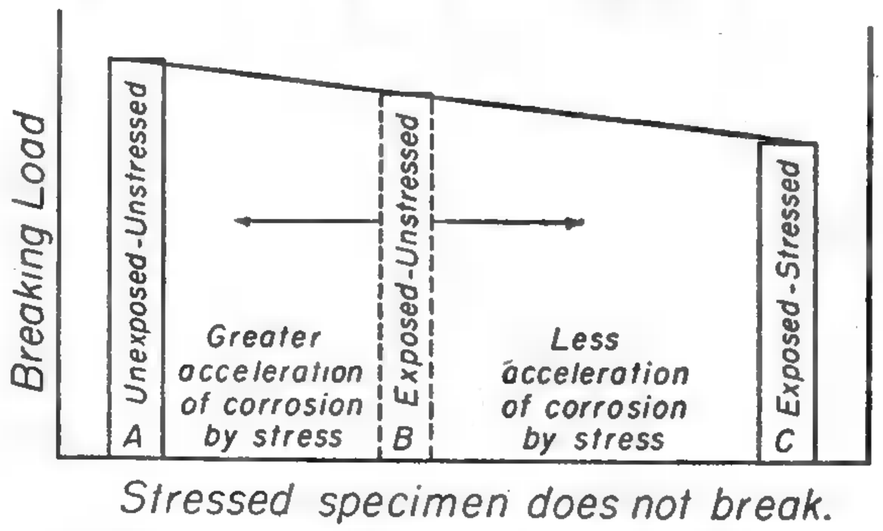

Fig. 1 Influence of stress and exposure on the rate of corrosion. (Dix and Brown)

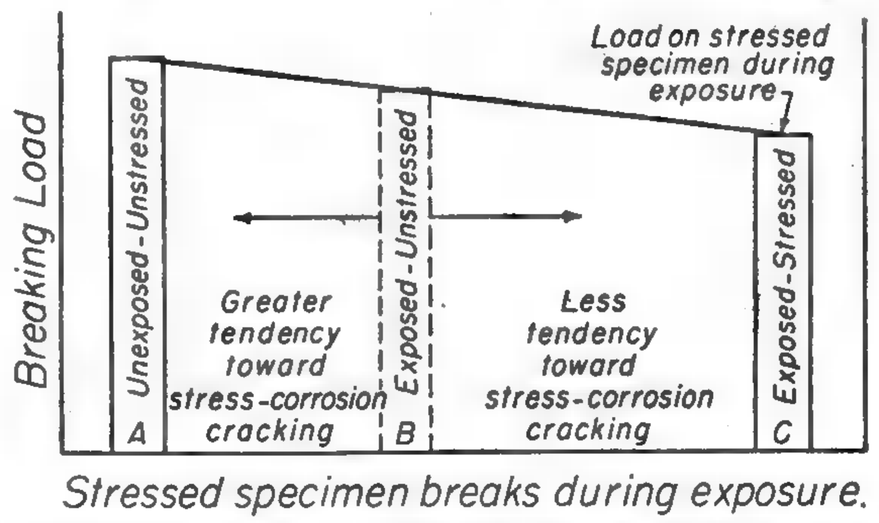

Fig. 2 Influence of stress and exposure on the tendency toward stress-corrosion cracking. (Dix and Brown)

* The members of this subcommittee are M. A. Hunter, *Chairman;* R. H. Brown, E. H. Dix, Jr., A. L. Jamieson and H. H. Uhlig.

represented in the diagrams by block *A*. Specimen *B* is exposed to a corrosive environment in the unstressed condition. Specimen *C*, exposed to the same corrosive environment, is stressed by a constant load equal, for instance, to three-quarters of the breaking load of specimen *A*.

During the period of exposure, specimen *C* may or may not break. Figure 1 represents the situation when *C* does not break. Specimens *B* and *C* are both tested. The breaking load of specimen *B*, as related to the breaking load of specimens *A* and *C*, shows the extent of the acceleration of the rate of corrosion of specimen *C* by the stress. The closer the breaking load of *B* to that of *C*, the less has been the acceleration of corrosion by stress; and the closer the breaking load of *B* is to that of *A*, the greater the acceleration by stress.

Figure 2 shows the situation when specimen *C* breaks under the combined action of stress and corrosion. The closer the breaking load for specimen *B* to the load on specimen *C* during exposure, the less the tendency toward stress-corrosion cracking. For example, if the breaking load for *B* is sufficiently close to the load on specimen *C* to be within experimental error, then although specimen *C* broke, the failure should not be attributed to stress-corrosion cracking, but rather to the probability that corrosion had reduced the cross section to such an extent that the specimen could no longer support the load. On the other hand, the closer *B* is to *A*, the greater the tendency toward stress-corrosion cracking to be ascribed to specimen *C*. It is common knowledge that stress-corrosion cracking often occurs, with very little general corrosion, in some of the metals that are considered resistant to corrosion.

Mechanism of Stress-Corrosion Cracking. Susceptibility to stress-corrosion cracking results when, within the structure of the metal or alloy, more or less continuous zones exist that are more susceptible to corrosion than the rest of the metal. Usually the corrosive attack in these zones occurs because they are anodic to the rest of the structure.[2,3] Fissures in the metal are initiated as a result of the electrochemical action between the anodic zones and the cathodic areas of the structure. If high tensile stresses are present at the surface, these small fissures increase the magnitude of local stress, tending to pull them apart. As the action proceeds, new metal at the base of the fissures is exposed and consumed by electrolytic corrosion. Thus, further concentration of the stress occurs and the depth of the fissures is increased. If the part breaks because of these mutually accelerated processes of increasing stress and corrosion, the failure is said to be from stress-corrosion cracking.

The rate of corrosion of many metals not susceptible to stress-corrosion cracking may be accelerated by high enduring tensile stresses at the surface. However, in those metals in which corrosion occurs selectively along more or less continuous zones, for the reasons stated above, the acceleration of the rate of corrosion by stress is much more marked.

The Stress Corrosion of Aluminum Alloys

By E. H. Dix, Jr.* and R. H. Brown*

GENERALLY, the magnitude of stress required to produce stress-corrosion cracking is high, perhaps half to three-quarters of the yield strength, and the stress must endure over a considerable period of time. Thus stresses induced by service loads are seldom the cause of stress-corrosion cracking. High residual stresses from quenching, forming, welding or misalignment in assembly are more likely to be the cause.

The Stress Factor. It is generally agreed that the stresses causing stress-corrosion failures are tensile or have tensile components at the surface of the metal, which is in contact with a corrosive environment. Such stresses are more likely to cause stress-corrosion cracking when they occur transversely to the elongated wrought grain structure. For example,[4,5] in aluminum alloy tubing sunk after heat treatment, the transverse stress was half the magnitude of the longitudinal stress, and yet longitudinal stress-corrosion cracks were caused by the lower transverse stress, in effect, pulling the grain fibers apart. No transverse cracks occurred, presumably because of the greater difficulty of following a more tortuous path.

In many metals high residual stresses may be reduced by stress-relieving treatments at temperatures lower than the recrystallization temperature. Unfortunately, with heat treated aluminum alloys, the temperatures[6] required to produce satisfactory stress relief have a markedly adverse effect on the mechanical properties and resistance to corrosion of the product. Therefore, in aluminum alloys susceptible to stress-corrosion cracking, manufacturing practices that will not produce high residual stresses should be employed; for instance, the alloy should be in the annealed temper when subjected to severe forming operations, and the part should be heat treated subsequently. Often too, the forming may be done shortly after quenching, at which time the yield strength is relatively low.

In the heat treatment of parts that are large in cross section, rapid quenching in cold water—a practice required by some alloys in order to produce maximum resistance to corrosion—may produce high residual stresses. For a certain alloy in large volume production, it was found that

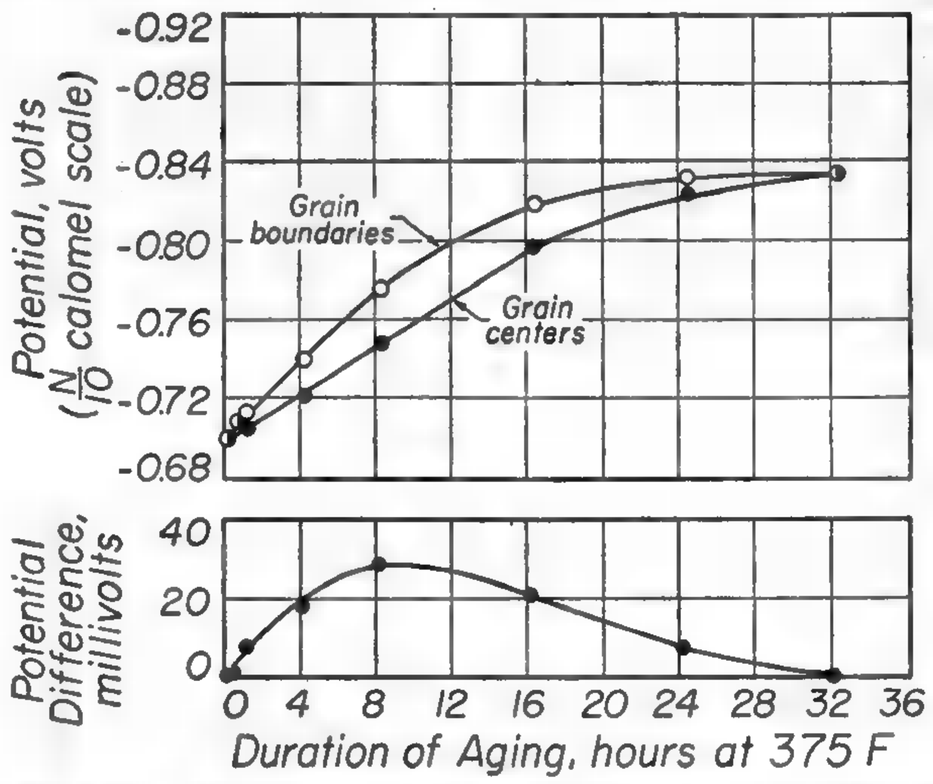

Fig. 3 Effect of duration of aging at 375 F on the electrode potentials of grains and grain boundaries of a high-purity aluminum-copper alloy containing 4.10% Cu (R. H. Brown)

quenching in boiling water, thus producing a much lower order of residual stress, avoided stress-corrosion cracking in service even though the slower quenching produced lower resistance to corrosion.

The Electrochemical Factor. The importance of electrochemical relationships within the structure of the metal or alloy, may be illustrated by considering the effect of thermal treatments on the susceptibility to stress-corrosion cracking of an aluminum-copper alloy. For an alloy of aluminum containing about 4% Cu, a solution treatment that puts most of this copper in solid solution, changes the electrode potential of the alloy from about minus 0.84 v to minus 0.69 v. Artificial aging at temperatures in the vicinity of 375 F produces precipitation from the aluminum-copper solid solution and a subsequent increase in the electrode potential of the alloy.

By a technique previously described,[7] it is possible to measure the potential at the grain boundaries and at the grain centers. Figure 3[3] shows the change in potential at the grain boundaries and grain centers with the duration of aging at 375 F. It will be observed that precipitation occurs more rapidly at the grain boundaries than within the grains, the boundaries becoming anodic to the grain centers. The maximum difference in potential between the grain boundaries and grain centers, as shown by the lower curve, occurs after aging for about 8 or 9 hr at this temperature. Beyond this period, the precipitation

* Assistant Director of Research, Aluminum Company of America, New Kensington, Pa.
* Chief, Chemical Metallurgy Division, Aluminum Research Laboratories, New Kensington, Pa.

within the grain centers begins to catch up with that at the grain boundaries, and after the alloy has been heated for approximately 32 hr, virtually complete precipitation has occurred both at the grain boundaries and within the grains. Thus, the difference in potentials between the two has been reduced to almost zero.

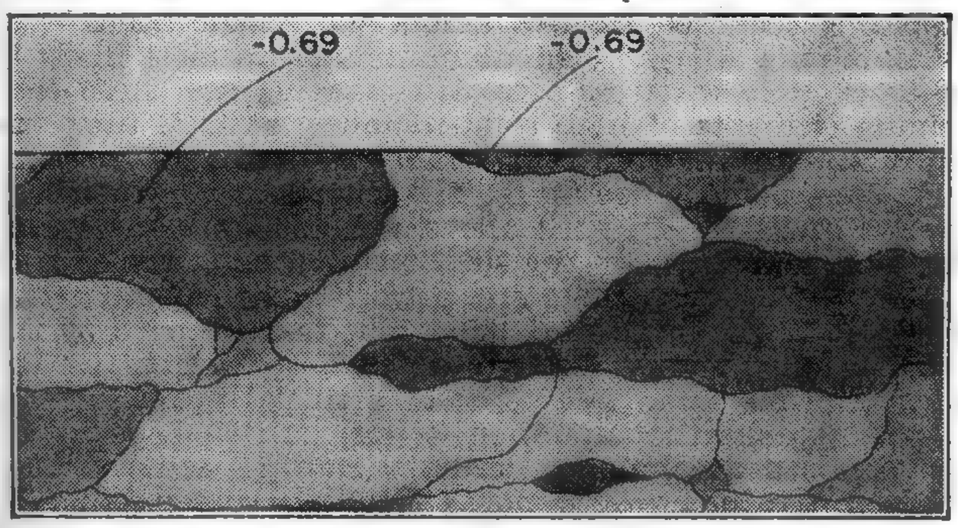

Fig. 4 Schematic illustration of the microstructure of a wrought aluminum-copper alloy containing 4% Cu. A uniform solid solution has been retained after rapid quenching from the temperature of solution heat treatment. The electrode potentials of grains and grain boundaries are equal.

The microstructural changes that bring about these differences in electrode potential are illustrated schematically in Fig. 4 to 7, inclusive. Figure 4 illustrates the uniform solid solution of copper in aluminum, produced by rapid quenching following a solution treatment. The electrode potential both within the grains and at the grain boundaries is minus 0.69 v. Figure 5 illustrates the beginning of precipitation caused along the grain boundaries by the first short periods of reheating at 375 F. The electrode potential of the grain masses has not changed measurably, but that of the depleted solid solution immediately surrounding the precipitated particles has become slightly more anodic. The precipitated particles of aluminum-copper constituent have an electrode potential of minus 0.53 v. Figure 6 illustrates the condition that exists at the time of maximum difference in electrode potential between the grains and boundaries. At this stage, the anodic material along the grain boundaries forms an almost continuous network that is anodic to the grain masses and to the particles of precipitate. In this condition the alloy is markedly susceptible to intergranular corrosion and, in the presence of high enduring tensile stresses at the surface, to stress-corrosion cracking. Figure 7 illustrates the structure after precipitation is nearly complete. There is no measurable difference in electrode potential between the grain boundaries and the grain masses, so this cause of selective corrosion has been eliminated. In a corrosive environment, electrolytic corrosion will occur between the particles of constituent and the base material, but the attack will be spread fairly uniformly, since the whole mass of metal, rather than just the grain boundaries, is anodic to the precipitate.

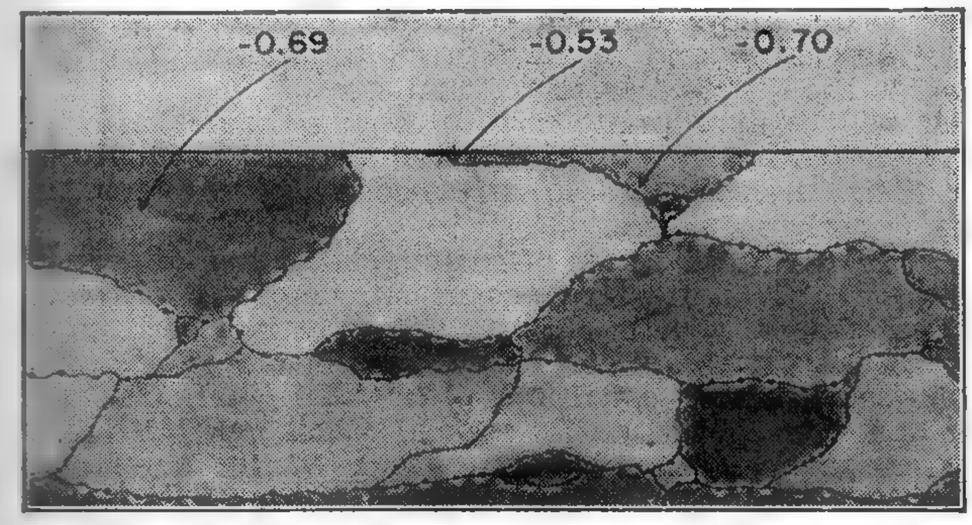

Fig. 5 The same alloy as Fig. 4 after a short period of reheating that caused the beginning of precipitation along grain boundaries. Surrounding each particle of the precipitate is a volume of solid solution that has been depleted in copper content and is anodic to the rest of the structure.

Fig. 6 The same alloy as Fig. 4 after a period of reheating that caused a maximum difference between the electrode potential of the grains and that of the grain boundaries. The volumes of solid solution immediately surrounding the precipitate form continuous zones along the grain boundaries.

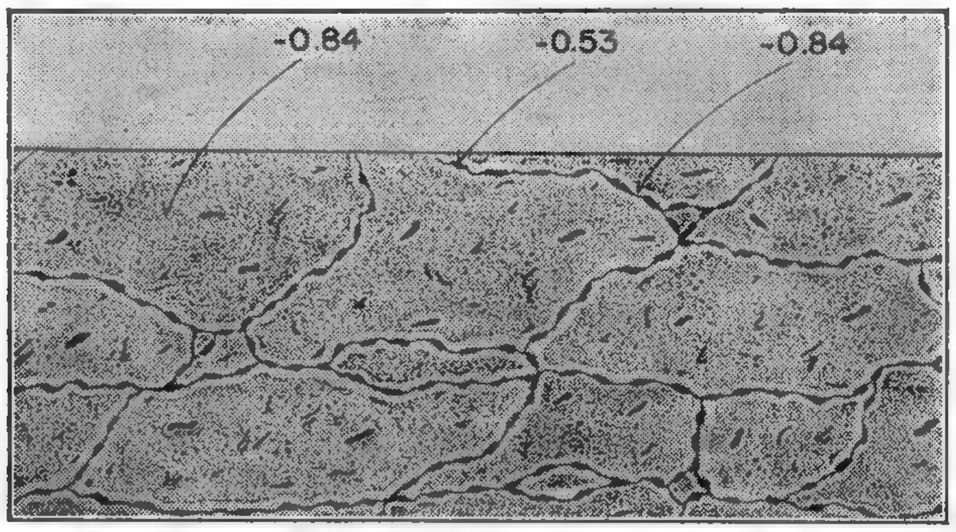

Fig. 7 The same alloy as Fig. 4 after a long period of reheating that caused nearly complete precipitation. The centers of grains and the volumes of solid solution at the grain boundaries have equal electrode potentials; both are anodic to the particles of precipitate.

Table I gives a number of values for electrode potential of interest in connection with various commercial aluminum alloys. It will be observed that the addition of manganese, or of magnesium and silicon in the ratio of the compound Mg_2Si, does not alter appreciably the electrode potential of the alloy, whereas copper in solid solution lowers the potential, and magnesium and zinc in solid solution raise the potential.

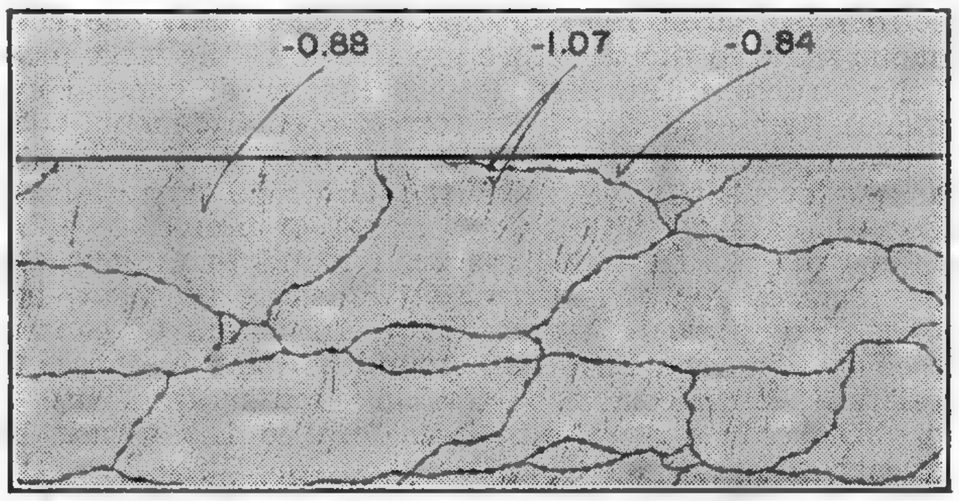

Fig. 8 Schematic illustration of the microstructure of a cold rolled aluminum-magnesium alloy containing 10% Mg. Continuous zones of anodic particles of precipitate occur on grain boundaries and slip planes.

In the aluminum-magnesium alloys containing magnesium in excess of the solubility limit, the aluminum-magnesium constituent is anodic to the aluminum-magnesium solid solution. Under certain conditions, precipitation may occur in a more or less continuous zone, either at the grain boundaries or along planes of slip caused by plastic deformation. In a corrosive environment, selective corrosion of these chains of precipitated particles will then occur and, in the presence of enduring high tensile stresses at the surface, the metal will fail by stress-

corrosion cracking. This microstructural condition is illustrated schematically by Fig. 8.

The importance of electrochemical relationships in the mechanism of stress corrosion is further emphasized by the fact that the application of a sufficiently large cathodic current will prevent failure of an alloy in a solution in which the alloy is normally susceptible to stress-corrosion cracking.[8]

Table I. Electrode Potentials of Aluminum Solid Solutions and Constituents[a]

Solid Solution or Constituent	Potential, volts 0.1 N Calomel Scale[b]

Copper	−0.20

(a) Data from Aluminum Research Laboratories
(b) Measured in an aqueous solution of 53 g NaCl + 3 g H_2O_2 per liter

The values of electrode potential quoted in the foregoing discussion are those obtained against a 1/10 normal calomel electrode in a sodium chloride solution to which hydrogen peroxide has been added.[8] Measurements obtained by this method have been found to indicate potential relationships that agree well with the behavior of the alloys in most service environments. However, in acid or strongly basic solutions, these relationships are no longer maintained. In fact, cold worked aluminum-magnesium alloy specimens (10% Mg) that cracked in a 6% NaCl solution, did not crack when 10 g per liter of sodium hydroxide was added in the solution.[2]

The Environment Factor. The preceding discussion has indicated that the corrosive environment most likely to produce stress-corrosion cracking is one in which the electrode potential relationships are such that the continuous zones in the structure are anodic to the large mass of the structure. Further, it is a matter of general experience that even very mild corrosive environments such as atmospheric moisture, will produce stress-corrosion cracking eventually, provided the electrode potential relationships are as indicated. Coatings of protective paint or films of oil and wax have been found to prolong the time required for stress-corrosion cracking to occur, but they do not prevent the cracking. Inhibitors of general attack by corrosion have been found in some instances to accelerate stress-corrosion cracking markedly. This is probably because such inhibitors localize the attack by corrosion under some conditions.

The above discussion suggests some of the reasons why evaluation of susceptibility to stress-corrosion cracking by accelerated laboratory tests entails so many difficulties.[9] Reliance should not be placed in results of accelerated laboratory tests unless the testing method has been correlated with actual service experience for the particular type of alloy under investigation. It is probable that almost any metal or alloy can be made to crack when highly stressed and exposed in specially selected solutions. However, such results may be entirely unrelated to conditions that would be encountered in normal service.

Other Factors. It has been explained that precipitation in aluminum-base alloys may produce localized zones anodic to the mass of the metal. Extensive testing and experience in service have indicated beyond a doubt that this condition may be one cause of susceptibility to stress-corrosion cracking. Experience with some other metals seems to indicate that precipitation is not the only cause, although more exhaustive fundamental research may indicate that, even in those instances, constituents are precipitated that are not now recognized. It has been suggested that the disorganized nature of the crystal structure at the grain boundaries or high localized stresses may also produce differences in electrode potentials. Other factors also increase susceptibility to stress-corrosion cracking. For example, volume changes resulting from precipitation from solid solution may induce microscopically localized stresses across the anodic zones.

Aluminum Alloys.* The aluminum alloys most likely to be susceptible to stress-corrosion cracking are those containing elements of high solid solubility at high temperatures, and in amounts considerably in excess of the solubility at room temperature, for instance, copper, magnesium and zinc. In such alloys, the microstructural condition is influenced by the solution treatment, the rate of cooling during quenching, and artificial and natural aging. The rate of cooling during quenching is influenced by the mass of the product being quenched, as well as by the quenching medium. The effect of artificial aging in some alloys, notably the aluminum-copper alloys, depends on the previous quenching procedure. Natural aging after a solution treatment does not affect the susceptibility to stress-corrosion cracking of alloys of the aluminum-copper group, but does have a marked effect on the susceptibility of wrought aluminum-magnesium alloys that contain more than about 4½% Mg.[11] In this group, a period of months or even years is required before precipitation is sufficient to make the alloy susceptible to stress-corrosion cracking. Often the aging process is proceeding simultaneously with exposure to a corrosive environment. Because of this characteristic, available information concerning aluminum-magnesium alloys is often confused. Plastic deformation may accelerate and localize precipitation and may also change the distribution of residual stress.

It will be appropriate now to discuss the various types of aluminum alloys, both cast and wrought, with respect to their susceptibility to stress-corrosion cracking and the underlying causes.

Aluminum. Aluminum of commercial or higher purity is not susceptible to stress-corrosion cracking. However, very high-purity aluminum, 99.95% min, has been shown to be susceptible to intergranular corrosion in hydrochloric acid under conditions of thermal treatment[12] that make the grain boundaries anodic in this acid.[8] No satisfactory explanation has been suggested for the anodic condition of the grain boundaries.

Aluminum-Manganese Alloys. The solid solubility of manganese in aluminum is low and the aluminum-manganese constituent has about the same electrode potential as aluminum; hence no susceptibility to stress-corrosion cracking would be anticipated and none has been found in accelerated tests or experience in service.

Aluminum-Silicon Alloys. The solid solubility of silicon in aluminum is relatively low and precipitation is sluggish. The electrode potential of the silicon constituent is strongly cathodic to aluminum, but aluminum and the aluminum-silicon solid solution have nearly the same potential. Aluminum-silicon alloys are used far more extensively in castings than in wrought products. No examples have been reported of susceptibility to stress-corrosion cracking in cast or wrought products of these alloys.

Aluminum-Magnesium Alloys. The solid solubility of magnesium in aluminum near the eutectic temperature is about 15% but is less than about 2% at room temperature. The aluminum-magnesium constituent is highly anodic to aluminum and the aluminum-magnesium solid solution. Binary alloys containing more than about 4½% Mg are susceptible to stress-corrosion cracking, particularly when they are cold worked.[11] By the addition of inhibitors such as manganese and chromium, satisfactory freedom from stress-corrosion cracking can be obtained in aluminum-magnesium wrought products containing as much as 5½% Mg.[13] Castings that contain about 10% Mg, although susceptible to stress-corrosion cracking, have been used successfully with no reported failure from this cause.

Aluminum-Magnesium-Silicon Alloys. When magnesium and silicon are present in commercially useful aluminum alloys in the ratio of the compound Mg_2Si, the electrode

* For further discussion see reference 10.

potential of the alloy is not affected by a variety of thermal treatments. Several commercial wrought alloys containing these elements in the compound ratio are highly important because of their good resistance to corrosion. They are not susceptible to stress-corrosion cracking. One of the older wrought alloys that contains silicon in excess of the Mg_2Si ratio, when in the artificially aged temper, is susceptible to intergranular corrosion and, under some conditions, to stress-corrosion cracking.

Aluminum-Silicon-Magnesium Alloys. An important group of casting alloys contains from 5 to 7% Si with less than about 0.5% Mg. These alloys have high resistance to corrosion and have not been found susceptible to stress-corrosion cracking. The addition of about 1½% Cu increases the tensile strength but lowers somewhat the resistance to corrosion, and produces susceptibility to stress-corrosion cracking. Still, no examples have been reported of stress-corrosion cracking in service from castings made of alloys of this type.

Aluminum-Copper Alloys. The aluminum-copper alloys have already been discussed. When rapidly quenched and naturally aged, these alloys are not susceptible to stress-corrosion cracking. After being reheated under some conditions or after being artificially aged to maximum strength and hardness, these alloys are susceptible to stress-corrosion cracking. For several decades large tonnages of aluminum-copper alloy castings, both in the "as-cast" and heat treated conditions, have been used under a variety of service environments without difficulty from stress-corrosion cracking, even though many were used in the artificially aged temper.[14]

Aluminum-Copper-Magnesium Alloys. In general, these alloys behave the same as aluminum-copper alloys except for the influence of magnesium on the aging characteristics. Thus, when rapidly quenched, they are not susceptible to stress-corrosion cracking although, under some conditions of reheating, they become susceptible. The rate of aging of one of these alloys (24 S) is influenced by cold working subsequent to the solution treatment, and this alloy, if artificially aged to just a little past maximum strength and hardness, is free from susceptibility to stress-corrosion cracking.[15] Examples of stress-corrosion cracking in service are rare.

Aluminum-Copper-Magnesium-Silicon Alloys. In these alloys, the silicon in excess of the Mg_2Si ratio, affects markedly the response to artificial aging. In the rapidly quenched condition, these alloys are not susceptible to stress-corrosion cracking. When slowly quenched and naturally aged or when rapidly quenched and artificially aged to maximum strength and hardness, these alloys are susceptible to stress-corrosion cracking. However, when the rate of cooling during quenching is relatively slow, either because of the quenching medium or because of the mass of the section, artificial aging is not harmful and may even be beneficial, especially if the quenching rate is properly controlled. Only isolated instances of stress-corrosion cracking have occurred in service.

Aluminum-Zinc Alloys. These alloys were among the first to be recognized as susceptible to stress-corrosion cracking. The solubility of zinc is high and the aluminum-zinc constituent is strongly anodic to aluminum. The high-zinc aluminum-base alloys have not achieved commercial importance.

Aluminum-Zinc-Magnesium Alloys. This series of alloys, with other additions, offers the greatest possibilities for high-strength aluminum alloys. The development of these alloys has been limited because of marked susceptibility to stress-corrosion cracking. Within recent years, by the proper selection and control of the zinc and magnesium contents, together with additions of copper and of inhibiting agents such as chromium, alloys have been developed that are satisfactory in resistance to stress-corrosion cracking, and they are giving satisfactory service.[15,16]

Practical Considerations. Very few aluminum alloy parts have failed in service because of stress-corrosion cracking. Aluminum is not susceptible to stress-corrosion cracking, nor are the aluminum alloys that are not heat treatable and that are in commercial use in this country. One group of such alloys used abroad, namely the wrought aluminum-magnesium alloys containing more than 5% Mg, have been used successfully in many applications, in spite of the fact that under some conditions of service they are susceptible to stress-corrosion cracking. The heat treatable alloys containing magnesium and silicon in the ratio of Mg_2Si, compose an important group of alloys used because of their high resistance to corrosion, their good forming characteristics, and weldability; these alloys also are not susceptible to stress-corrosion cracking.

In the higher-strength heat treatable aluminum alloys containing principally copper or magnesium and zinc, susceptibility to stress-corrosion cracking may be present under some conditions of thermal treatment. However, these conditions are well understood and the available knowledge has made it possible to avoid stress-corrosion cracking in service except in a few isolated instances.

It should be repeated that in order for stress-corrosion cracking to occur, high enduring tensile stresses must be present at the surface. In structural applications, stresses from working loads must be kept lower than the value required to produce stress-corrosion cracking, because of normal factors of safety, avoidance of fatigue failures, and other considerations. An exception to this statement should be made in such an application as gas cylinders, produced from high-strength aluminum alloys, in which the surface stresses may approach those required for stress-corrosion cracking, and these high stresses act for long periods of time. Failures of aluminum castings in service because of stress-corrosion cracking are virtually unknown. A contributing influence is the larger factor of safety employed for castings, and the generally thicker section that tends to reduce assembly stresses.

In wrought products, residual stresses may be kept to a minimum, in quenching, fabricating and assembly, by the use of information now available, so that stress-corrosion failures in service may be avoided, even in alloys that are susceptible to stress-corrosion cracking.

The Season Cracking of Copper Alloys

By A. L. Jamieson*

SEASON cracking is the apparently spontaneous cracking of stressed copper alloys, with little or no deformation of the adjacent metal. The mechanism of the formation of these cracks is obscure although the factors involved are well understood.

Two factors, stress and corrosion, are prerequisites; the other factors, composition and microstructure, affect only the rate of progress of the cracks. However, these factors can be controlled and the occurrence of season cracks can be substantially eliminated through the use of improved fabricating techniques and preventive measures after fabrication. Several methods have been developed for detecting the tendency of an article to season crack, and the success of an article in passing these tests is indicative of freedom from the tendency to season crack, although such an indication should not be mistaken for assurance of freedom from season cracking.

Stress. When related to season cracking, stresses are divided into two sources, that is, applied and residual, although there is no evidence that the origin of stresses has any effect on the mechanism of failure.

Applied stresses result from either an assembly operation or a service load. Assembly stresses result from the joining of two or more integral parts by welding, riveting, screwing or inserting. Service stresses, although usually quite obvious, are frequently overlooked when they are cyclic or fluctuating.

Residual stresses are of two types—strain hardening and cooling. Strain hardening stresses originate from a nonuniform cold working process, such as drawing, pressing, rolling, stretching, spinning or bending. Cooling stresses result from nonhomogeneous thermal contraction or change of volume that occurs during quenching (with differential cooling rates) and phase transformations.

The magnitude of the stresses, however, is vitally important, since the tendency to season crack is a function

* Metallurgist, Frankford Arsenal, Philadelphia

of the magnitude of the stress. In specimens exposed to ammoniacal corrosion, the rate of cracking is relatively low for values of stress considerably lower than the elastic limit, but with stresses near the elastic limit, corrosion may proceed very rapidly.

The relationship of cold work to elastic limit and hardness, has led to the erroneous belief that season cracking is a function of hardness. Although the maximum possible stress is equivalent to the elastic limit, numerous investigations have indicated that residual stresses are a function of the method of fabrication and that high degrees of cold work may be obtained with little or no residual stress. In drawing, the two most important factors involved in obtaining low stresses are the angle of the die[17] and the ratio of hollow sinking to ironing.[18] Dies of shallow angle (4 deg) do not stress tubes as much as dies of steeper angle (25 deg). Crampton[18] demonstrated that residual stresses in tubes are increased by increased wall thickness, by hollow sinking and by greater reduction of diameter, and are decreased by greater reduction of wall thickness. It is possible, therefore, to plan most drawing operations so that season cracking is negligible. Other operations usually involved (upsetting, spinning, stretching, bending) are more difficult to evaluate, and freedom from residual stresses is impossible to obtain by operational control.

Corrosion. Although season cracking occurs in what seems to be clean air, it is known that such cracking will not occur in the absence of a corrosive environment.[19] Therefore, the agents necessary for producing the specific corrosion must be present virtually always in the normal atmosphere. Of the numerous reagents known to cause stressed copper alloys to crack,[19–23] ammonia and its derivatives are the only ones usually found in the atmosphere. It has been proved recently[24] that ammonia in the absence of oxygen and water vapor will not cause cracking. It has been demonstrated that several other reagents,[24,25] such as CO_2, accelerate the cracking in ammoniacal atmospheres, but they are not essential to the instigation of cracking. The minute quantities of ammonia usually found in the air seem too small to produce cracking, but the concentration that develops in the adsorbed moisture film soon becomes appreciable.

Composition. Apparently all copper alloys, regardless of the alloying constituents, are susceptible to season cracking. In copper alloys, the tendency to season crack increases as the zinc content increases to a maximum of 40%. Practical experience indicates that brasses with less than 15% Zn are usually immune to season cracking although, under severe conditions, commercially pure copper has season cracked.[26] Experimentally[27] in an atmosphere of ammonia, copper is immune to season cracking, but the addition of as little as 3% Zn increases the susceptibility markedly. Brasses with 40% Zn, although highly susceptible, are only slightly more so than alloys that contain 20% Zn. The susceptibility of copper alloys to season cracking has been attributed to impurities. Recently[28] it has been shown that high-purity cartridge brass (70% Cu, 30% Zn) containing only spectroscopically detectable traces of impurities, has the same tendency as commercial cartridge brass to season crack. Additions of various elements have been investigated systematically in regard to their effect on the season-cracking tendency of cartridge brass, and no acceleration of season cracking was indicated. Several elements (P, As, Ba, Ce, Mg, Te, Sn, Be and Mn) decreased the susceptibility to season cracking under some conditions. Silicon additions of as much as 1.5% decreased the season-cracking tendency of brasses under all conditions.

Microstructure. The importance of microstructure in the season-cracking phenomenon is frequently dismissed as inconsequential because it is not an essential factor. However, since it has been established that rapidity of cracking correlates definitely with the grain size and structure of the metal, microstructure is of considerable practical importance.

When all other conditions are identical, the rapidity of season cracking increases proportionally with the grain size and inversely with the degree and direction of cold work. In single-phase alpha brasses where the cracking is intercrystalline, it is obvious that the shorter path is the reason. In the limiting condition, that is, in a single crystal, the tendency to crack is at a minimum but not eliminated.[27] A similar grain-size effect is more obscure in alpha-beta alloys, because the cracks run between the phases or through the beta phase.[18]

Since the structure of all metals depends on composition and on thermal and mechanical treatment, it is understandable that the effects of structure on season cracking are obscure and interlocked with both the composition and the stress factors. Because of this effect of interlocking, it is difficult to separate the influence of structure from the other influencing factors, and in some instances the effects of structure may appear to be contradictory. For example, although it is known[29] that traces of beta in brass that is assumed to be wholly alpha, increase the susceptibility to season cracking, a slowly cooled alpha-beta brass has a greater tendency to season crack than the same alloy that has been quenched to retain a greater percentage of beta.[30] This apparent anomaly is the result of varied cooling stresses (from volume change and quenching) functioning in the quenched alloys, and compositional differences in the slowly cooled alloys. The increased resistance achieved by quenching brasses that contain silicon, is an excellent example of the influence of structure. The improvement results from the introduction of a second phase, which persists through cold working but is destroyed by annealing at a low temperature.

Detection of Season Cracking. The tendency to season crack may be detected by several methods. The simplest method is the mercurous nitrate test, which reveals whether stresses that exist in the cold worked or stressed brass, are of a magnitude likely to cause the brass to season crack. Briefly,* this test consists of immersing the clean article to be tested in an acidified (1% HNO_3) aqueous solution of mercurous nitrate (usually 1 or 10% $HgNO_3$) for a predetermined period (15 min to 1 hr) and then examining for cracks. The presence of cracks indicates that the article is likely to season crack in service. Mercury, like liquid tin, lead and solder, is a reagent that causes copper alloys to fail in a brittle way at stresses considerably lower than the yield strength. These reagents will not cause cracking at stresses lower than a definite minimum, but that minimum stress may result in season cracking. It is because of this threshold stress (12,000 psi) that the mercury cracking test, although fairly reliable, is not a positive test for susceptibility to season cracking. However, experience has indicated that if an article can pass a 15-min immersion period successfully, its susceptibility to season cracking is fairly low.

A second method of testing consists in exposing the brass to a gaseous atmosphere of ammonia, water vapor and air for 4 to 24 hr before the examination for cracks.[32] It is common practice to deform the article slightly in order to exaggerate the cracks, which are frequently very fine. This test has not been used sufficiently to permit a correlation of test results with service failures and therefore has not been generally accepted; also this test is more difficult to maintain and requires equipment of a more specialized nature than the mercury test.

A third method of testing, a mechanical method for measuring stress, stems from the method used originally by Heyn,[31] in which stresses were measured by evaluating the dimensional changes that occur with the removal of small successive increments of metal. From this technique, modified by a number of investigators, the split ring, the tongued beam, and several methods involving drilling have been developed. Through the use of these various techniques, the stresses in complicated shapes may be evaluated, but the accuracy decreases with the complexity of the article that is being tested. This obviously difficult and time-consuming procedure does permit the evaluation of the magnitude of the average stress, but does not reveal concentrated or localized stress peaks.

A fourth method for detecting susceptibility to season cracking uses a complicated X-ray diffraction technique that is controversial when applied to copper alloys. This

* In ASTM Standard Method B 154-45

method, which measures distortion of reflected rings, has one advantage over all the test procedures mentioned previously; that is, it is a nondestructive test. Like the mechanical method, this procedure measures the stresses only in the area examined, whereas the ammonia and mercury tests have the advantage of testing the entire surface of the article. For this reason the mercury test, though not infallible, remains the standard industrial test for season cracking. Material used in either the mercury or ammonia test should be considered destroyed even if cracking does not occur during the test, since any subsequent use may result in premature failure if the material is subject to additional stress or strain.

Prevention. There are only two effective preventives for season cracking: one is the elimination of the stress factor; the other is the elimination of the corrosion factor. Obviously neither of these factors may be eliminated in service, but either or both may be reduced to a minimum where season cracking is an improbability.

Residual and assembly stresses may be eliminated by a recrystallizing anneal, after the final operations of forming or assembling. Such a softening anneal is often unsatisfactory, since the properties of the strain hardened metal may be required for satisfactory functioning of the material. When such a condition exists several methods are practicable for reducing the stresses to a safe magnitude without affecting the properties desired. The most common procedure, thermal stress relieving,* consists in heating the cold worked article for a short period at a low temperature. The exact time and temperature depend on the severity of the deformation, the composition of the metal and the degree of softening permissible. For most copper alloys the time varies from 30 min to 1 hr and the temperature varies from 300 F (150 C) to 575 F (300 C). The typical treatments for stress relieving, shown in Table II, may not be adequate for a given article but are indicative of the usual temperature and time.

Table II. Typical Thermal Stress-Relieving Treatments for Copper Alloys

Alloy	Composition, % Cu	Zn	Sn	Ni	Temp deg Fahr	deg Cent	Time, hr
Copper	100	..	..	..	300	150	½
Commercial Bronze	90	10	..	..	400	215	1
Low Brass	80	20	..	..	500	265	1
Cartridge Brass	70	30	..	..	500	265	1
Yellow Brass	63	37	..	..	475	250	1
Muntz Metal	60	40	..	..	375	200	½
Admiralty Metal	70	29	1	..	575	300	1
Cupro-Nickel, 15%	85	..	..	15	475	250	1
Cupro-Nickel, 30%	70	..	..	30	475	250	1
Nickel Silver	64	[illegible]	..	[illegible]	475	250	1
Phosphor Bronze	95	..	5	..	375	200	1
Phosphor Bronze	90	..	10	..	375	200	1

Several less common methods—stretching, flexing, bending, straightening between rollers, reeling and peening (shot blasting)—used to reduce the residual stress to a safe minimum, depend on plastic deformation to decrease dangerous tensile stresses or to convert them into the less objectionable compressive stresses.

In establishing any procedure for relief of stress, it is essential that treated pieces be tested in order to make sure that the stresses have been sufficiently relieved. Care should be taken also to ensure that no subsequent operation follows the stress relieving, since a further operation may introduce high stresses.

Because it would not be feasible to stipulate the corrosive atmosphere to which a fabricated article may be subjected in service, elimination of corrosion is difficult. It is possible, however, to minimize the corrosion by protecting the fabricated metal with a nonporous coating of lacquer or electroplated metal. To rely on either of these coatings alone is unwise, since they may be removed by corrosion, abrasion or chipping.

The most reliable procedure for eliminating season cracking is to combine the techniques for elimination of stresses and for protection against corrosive atmosphere. When such a combination is commercially impracticable or economically unsound, the procedure for stress relieving is the most desirable of the techniques for prevention of season cracking.

* For additional information on the thermal stress relieving of copper alloys the reader may refer to the COPPER SECTION.

The Stress-Corrosion Cracking of Iron and Some Ferrous Alloys

BY H. H. UHLIG*

MILD steel and other low-alloy steels, iron-nickel alloys, and austenitic stainless steels are the ferrous materials that have been studied most extensively in relation to stress-corrosion cracking.

Mild Steel and Other Low-Alloy Steels. Stress-corrosion cracking of mild steel in alkaline solutions is called "caustic embrittlement" or sometimes "boiler embrittlement". The failure is largely intergranular and usually occurs only with concentrated sodium hydroxide in the presence of one or more impurities that act as accelerators. Stress-corrosion cracking may occur when certain kinds of alkaline boiler waters concentrate at seams of riveted boiler drums or wherever slow leakage acts to concentrate the boiler water. Welded boilers are less susceptible to damage from this source.

Failure may be accelerated by the presence of silicates[32] in waters of high-pressure boilers, but damage can be retarded or completely inhibited by sodium nitrate[33] (added to the extent of 20 to 30% of the alkalinity expressed as sodium hydroxide), quebracho extract[33] or phosphates.[34] However, with boiling temperatures at atmospheric pressure in contrast with higher pressures, 0.13% $NaNO_3$ in 33% NaOH solution accelerated stress-corrosion cracking of steel.[35] Among other accelerants at atmospheric pressure are PbO, $KMnO_4$ and Na_2CrO_4.

Formerly sodium sulfate was added in concentrations prescribed by the alkalinity of boiler waters, but it has not prevented caustic embrittlement detectors from failing[33] and is no longer considered necessary.

Iron and steel are subject to rapid stress-corrosion cracking in nitrate solutions.[36] The fractures are largely intergranular. Mixtures of concentrated calcium and ammonium nitrates at the boiling temperature are especially effective in causing damage, as are 60 to 95% ammonium nitrate solutions.[37] Concentrated HNO_3 at 20 C can also cause cracking of stressed specimens,[37] as can dilute nitric acid containing a small amount of $MnCl_2$ as accelerator, held at 60 to 80 C. However, 46% $MgCl_2$ at 125 C is ineffective despite its ability to crack stressed stainless steels.[37]

A 0.7 to 0.8% C steel wire, used as bridge cable, failed in service by stress-corrosion cracking and afterward was found to crack within 3½ to 9½ months when highly stressed and immersed in 0.01*N* NH_4NO_3 or in 0.01*N* $NaNO_3$. No cracking occurred in distilled water, in 0.01*N* $(NH_4)_2SO_4$, NH_4NO_2 or NaOH.[38]

Stresses beyond the elastic limit (plastic flow) are especially conducive to stress-corrosion cracking of iron in caustic solutions; hence rivet holes of boilers are likely to show cracking first, if cracking occurs at all. Stresses lower than the elastic limit can cause rapid cracking of iron or steel in calcium-ammonium nitrate solutions at 100 C.[39]

Stresses lower than the elastic limit also cause cracking of mild steel or low-alloy steels in aqueous solutions of HCN. The fractures are *transgranular* in contrast with intergranular fractures in caustic or nitrate solutions mentioned above. A 0.4% C – 0.6% Cr – 0.3% Mo – 0.5% Ni steel (elastic limit, 125,000 psi) stressed to 57,000 psi and immersed in a solution of 2.6 g HCN per liter of water, failed within 14 days; in a solution of 3.5 [illegible] HCN per liter of water, the steel failed within 7 days. Stressed to 99,500 psi, this same steel failed within 7 days in the first solution.[40]

Failures resulting from the presence of HCN have occurred when illuminating gas was stored under pressure in steel tanks. The gas contained both moisture and traces of HCN as impurities.[40] It has been suggested that failures

*Associate Professor of Metallurgy, Massachusetts Institute of Technology, Cambridge, Mass.

caused by HCN could be avoided to some extent by drying the illuminating gas; by removing HCN; or by employing zinc-coated or aluminum-coated steel.

Steels containing interstitial nitrogen appear to be more susceptible than low-nitrogen steels to stress-corrosion cracking in alkalies and nitrates, but it has not been established conclusively that nitrogen is the only factor, nor the only important one. Increased carbon content reduces the tendency of a steel to fail by intergranular corrosion cracking.[37] Stressed aluminum-killed steels show less tendency to crack in caustic soda at 200 to 250 C[38] or in concentrated nitrates at 100 C[37] than those free from aluminum. Apparently, low concentrations of phosphorus and nitrogen in steel, made possible by reaction of these components with aluminum, accompany optimum resistance to corrosion cracking.[41,42] The factors that decrease aging of iron appear to decrease susceptibility to intergranular corrosion cracking.[37,41,42]

Preliminary heat treatment for 2 to 4 hr at high temperatures (1080 to 1230 C) in CO_2, H_2O and especially nitrogen, is detrimental to the life of stressed steel in nitrate solutions. Heating in air at 1050 to 1200 C followed by slow cooling, is likewise detrimental.[37]

Iron-Nickel Alloys. Alloys of iron and nickel may stress-corrosion crack in dilute hydrochloric or sulfuric acid unless the nickel content is greater than 35%.[43] Stressed alloys containing 18% and 28% Ni were found to crack in 0.4% HCl or 16.4% H_2SO_4 in 2-month tests at room temperatures. The alloy containing 28% Ni, 16 to 18% Mo and 2.5% Cu is not subject to cracking in the same mediums under identical test conditions.

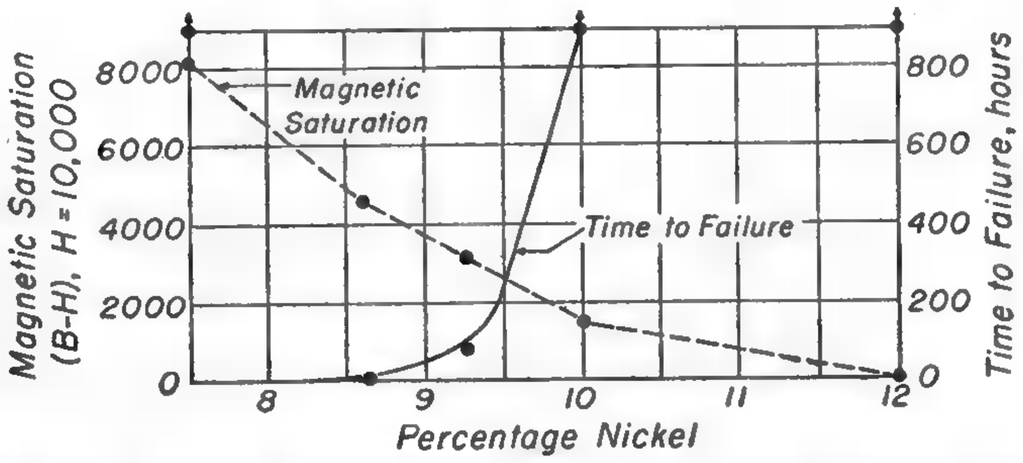

Fig. 9 Influence of nickel content on stress-corrosion cracking of 18% Cr-Ni steels (stressed 28,450 psi) in $CaCl_2 + HgCl_2$ at 80 to 100 C. Values of magnetic saturation are for alloys extended 30%.

Stress-corrosion cracking of the 25% Ni-Fe alloy in the form of steam turbine blades has been reported. The cracks were transgranular.[44]

Stainless Steels. Stainless steels are subject to stress-corrosion cracking in specific mediums, particularly acid chlorides or dilute hydrochloric acid. The failures of annealed and quenched alloys are usually transgranular, distinguishing stress-corrosion cracking of these alloys from intergranular corrosion not requiring stress. Intergranular corrosion occurs particularly with austenitic alloys when they have been heat treated so that carbides precipitate at grain boundaries. Stress-corrosion cracking of stainless alloys does not depend on precipitated carbides. It rarely occurs in service, but a few instances have been observed; for example, in deep-drawn coffee urns and in equipment to condition wool or handle dye solutions.[45]

Boiling 42% $MgCl_2$ is extremely active in producing transgranular cracking of stressed 18-8 alloys, including alloys stabilized with columbium or titanium. Types 302, 304, 316, 317, 321 and 347 have cracked in short-time tests in this medium. $BaCl_2$ is not effective in the same sense as $MgCl_2$ but accelerated cracking has been accomplished by the use of boiling solutions of $CaCl_2$, $CoCl_2$, $ZnCl_2$, LiCl, or NH_4Cl.[46,47] Ethyl chloride containing water has caused stress-corrosion cracking of 18-8,[48] presumably because of liberated hydrochloric acid. A solution of 100 g NaCl and 9.3 g H_2O_2 per liter at room temperature will cause stress-corrosion cracking of stainless steels within periods of weeks.[49]

Free-machining stainless steel is very susceptible to corrosion cracking in some of the caustic and nitrate solutions used by Schroeder, Berk and O'Brien to test mild steel.[35]

The stress necessary to cause transgranular cracking of stainless steels in specific mediums can be residual or applied. Stencil-stamped specimens and deep-drawn 18-8 sheet crack in some of the hot chloride solutions listed above. Stresses resulting from cold straightening, quenching, grinding or differential thermal expansion are sufficient to cause stress-corrosion cracking.[50] A type 316 steel (18-8 containing molybdenum), water-quenched from 1070 C (1950 F), cracked when exposed later to a boiling calcium-magnesium chloride brine, but resisted cracking in a 17-day test after being stress-relieved at 730 C (1350 F) for 1 hr and then cooled in the furnace.[51] The applied threshold stress necessary for cracking 18-8 in boiling 42% $MgCl_2$ is less than 20,000 psi.[50]

Ferritic stainless steels are less susceptible to stress-corrosion cracking than are the austenitic alloys. Austenitic chromium-nickel steels immersed in boiling 42% $MgCl_2$ and stressed to 40,000 psi, cracked in 7 to 72 hr, whereas 18.6% Cr steel (type 430) and 12% Cr – 0.2% Al steel (type 405) when stressed the same amount, did not crack in tests continued for 504 to 624 hr.[50]

In the 18% Cr-Ni alloys, stressed 28,450 psi and immersed in 40 to 60 parts $CaCl_2$, 60 to 40 parts water plus 0.1 to 1% $HgCl_2$ at 80 to 100 C, resistance to cracking increases with the nickel content (Fig. 9). From the behavior of the magnetic saturation for specimens extended 30%, the resistance to cracking in the $CaCl_2$ medium appears to be a function of austenite stability, since the 12% Ni alloy exhibits both maximum resistance to stress corrosion and least tendency to transform to ferrite during cold working.[52]

The sensitivity of 18-8 to cracking, increases with carbon content up to 0.045% C and then decreases. For similar alloys containing higher percentages of nickel, the corresponding carbon content for greatest sensitivity is higher.

The Stress Corrosion of Magnesium Alloys

By M. A. Hunter*

FORMERLY the behavior of magnesium alloys under stress corrosion was not a matter of recognized importance. However, the extended use of these alloys as structural materials in airplane manufacture, during the recent war, has sharply focused the attention of designers on the possibilities of structural failure arising from the stress-corrosion cracking of magnesium alloys used in construction.

Recent research projects have determined many of the conditions that lead to stress-corrosion sensitivity and have indicated means by which such sensitivity can be minimized or perhaps even eliminated. The recently published symposium on Stress-Corrosion Cracking of Metals[53] contains several papers that summarize the results of some of these investigations.

General Susceptibility of Magnesium Alloys. Investigators agree that failures of magnesium alloy castings in service because of stress-corrosion cracking are virtually unknown. This statement seems to hold for all cast alloys, regardless of composition. However, cast test bars of several magnesium alloys, stressed to approximately one-half the yield strength, have failed by stress-corrosion cracking during outdoor atmospheric exposures.

Some wrought alloys appear to be particularly sensitive under certain conditions, while others appear to be immune under all conditions encountered in service. The three most important alloys used in sheet form are:

ASTM Designation	Nominal Composition
M1	Mg — 1.5% Mn
AZ31X	Mg — 3 Al — 1 Zn — 0.3 Mn
AZ61X	Mg — 6.5 Al — 1 Zn — 0.2 Mn

No stress-corrosion cracking has been reported in the M1 alloy, either in laboratory experiments or during extensive field tests in various atmospheres. However, AZ61X

* Department of Metallurgical Engineering, Rensselaer Polytechnic Institute, Troy, N. Y.

can be very sensitive to stress-corrosion cracking; the susceptibility depends on the physical condition of the alloy. Alloy AZ31X, with a lower aluminum content, is less sensitive than AZ61X, but is still not immune to cracking, under all conditions.

Mechanism of Cracking in Magnesium Alloys. Stress-corrosion cracking in aluminum alloys has been the subject of intensive investigation.[54] In aluminum-base alloys stress-corrosion cracks are intercrystalline; in magnesium alloys cracks may be transcrystalline or intercrystalline, depending on the conditions of the experiment.

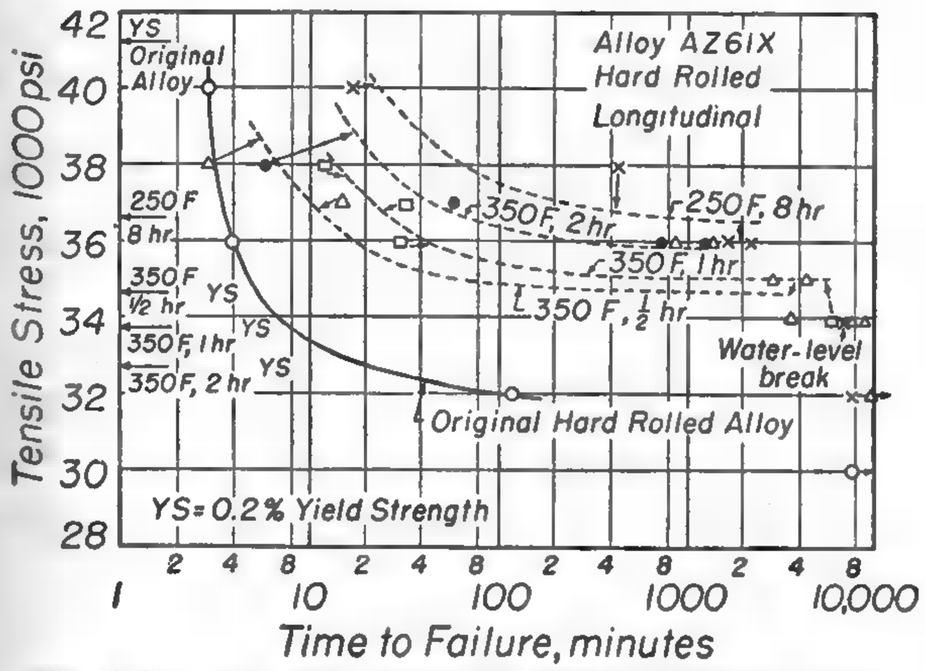

Fig. 10 Stress-corrosion cracking of AZ61X magnesium alloy, longitudinal specimens

L. Graf[55] investigated the processes leading to the formation of cracks and attempted to determine the possible cause. Samples of AZM alloy (AZ61X) under a tensional stress were observed directly under the microscope, with distilled water as the corroding agent. In polycrystalline specimens, cracks appeared perpendicular to the direction of tension, diagonally through grains, and occasionally along grain boundaries or slip bands or twin lamellae. Graf concluded that the fine lines that appear in plastically deformed material are not the primary cause of the cracks in stress corrosion; neither are the twin lamellae the chief cause of these cracks.

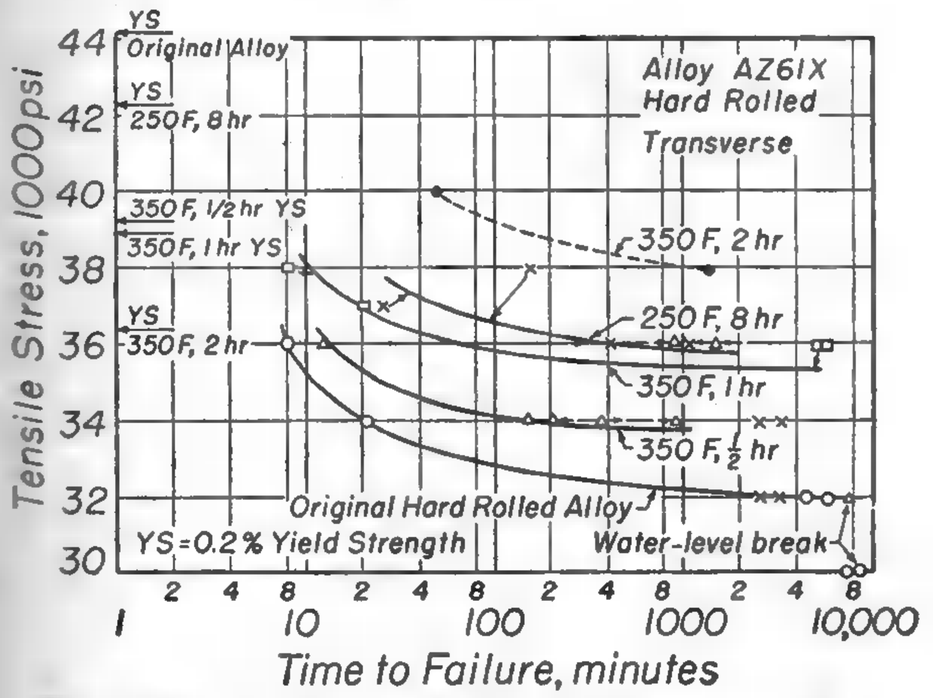

Fig. 11 Stress-corrosion cracking of AZ61X magnesium alloy, transverse specimens

In single crystals of AZM sheet, 0.5 mm thick (oriented so that the hexagonal base is nearly perpendicular to the plane of the sheet and nearly parallel to the longitudinal axis or direction of tension), Graf found cracks developing as fine lines, exactly straight and exactly perpendicular to the direction of tension, with no preference for any crystallographic direction in the sample. Small inclusions of differently oriented crystals did not disturb the exact alignment of cracks perpendicular to the pull.

In this connection, Mears, Brown and Dix report[56] that in an accelerating solution containing 35 g NaCl and 20 g $K_2Cr_2O_7$ (pH = 5.0), specimens from AZ61X failed when exposed in a stressed condition along a path that followed grain boundaries or slip planes. When the same alloy was exposed to a similar solution (pH = 8.1), the failure was transgranular and had little relation to boundaries or slip planes. From an electrochemical viewpoint, it would appear that in acid solutions the grain boundaries and slip planes are anodic to the rest of the metal, whereas these zones are cathodic when the solution is basic.

The greater the number of localized paths of corrosion, the longer the period required for complete failure. If there is considerable general corrosion, stress-corrosion cracking may not occur. If the corroding paths are regarded as notches in the surface of the specimen, the stress concentration at the base of each notch will be less than if only one notch were present.[56] According to this line of reasoning, any form of transgranular stress-corrosion cracking of magnesium alloys can be attributed to the combination of stress and electrochemical action.

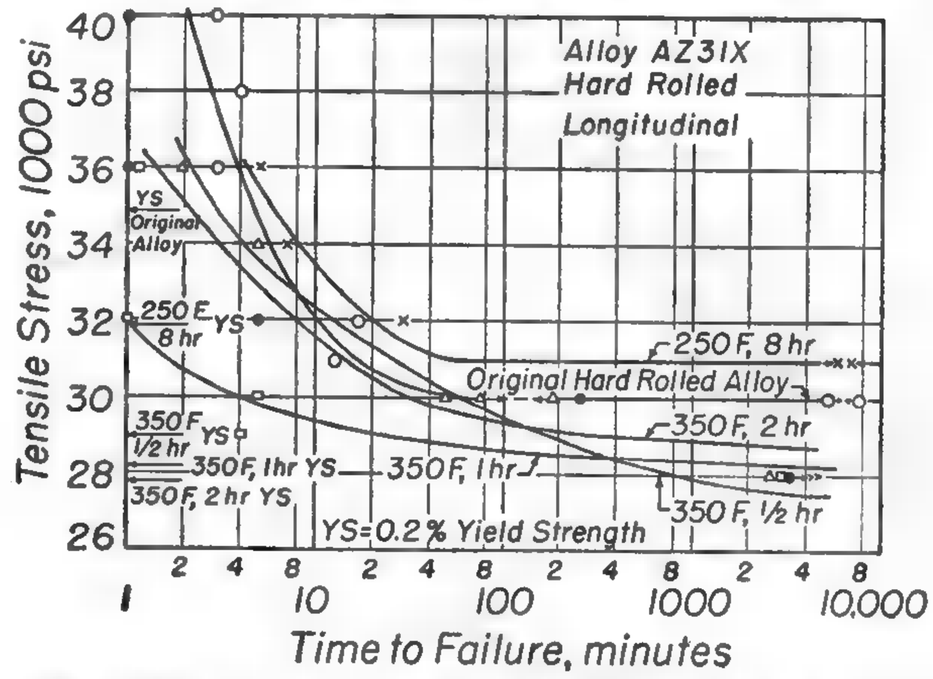

Fig. 12 Stress-corrosion cracking of AZ31X magnesium alloy, longitudinal specimens

Effect of Plastic Deformation. Graf[55] found that the "stress-corrosion limit"* below which no breaks occurred was 8 kg per sq mm (11,400 psi) for samples of AZM (AZ61X) corroding in distilled water. This value is lower than the 0.2% offset value for yield strength of 20 kg per sq mm (28,400 psi) and even lower than the 0.02% offset value for elastic limit of 12 kg per sq mm (17,000 psi). On the stress-strain curve for the material, the stress-corrosion limit coincides closely with beginnings of plastic deformation.

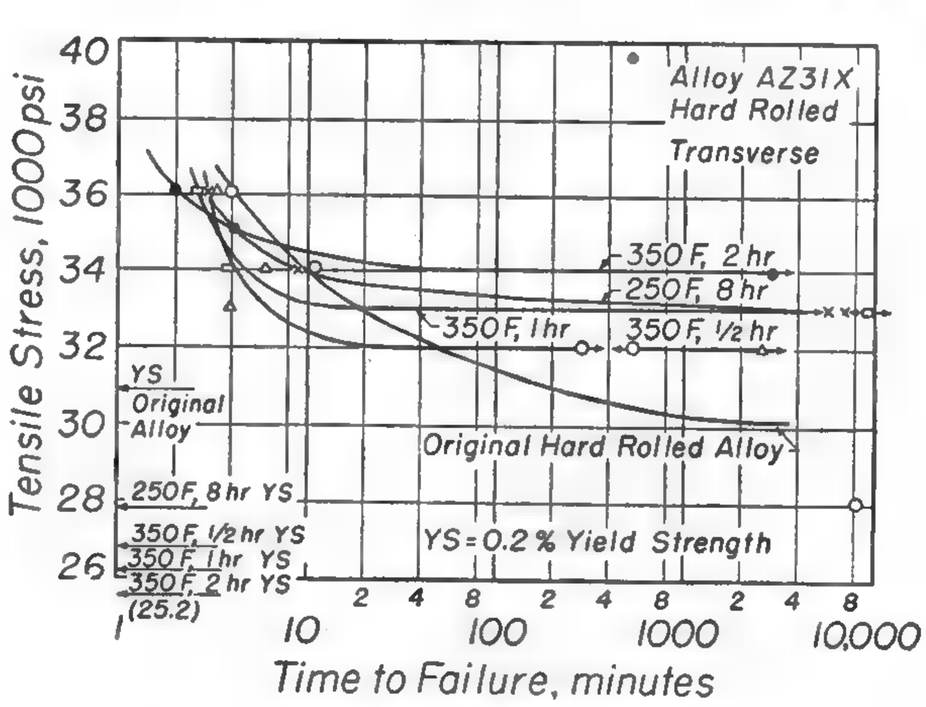

Fig. 13 Stress-corrosion cracking of AZ31X magnesium alloy, transverse specimens

* The "stress-corrosion limit" is the maximum stress, resulting from external load, that the sample can carry in the particular corroding environment without cracking during an indefinitely extended period of time.

A number of samples were deformed about 8% in a tension-testing machine. Samples of deformed and undeformed material were subjected to corrosion alone with no application of external stress. When samples were tested in tension and torsion at definite intervals, no perceptible difference was observed in the two classes of material. In the absence of an external load, both were equally resistant to corrosion.

Specimens were then predeformed to the extent of 0.2%, 2% and 8%, as well as 8% by rolling, and were subjected to corrosion while under stress. With increasing plastic deformation the stress-corrosion limit moves to lower and lower values of stress and, at great deformation, could become vanishingly small. This establishes the fact that with high residual stresses from previous plastic deformation, the stress-corrosion limit can be very low indeed. Such material is highly sensitive to stress-corrosion cracking.

Heat Treatment and Sensitivity to Stress Corrosion. Heat treatment affects the behavior of magnesium alloys to a marked degree in stress corrosion. Figures 10 and 11 give typical examples of the variations in sensitivity to cracking that can be produced in longitudinal and transverse specimens of AZ61X by variations in heat treatment. Figures 12 and 13 give similar variations for AZ31X.[57] These observations were made by a cantilever testing method,[58] using a salt-chromate bath to accelerate corrosion.

It is evident from these figures that the original cold rolled material of AZ61X has a much lower stress-corrosion limit in both longitudinal and transverse directions than similar material subsequently heat treated for various periods at 250 or 350 F. The same is true, though less pronounced, for the AZ31X alloy.

The effect of these various heat treatments on the yield strength and on the stress-corrosion limit is given in Fig. 10 to 13. If both yield strength and stress corrosion must be considered, a heat treatment of 8 hr at 250 F appears to give the best results. Where the time element is important, 2 hr at 350 F is a satisfactory period.

Before heat treatment the cold rolled specimen gives no evidence of precipitation, but after heat treatment, precipitation appears to be complete. It is safe to conclude that this precipitation, along with a reduction in residual stress, has had an effect in raising the limit of stress-corrosion cracking or reducing the sensitivity to cracking.

Service Tests for Determining Susceptibility. Many of the tests that have been devised for determining susceptibility do not represent actual conditions of service. This is particularly true of those experiments that are carried out under laboratory conditions in solutions that accelerate cracking but find no counterpart in actual service. Although such methods are useful in evaluating the effect of variations in composition in new alloys and the effects of mechanical procedures and heat treatments in fabrication, still these methods cannot be used as infallible guides in determining the life of magnesium alloys as structural materials or in industrial service.

Service tests using outdoor exposures have been devised by B. C. Madden, Jr.,[60] by Sager, Brown and Mears,[61] and by Loose and Barbian.[62] Reports by these investigators may be consulted for further information.

The results of Loose and Barbian[63] concerning service data can be summarized as follows:

1 M1 alloy is not sensitive to stress-corrosion cracking under any conditions of testing devised so far (1946).
2 When AZ31X (annealed at 275 F) is subjected to constant axial stress, the stress-corrosion limit is about 20,000 psi.
3 With bending stress under constant load, the minimum stress to produce fracture was 25,000 psi. Four sheets stressed at the tensile yield strength of 34,000 psi had not cracked in 220 days.
4 Under constant deformation stress, no failures occurred at 95% of the tensile yield strength after 17 months of exposure.
5 The stress-corrosion limit under axial loading of AZ61X sheet (annealed at either 350 or 600 F) appears to be of the order of 12,000 to 15,000 psi. Under a constant load in bending, the limit is 15,000 to 20,000 psi.

Loose and Barbian conclude that because of superior resistance to stress corrosion, equal or better physical properties and superior toughness, AZ31X sheet is preferable in all structures except in those that require welding.

Summary of Service Information. J. D. Hanawalt[64] reviews the salient facts about stress corrosion in service and concludes that stress corrosion will not limit the use of magnesium alloys in applications for which they are otherwise adapted. The susceptibility to cracking that results from high residual stresses can be removed by an anneal at a temperature that does not decrease the mechanical properties greatly. Shot peening also is suggested as a means for reducing the sensitivity.

If a constant service stress exists, approaching the tensile yield point, the regular AZ31X or AZ61X should be clad with the magnesium-manganese alloy that is not susceptible to stress-corrosion cracking. A sheet clad with this material has developed no cracks in a seacoast exposure of more than six months, when loaded at 90% of the tensile yield strength in a direct tension test.

In situations where lower service stresses are encountered, AZ31X (annealed at 275 F) is considered a satisfactory material. Under a constant stress in tension, numerically equal to 70% of the compressive yield strength, no cracks occurred in samples exposed for one year at Kure Beach (a seacoast exposure).

In the absence of stress, AZ31X and AZ61X resist corrosion so well that cladding is not needed—that is, not to combat corrosion alone. In four years of seacoast exposure in the unstressed condition, test bars lost about 4% of their tensile strength.

With the knowledge that is now available concerning stress corrosion in wrought magnesium alloys and methods for its control, stress corrosion is not a determining factor in limiting the structural applications of wrought magnesium alloys.

Relief of Residual Stress

BY THE SUBCOMMITTEE ON RELIEF OF RESIDUAL STRESS*

RESIDUAL stress, frequently called "locked-up" stress or "internal" stress, refers to the stress existing in a component part or assembly free from external loads.

Residual stresses can be produced in metal in various ways. When molten metal cools, certain portions—usually the outer layers—solidify first. As the metal proceeds to thermal equilibrium, further contraction is opposed by the material that has already become set, introducing residual stresses. Residual stresses may also be produced in a piece of material by thermal gradients, by cold working, shaping and forming, machining, and other processes that cause local plastic flow, and by changes in volume and coefficient of expansion that accompany metallurgical phase transformations.

Residual stresses caused by differential plastic flow, resulting from rapid and uneven cooling of hot metal, or from mechanical loading or working, are usually distributed through appreciable volumes and are referred to as "macrostresses". Residual stresses accompanying phase transformation are usually distributed through microscopic volumes only, and are called "microstresses".

The assembling of component parts into ■ structure may relieve some residual stresses but, in general, especially if fabrication includes welding, many additional residual stresses are introduced. Such stresses may or may not be harmful. Suitable residual stress or prestressing is helpful in increasing strength and life; for example, it is common practice to introduce residual compressive stresses into those parts of structures that must withstand tensile stresses in service. Compressive stresses are introduced by shrink-fits, as in built-up gun barrels, enabling parts that are so treated to withstand higher tensile loading without yielding. Surface compressive stresses, which may be introduced by shot peening, cold rolling, cold forming, nitriding, and carburizing, increase resistance to fatigue by changing the range of the tensile stresses at or near the surface, where fatigue cracks start. Thus, residual stresses are helpful if they are of such a nature as to oppose the working stresses at the point where failure would otherwise occur, but they are harmful if they add to the working stresses.

If tensile residual stresses and tensile service stresses act in two or three perpendicular directions, the resulting condition is particularly harmful because analysis indicates that the shearing stresses that cause plastic flow are inhibited and the ductility preceding fracture is decreased. Triaxial tensile stresses of nearly equal magnitude can so inhibit shear that yielding does not occur under stresses lower than the ultimate strength. The brittle fractures that result take place with deformations so small as to be considered elastic, permitting no readjustment or ironing out under proof or service loading.

Unfortunately, most macrostresses cannot be controlled, since they are usually of unknown magnitude and random orientation; however, by the simple law of equilibrium, and in the absence of external loading, opposing internal forces and moments must balance. Hence, the introduction of residual compressive stresses into one critical part of a structure must establish residual tensile stresses in another part, and the result may be a weaker structure. For example, excessive peening, cold working, nitriding, or carburizing at the surface, will produce high tensile stresses below the surface, which may cause failure.

Determination of Residual Stresses. It is difficult to determine the magnitude and direction of residual stresses. Several methods have been devised for sectioning or boring specimens carefully for detailed analysis of residual stresses throughout the interior of metal objects. In one of the first methods attempted, a hole was drilled in the metal and strain gages were used in an effort to determine the change in strain as a result of the stress relief at the free surface.[1] This method lacks accuracy in the field because of the complicated technique involved, especially if the directions of the principal stresses are unknown. Another method is to trepan a plug and measure the change in strain on three or more axes on both surfaces of the plug.[2] This method also lacks accuracy unless the residual stresses are essentially of the same magnitude and the same sign over the entire plug. If the hole is later

Kellogg Company), Charles Lipson (Detroit Testing Laboratory), G. L. Snyder (Lukens Steel Company), J. R. Stitt (R. C. Mahon Company), K. R. Van Horn (Aluminum Company of America), and D. F. Windenburg (Navy Department, David Taylor Model Basin).

filled with weld metal or the plug is welded back into position, a worse stress condition may result. A third method, which is nondestructive, employs X-ray diffraction, using a back-reflection camera.[3] This method detects surface stresses only. No satisfactory method has yet been devised for measuring the distribution of residual stresses nondestructively throughout a metal object.

Since residual stresses may affect safety or utility, and since no practicable method exists for determining the magnitude and distribution of stresses in a given location, the only safe recourse is to decrease their magnitude by stress relieving or, where possible, to introduce additional stresses deliberately that are opposite in sign to the working stresses.

Definition. The term "stress relief" is applied to any means for reducing residual stresses substantially. Such methods may be thermal, mechanical, or combinations of both; these methods will be discussed later in this article.

Unfortunately, there is considerable confusion regarding the term "thermal stress relief" and certain anomalies occur in the manner in which it is used. For purposes of this article, the term will be applied only to thermal treatments that are performed specifically for the purpose of reducing residual stress. Treatments such as normalizing, annealing, and quenching and tempering, will not be considered stress-relief treatments.

Reasons for Stress Relieving. Probably the most important reason for stress relieving is to effect sufficient reduction in residual stresses that might produce a harmful system of multiaxial tensile stress when combined with service stresses. Harmful tridimensional stress systems are not present in the majority of relatively light structures, as evidenced by satisfactory performance without stress relief. Some opinion justifies the omission of stress relieving when an adequate proof test precedes service. However, a stress level just short of failure may be present during this initial short-time loading, and the influences of time and repeated applications of load may produce later failure at this lower level.

Another reason for stress relieving is to improve the dimensional stability of structures, especially where close tolerances must be maintained. Residual stresses may be introduced by some types of machining, particularly rough machining and grinding operations. If not otherwise relieved, residual stresses will be reduced during light machining operations, since the removal of metal disturbs the equilibrium, with attendant readjustment and warping. Therefore, stress relieving is often performed between rough and finish machining. Stress relieving may also cause microstructural changes that decrease the variation in hardness somewhat, so that machining to close tolerances is more easily accomplished.

Stress relieving is important for structures subjected to cyclic loading, because stress reversals involving stress ranges approaching the yield strength, result in lower fatigue strength than the same number of reversals in stress ranges well below the yield strength. The hazard of stress corrosion and corrosion fatigue is also reduced or eliminated by stress relief or by the introduction of compressive stresses at the surface.

Stress relief is generally considered important for structures subjected to appreciable dynamic loading, since shock fractures usually originate at stress raisers, particularly on equipment that operates at subzero temperatures. Complete heat treatment is frequently specified in such instances, for homogenization and removal of the heat-affected zones of welds.

Mechanism of Stress Relief. For adequate stress relief, it is necessary that a structure be relatively free to adjust itself under the action of the residual stresses, since residual stress or strain can be reduced in magnitude only by plastic flow. This reduction can be accomplished mechanically by superposing additional strain through external or internal loading, or thermally, by reducing the yield strength of the material.

Both the modulus of elasticity and the yield strength of most metallic materials decrease with increasing temperature, and the reduction of the yield strength is usually relatively greater than that of the modulus at high temperatures. Only when the yield strength decreases by a greater percentage than the modulus, is stress relief achieved by temperature changes alone. However, when the influence of time is combined with that of temperature, plastic flow occurs at stresses well below the yield strength of the material because of creep or relaxation. The rate of flow is a function of both the stress level and time. Thus thermal stress relief combines the twofold action of reducing residual stress by the relatively greater reduction of the yield strength as compared with the modulus, and by relaxation in proportion to the soaking time.

Moderate heating sometimes produces a greater amount of stress relief than can be explained on the basis of increased relaxation or decreased yield strength. For example, residual stresses in steel are somewhat decreased as a result of heating to about 400 F. At this temperature, which is in the "blue brittle" range, the yield strength actually increases instead of decreasing, while the relaxation of steel is negligible. The exact reason for this phenomenon is not known.

Ideally, stress relief should reduce residual stresses without any change in dimension, since the permanent set induced should equal exactly the removed elastic strain, provided the stress distribution is uniform and the areas of opposing stresses are equal. In practice, particularly where complex distribution of stresses is involved, the uniformity necessary to maintain an equilibrium of stress and force distribution is not attained. The influences that disturb the equilibrium result in changes of the internal forces or moments that manifest themselves as dimensional changes if forces are affected, or as a curvature or distortion if moments are affected.

Stress Relieving by Thermal Means. Thermal stress relieving may be defined as reduction of the residual stress level by increasing the temperature of a metal object to a suitable value, and holding at that temperature for a suitable time. Since most high residual stresses are produced by thermal gradients caused by too rapid or uneven cooling, with attendant plastic flow, it is apparent that such stresses can be lowered or removed if the structure is properly reheated and then cooled slowly and evenly. Similarly, residual stresses can be decreased initially by reducing the thermal gradient, as in preheating before welding, thus minimizing the necessity for stress relief. Thermal methods are the most important and widely used of all procedures for stress relief, and when properly applied, they ordinarily achieve a greater reduction in the level of residual stress than any other method.

Metallurgical Limitations. Thermal stress relief cannot be applied freely to all materials, since the thermal cycles sometimes produce undesirable changes, either microstructural or of other kinds. For example, heat treatable aluminum alloys are aged at about 300 F after solution heat treatment, to produce a definite microstructure and definite mechanical properties. Temperatures of the order of 450 to 500 F are required for producing substantial relief of residual stresses in these alloys in a reasonable length of time, but these temperatures destroy the effects of the previous aging treatment. However, a compromise of slightly lower temperatures, or shorter times at these temperatures, is used for obtaining an optimum combination of the required mechanical properties and stress relief. It has also been found that the residual stress level in these alloys can be reduced to a very low value through a decrease in the temperature gradient during quenching, by the use of a boiling water quench rather than a cold water quench after solution treatment. This procedure does not usually reduce the tensile properties greatly, and yet it provides material comparatively free from stress.

At times it is impossible to avoid introducing residual stresses into a metal by treatments designed to enhance certain properties. Steels are often quenched from the hardening temperature in order to produce a fine-grained structure, which improves fatigue resistance, and to increase hardness, which improves wear resistance. The residual stresses induced by the rapid cooling may never be removed completely if low tempering temperatures are used to retain hardness. For some materials, such as copper and chromium-nickel stainless steels, maximum softness is obtained by rapid cooling. Many parts are

surface hardened by highly localized heating or by peening, carburizing, nitriding, or similar treatments that introduce residual stresses at the surface. In all such instances, the use of thermal stress relief must be limited or sacrificed, in deference to the other desired properties.

Residual stresses are lowered in many materials by the combined effects of temperature and time at temperature. Some materials, such as the austenitic heat-resistant steels, undergo very slight reduction in yield strength at the usual stress-relief temperatures; therefore the soaking time is prolonged, or the temperature is raised, or both measures are employed to increase relaxation. However, a greater degree of stress relief is apparently attained in these materials than would be expected from their decreased yield strength and increased creep at the higher temperature. This is indicated by the fact that work hardening disappears rapidly even at moderate temperatures, and it may also be connected with the time-elongation characteristics of some of these steels, which are stepped rather than continuous, and involve repeated cycles of strain hardening and softening.

Method of Heating. The input of heat required for thermal stress relief can be secured by combustion convective or radiant heat transfer, or both, or by electrical or electronic heating. The temperatures required for stress relief are lower than those commonly used in heat treatment, and furnaces of the convection type are employed more often, since better control of temperature is possible. Further improvement is usually obtained through recirculation of the furnace gases, in either stationary or portable furnaces. Electric resistance furnaces of the stationary type have been utilized occasionally; portable furnaces that heat by electrical resistance are used frequently. For some applications, particularly for high temperatures, resistance heaters of the radiant type, such as globar units, have been used. Induction heating is commonly applied for relieving local stress in both magnetic and nonmagnetic materials. Regardless of the method used, the source of heat should be such that the thermal input is distributed evenly over the receiving surfaces, and is controlled, preferably by instrumentation, to assure the desired rates of change in temperature. Instrumentation is particularly important where high rates of heating are possible, as in induction heating.

Proper control of change in temperature involves accurate measurement of the furnace gas temperature, and more particularly of the metal temperature. The generous use of thermocouples is advised, preferably in connection with a recording pyrometer; the location of the points for measuring the temperature of the metal is an important factor. The most critical locations are those that increase in temperature either more slowly or more rapidly than the average; for example, the temperature increases more slowly in heavy sections and more rapidly in extended sections, such as nozzles on pressure vessels. For reasonable accuracy, the thermocouples should be made of metals that resist oxidation at the furnace temperature, and the couples should be peened or inserted directly into slots in the structure rather than installed in blocks attached to the structure, in order to avoid heat input or loss resulting from the couple attachment. With high input of radiant heat, it may be necessary to surround the couple with a metallic shield.

In selecting a method of heating, consideration should be given to the ratio of heat-input surface to volume or weight of metal to be heated; where several parts are loaded into a single furnace, all surfaces should be exposed freely to the heating medium. Parts should be supported adequately in the furnace because of the decreased mechanical properties of the material at the stress-relieving temperature. Adequate support not only minimizes the bending moments involved, but also distributes the reactions at the points of support, so that undesirable localized bending is avoided.

Thermal Stresses. Thermal expansion with rise in temperature does not induce stress unless the object being heated is restrained; such restraint is possible not only from mechanical effects, such as friction at the points of support, but also from thermal effects where contiguous elements are not at the same temperature. Thermal stresses may exist through the thickness, when high rates of heat input are involved, or along the length, when the heat input varies; additional dynamic stresses are possible where extremely rapid change in temperature or thermal shock occurs. Thermal stresses of sufficient magnitude, alone or in combination with other stresses, will cause yielding with attendant distortion, and are particularly undesirable at stress raisers or where tridimensional stresses may exist.

Rates of Heating and Cooling. No clear-cut analysis has been made for establishing permissible rates of heating and cooling during thermal stress relief. Except in extreme degree, rates of temperature change are not significant in themselves; instead, the important factors are the resulting differences in temperature that provide the restraint necessary for producing temperature stress. Interruptions in flow of heat that result from inclusions, cracks and the like, are focal points for highly localized temperature stresses and, in sufficient degree, may propagate such defects. The maximum temperature stress permissible during heating, depends on the magnitude of the residual stresses already present, since if distortion is to be avoided, the combination of the two stresses must not exceed the yield strength at the temperature of stress relief. The maximum temperature stress permissible during cooling should be less than the yield strength at the stress-relief temperature in order to avoid the introduction of stress during cooling.

A moderate rate of cooling is generally favored—about one-half the rate of heating. When possible distortion and tridimensional stress failure are considered, however, the rate of heating assumes importance equal to that of the rate of cooling, if not greater.

Duration of Stress Relieving. As already pointed out, the soaking period is intended to promote stress relief through relaxation, and theoretically should depend on the creep strength of the material and be independent of the thickness. However, since tridimensional stresses are encountered more frequently in thick materials than in thin, longer periods are required for the adequate stress relief of heavy sections. In addition, large sections require long periods for reaching the furnace temperature. Accepted practice associates soaking time with thickness.

Unfortunately, no correlation has been established between rates of first-stage relaxation and the amount of stress relief produced by various soaking times. Some arbitrary standards have been set up on the basis of subjecting test specimens to various thermal cycles and measuring the amount of reduction in stress by unloading, or by boring or machining operations. The results from these methods indicate that a small increase in temperature is more effective in the relief of residual stress than a much greater soaking time at a lower temperature.[9,10] For example, SAE 4130 steel originally stressed to 62,500 psi, retains a residual stress of only 1900 psi after 1 hr at 1200 F. However, it retains a residual stress of 3150 psi after 8 hr at 1100 F and 15,300 psi after 8 hr at 900 F.[9]

Temperature Ranges for Stress Relieving. The three different temperature ranges listed below are generally used in thermal stress-relieving operations; the soaking time is increased as the temperature is reduced.

1 Elevated temperatures (just below the transformation range for steel) are used where the yield strength is reduced markedly, relative to the modulus.
2 Mildly elevated temperatures are used where the yield strength is reduced only slightly, relative to the modulus.
3 Low temperatures, slightly above room temperature, are used where the yield strength is not reduced or may even be increased.

For steel, thermal stress relief is generally performed at temperatures just below the transformation range. The temperature should be as high as practicable, but not high enough to impair the structure produced by any previous heat treatment. Where additional softening is required, and some structural transformation is not harmful, temperatures at the lower end of the transformation range are used. Subassemblies are often stress relieved before final assembly. One or more intermediate operations may be necessary for relieving stresses in heavy welds or complicated structures.

The usual temperatures for stress relief of steel range from 1100 to 1300 F. Stress relief at mildly elevated temperatures (approximately 900 F) is also used when, for any reason, higher temperatures are not possible.

Low-temperature stress relieving, sometimes called "aging", refers to those stress-relief treatments in which the part is held at room temperature, or at some slightly elevated temperature, generally below 300 F, for a considerable length of time in order to permit residual stresses to "creep" out. The time of holding may vary from about 8 to 75 hr, depending on the type of part and the relaxation rate of the material from which it is made. Aging has been used for parts such as cast-iron cylinder blocks for automobile engines, machine bases, aluminum and magnesium parts, and cold drawn austenitic steel wire.

Tables I and II show typical stress-relief treatments commonly used in industry. Readers of the Handbook are cautioned, however, that these represent only average practice for average work. Faster heating and cooling rates could be used for simpler structures, whereas slower rates are required for more complex structures. For example, a simple cylinder, without closures, openings or such, can withstand extreme rates of change in temperature without excessive stress. On the other hand, a complete pressure vessel, with many manholes, nozzles and the like, can withstand only slight nonuniformity in temperature without yielding and distortion.

Stress Relieving as a Unit. "Stress relieving as a unit" refers to those treatments in which the stresses in an entire part or structure are relieved at one time, generally in a furnace. Large vessels are sometimes heated by the circulation of hot gases from flue-gas generators, with or without recirculation, or from burners within the vessel.

In several borderline variations of stress relieving as a unit, large parts are heated in sections; or are heated progressively by passage through a furnace or by proximity to a portable furnace that is moved along the part. When parts are heated in sections, sufficient overlapping of successive steps is essential; with progressive methods, the rate of movement must not be excessive. Care is required to protect the portion adjacent to the heated zone from serious temperature gradients.

Local Stress Relief. Local stress relief is commonly applied to structures that have dimensions exceeding available furnace capacity, to heavy or complicated parts where the treatment serves as an intermediate step for the limiting of stress accumulations, or to field girth welds of critical piping. The degree of stress relief attained depends on the details of application and control, which, as in stress relieving as a unit, determine the magnitude of the thermal stresses introduced. However, in addition to the thermal gradients possible because of unevenness and excessive rates of heating, local stress relief involves thermal gradients around the boundary of the heated area, which introduce stresses into both the boundary and the heated zones.

Table II. Typical Stress-Relief Treatments for Certain Nonferrous Alloys[a]

Material	Temperature, deg Fahr	Time at Temperature, hr
Copper Alloys		
Copper	300	½
90 Cu – 10 Zn	400	1
80 Cu – 20 Zn, 70 Cu – 30 Zn	500	1
63 Cu – 37 Zn	475	1
60 Cu – 40 Zn	375	½
70 Cu – 29 Zn – 1 Sn	575	1
85 Cu – 15 Ni, 70 Cu – 30 Ni	475	1
64 Cu – 18 Zn – 18 Ni	475	1
95 Cu – 5 Sn, 90 Cu – 10 Sn	375	1
Magnesium Alloys		
M-1, Hard rolled sheet, 1.5 Mn	400	1
M-1 Extrusions, 1.5 Mn	500	¼
AZ31X Hard rolled sheet, 3 Al, 1 Zn, 0.3 Mn	300	1
AZ31X Extrusions, 3 Al, 1 Zn, 0.3 Mn	500	¼
AZ51X Hard rolled sheet, 5 Al, 1 Zn, 0.25 Mn	375	1
AZ61X Extrusions, 6 Al, 1 Zn, 0.25 Mn	500	¼
AZ80X Extrusions, 8.5 Al, 0.5 Zn, 0.15 Mn	400	1
AZ80X HTA Extrusions, 8.5 Al, 0.5 Zn, 0.15 Mn	600	¼
Nickel Alloys		
Nickel and Monel	525 to 600	3 to 1
"K" Monel and "KR" Monel	525 to 600	3 to 1
80 Ni – 20 Cr, Inconel, 60 Ni – 25 Fe – 15 Cr	700 to 900	3 to 1

(a) Optimum heating and cooling rates depend primarily on the size and shape of the part being treated.

Uniform change in temperature, without restraint, does not involve stress; this is equally true of a temperature gradient that permits every element of a structure to assume dimensions in proportion to its temperature. A cylinder that has a linear axial temperature gradient freely assumes conical shape; similarly a flat plate that has a linear temperature gradient across the width or thickness freely assumes curvature with the hot edge at the maximum radius.

On the other hand, if only a portion of the length of a cylinder or of the width of a flat plate is heated, the temperature gradient is interrupted, and expansion is almost completely prevented, even with moderate gradients at the boundaries. This causes temperature stress and plastic flow equal to the full amount of the strain produced by the temperature difference. Heating a small

Table I. Typical Stress-Relief Treatments for Certain Ferrous Alloys[a]

Type of Material, Composition, or Size of Section	Temperature, deg Fahr	Soaking Time,[b] hr per in. of thickness
Gray cast iron	800 to 1100	5 to ½
Carbon Steel		
Less than 0.35% C, less than ¾ in.	Stress relief usually not required[c]	
Less than 0.35% C, ¾ in. or greater	1100 to 1250	1
More than 0.35% C, less than ½ in.	Stress relief usually not required[c]	
More than 0.35% C, ½ in. or greater	1100 to 1250	1
Specially killed for service at low temperature	1100 to 1250	1
Carbon-Molybdenum Steel (all thicknesses)		
Less than 0.20% C	1100 to 1250	2
0.20 to 0.35% C	1250 to 1400	3 to 2
Chromium-Molybdenum Steel (all thicknesses)		
2% Cr, 0.5% Mo	1325 to 1375	2
2.25% Cr, 1% Mo and 5% Cr, 0.5% Mo	1350 to 1400	3
9% Cr, 1% Mo	1375 to 1425	3
Chromium Stainless Steel (all thicknesses)		
Types 410 and 430	1425 to 1475	2
Type 405	Stress relief usually not required for thicknesses less than ¾ in.[c]	
Chromium-Nickel Stainless Steel		
Types 304, 321 and 347	Stress relief usually not required for thicknesses less than ¾ in.[c]	
Type 316, more than ¾ in.	1500	2
Types 309 and 310, more than ¾ in.	1600	2
Welding Dissimilar Materials		
Cr-Mo steel to carbon steel or to C-Mo steel	1350 to 1400	3
Types 410 and 430 to any other steel	1350 to 1400	3
Cr-Ni stainless steel to any other steel	As required for the steel to which Cr-Ni stainless steel is joined	

(a) For chromium-nickel stainless steels and for weldments of dissimilar materials, the rate of heating should be less than 200 °F per hr. For the other materials a heating rate of less than 400 °F per hr is recommended. All materials should be cooled from the stress-relieving temperature at a rate not higher than 200 °F per hr.

(b) The interval during which the entire piece is at temperature (c) Unless necessary in order to obtain dimensional stability

local area of a flat plate or shell may cause elastic or plastic buckling. Since elastic buckling permits additional deformation, a higher temperature gradient can be sustained by the object without causing yielding. In plastic buckling, reintroduction of stress occurs in the boundaries and contiguous areas, and the most that can be accomplished is the relocation of the residual stresses.

When heat is applied to a complete circumferential band on a cylinder, the heated area expands, the boundary zone assumes conical shape, and restraint is limited to influences that provide continuity at the intersections of the heated boundary and cold zones. In this instance, the temperature stresses can be controlled by control of the gradient in the boundary zone, which establishes the angle of intersection between the cone and the cylinder.

The ASME Boiler Construction Code at one time contained provisions for stress relief of nozzles by heating a localized area around the nozzle. Some years ago the rules were revised to require all local stress relief to be applied around a complete circumferential band of the vessel with the nozzle in the center. Thermal stress relief of longitudinal elements in shells and of elements in flat plates is ineffective, as attested by many examples of failure or distortion. On the other hand, thermal stress relief that is achieved by heating a band on a surface of revolution, such as a girth weld on a pipe, is recognized as sound practice.

In the stress relieving of girth seams, the width of the heated band and the thermal gradients in the boundary zone determine the thermal bending stress in the heated area. The ASME and API-ASME Codes establish the total width of the heated band as 12 times the plate thickness, whereas the API-ASME Code limits the boundary gradient to 200 °F per ft along the shell. The width of the heated band should be sufficient to include the area of significant residual stress developed in the plate as a result of welding, and to prevent overstress that might develop at the center of the weld area as a result of overlapping of the bending effects induced from both sides by the thermal gradients in the boundary zone.

Stress Relieving by Mechanical Means. "Mechanical stress relieving" may be defined as the reduction of residual stresses by mechanical methods at moderate temperatures. This reduction is accomplished by introducing mechanically stresses that cause plastic flow. These stresses may be produced by direct loading, hydraulic pressure, cyclic loading, peening or similar means.

Mechanical methods of stress relief are applied to machines or structures either too large to be placed in a furnace, or of such a shape that thermal stress relief would cause excessive distortion. In contrast with stress relief by thermal means, mechanical methods usually involve less expensive equipment; however, they are seldom as effective.

Mechanical methods for relief of residual stresses can be classified as follows:

Hand Peening. This mechanical method of stress relief by hammer blows or similar means is used mostly for the relief of stress in welded structures, in order to cause plastic flow of the weld metal and thus to reduce the load that is placed on the structure as a result of weld shrinkage. The peened weld metal is cold worked and contains residual stress, which is removed to some extent by the penetration and heat of succeeding weld passes. For this reason, the depth of the weld pass should be proportioned to the effective depth obtainable from peening.

Hand peening is ordinarily performed with rounded tools used in pneumatic hammers; for soft alloys, wooden mallets are sometimes used. Many well-distributed, quick, light blows are preferable to heavy blows more widely spaced. Peening is omitted on initial passes until sufficient strength is developed to avoid cracking, and is also omitted after the last pass, which is often removed in the final dressing of the weld.

Although hand peening is frequently used, it is a somewhat uncertain method of stress relief because it is difficult to control; besides, there is some doubt as to its effectiveness. However, the process is considered useful where it is impracticable to stress relieve by more efficient methods. Good peening requires considerable experience and personal judgment. Frequently it is difficult to determine whether the weld has been peened sufficiently or whether it is overdone. Peening of austenitic materials is generally ineffective because of the tendency of these materials to work harden rapidly.

In order to obtain better control, punch marks are sometimes made in the base metal on opposite sides of a weld. Peening is then performed in such a manner as to maintain the separation of the marks, within about $\frac{1}{32}$ in., after the first two layers of weld metal have been deposited. When the weld has acquired a depth of 1¼ in. the subsequent movement of the gage marks is small, and peening is continued to the degree required initially. However, this method may result in overpeening of the weld.

Shot Peening. Shot peening is a process of projecting shot from an air nozzle, or from the rim of a rapidly rotating wheel, against the part to be treated. This method introduces compressive stresses at the surface of the metal, or reduces the maximum residual tensile stress at the surface if residual tensile stresses are present. In addition, the resistance to fatigue is increased—but only partly by the relief of the residual stresses. The increase can be attributed also to the work hardening of the material at the surface and to the resulting residual compressive stress. Shot peening can be applied to finished parts, such as springs, axles and gears, or to specific areas of large structural or machine parts. Careful control must be maintained for satisfactory results; the principal variables are the size and velocity of the shot and the time of exposure.

Stressing Beyond the Yield Point. Residual stresses may be reduced by mechanical means, such as direct loading or hydrostatic pressure, for stressing beyond the yield strength. The resultant plastic flow tends to obliterate the initial residual stress, with resulting cold work in proportion to the deformation produced. With drawn parts, such as bars, rods or tubes, this procedure is frequently combined with straightening.

One method of stress relief that falls into the classification of straining beyond the yield point is known as "overspeeding". It is applied to rotating parts, such as turbine wheels and centrifugal compressors, which operate normally at fairly high speeds.

In this process, the semifinished wheel is rotated in an evacuated test stand for ▮ to 10 min at a speed 10 to 15% greater than the highest speed at which it will be required to operate in service. Since the stresses in such rotating parts increase in proportion to the square of the speed, the stresses during overspeeding exceed the yield strength of the disk material. The resultant plastic flow helps to redistribute and reduce the residual stresses. In addition, because of the plastic yielding, the disk retains a certain amount of compressive stress at the center after the overspeeding has been completed. This residual compressive stress then increases the safe operating stress in the disk, since the operating stresses are all tensile, and are highest near the center.

Cyclic Loading. Structures are sometimes subjected to cyclic loading with low stress at their resonant frequency, by means of vibration generators.[7] This procedure is intended to reduce residual stresses by the stress that results from dynamic loading. Repeated slow loading at high stresses is sometimes used in order to produce a similar static effect. Care must be taken with this method to avoid stresses that are too high, or too many repetitions of stress, since either excess might lead to fatigue failure.

The data and information available, concerning the effectiveness of these methods, are insufficient to warrant the conclusion that vibration is a suitable method for stress relieving. Some evidence that superposed vibratory stresses produce relief of residual stress is found in the relieved stress condition of structures that have been in service. Formed plates, forced into position with considerable difficulty in the assembly of a ship, can be removed after the ship has been in service for a few months, and then replaced with ease. The plates may still contain high residual stresses, since extensive data, taken by using strain gages on board ships in service, indicate no appreciable decrease in residual stress resulting from normal operation.[8] However, the peak stresses have certainly been relieved, since the plates retain their original shape without forcing. It is probable that appreciable stress relief under cyclic loading is obtained only in those regions where the

increments of stress are sufficient to cause plastic flow.

Stress Relieving by Combined Mechanical and Thermal Means. Methods of mechanical and thermal stress relief are sometimes combined; that is, the mechanical loading required for producing plastic flow, is done while the structure is at a temperature above room temperature. The amount of thermal stress relief depends on temperature and time, thus reducing the mechanical stress relief required.

Peening at elevated temperature has the advantage that hot metal is less susceptible to failure from shock and lighter blows may be used; at the same time cold work is reduced in proportion to the temperature. The circularity of large pressure vessels may be improved or maintained if they are stress relieved by circulation of hot gases under pressure. Turbine and compressor disks are sometimes oversped while hot; if desired, only certain portions of a disk may be heated to produce local plastic flow. For example, a turbine disk with buckets welded to the out-

Table III. Code Requirements for Stress Relief

Reference	Materials Covered	Where Stress Relief is Required	Heating Rate, deg Fahr per hr	Stress Relief Temperature, deg Fahr	Soaking Time, hr per in. thick	Cooling Rate, deg Fahr per hr	Permissible Methods of Stress Relief*
ASME Power Boiler Code (Section I) Revised 6-4-46 Par. P-108	Killed and rimmed carbon steels, low-alloy and intermediate alloy steels, austenitic steels	All fusion-welded pressure parts of power boilers except welded carbon steel and C-Mo (0.20% max C) piping ⅜ in. thick and less	Slow and uniform	1100 to 1200 (Different temperature may be used where required by the characteristics of the material)	1 (min)	Slow, in still atmosphere to a temperature not exceeding 600 F	1, 2, 3, 4, and 5

*1 Heating complete drum as unit

2 Heating section of drum (head or shell-ring course) with attached parts before attachment to other sections of drum

3 When drum is stress relieved in sections, stress relieve final girth joints by heating uniformly a circumferential band having a minimum width six times the plate thickness on each side of welded joint, so that the entire band is brought up to the temperature and holding time specified in the above table. Maximum permissible gradient not specified.

4 Nozzles or other welded attachments may be stress relieved locally by heating a circumferential band around entire vessel (connection at middle of band). Band width to be at least 12 times the shell thickness wider than the attachment. Temperature and holding time to be as specified above. (Maximum permissible gradient not specified.) (Thickness refers to welded main seams, not to attachments.)

5 For welded joints in piping and tubing, the width of circumferential band should be at least three times the width of widest part of welding groove but in no instance less than twice the width of the weld reinforcement. (Maximum permissible gradient not specified.)

6 All connections and heavy attachments shall be stress relieved, where vessel is to be stress relieved.

7 All vessels for lethal or noxious gases shall be stress relieved.

8 Heating vessel as unit in an enclosed furnace (preferred whenever practicable)

9 Heating vessel in sections in an enclosed furnace, provided overlap of heated sections of vessel is at least 5 ft. Shell portion outside furnace should be protected so that temperature gradient will not exceed 200 °F per ft along shell.

10 Heating shell sections or portions of vessels or both before joining together. The final circumferential joints may be stress relieved after completion of the vessel, by heating uniformly a circumferential band having a minimum width six times the plate thickness on each side of welded joint. Shell portion outside furnace should be protected so that temperature gradient will not exceed 200 °F per ft along shell.

11 Mechanical peening is permitted by keeping punch marks on opposite sides of weld within ⅛ in. of original spacing for first two weld layers, and peening in same degree for remainder of weld.

12 Heating the complete structure as a unit

13 Heating a complete section containing the weld or welds to be stress relieved before attachment to other sections of work

14 Heating a part of the work by heating slowly a circumferential band containing the weld at the center. The width of the band that is heated to between 1100 F and 1250 F, should be equal to at least twice the width of the widest part of the welding groove, and the temperature should be allowed to diminish gradually outward from the ends of this band.

side periphery might be oversped while only the outside periphery near the weld is being heated; thus, the higher residual stresses could be reduced in this area.

The use of localized heating to provide mechanical loading and thus produce plastic flow in areas of residual stress, is properly a form of mechanical stress relief, but the practice is discussed in this section because of being commonly associated with stress relief by combined mechanical and thermal means. In its simplest application, localized heating is used to remove buckles or twists from plates or structural members. Recently a continuous or progressive method of thermal mechanical loading has been employed in the stress relief of welds in ship hulls, and has been described in a recent report.[12] In this reference, it is stated that the reaction stresses resulting from the shrinkage of the weld, against the restraint of the surrounding structure, are of secondary importance and that they may be minimized by proper welding procedure and sequence. On the other hand, residual stresses in the weld joints, or immediately adjacent to them, caused by the longitudinal shrinkage of the weld, are found almost invariably to approach the yield strength of the weld. The reference article describes the removal of these stresses by the heating of parallel bands progressively on each side of the weld, followed by cooling, in order to produce tensile stresses of sufficient magnitude to cause plastic flow in the weld and adjacent plate areas. Although a temperature differential of 225 F should be sufficient to produce stresses of yield point magnitude in mild steel, it was found that temperatures between 300 and 400 F were actually required because of the inevitable rise in temperature of the adjacent metal. The results of tests on unrestrained sample plates are given; residual stresses were evaluated by the removal of specimens to which electrical-resistance strain gages had been attached. As pointed out above, the measurement of residual stress by removal of a specimen may lack accuracy.

Removal of longitudinal weld stress by this method should be of considerable value in large structures for which no other satisfactory procedure for stress relief is available at present; however, adequate control and continuous inspection would be essential in order to obtain uniform results. All forms of mechanical loading involve the hazard of failure if tridimensional residual stresses of sufficient magnitude are present, and the additional loading involved would be expected to propagate flaws more readily than if such loads were not applied. Without such failure, reduction in the longitudinal residual stress in the weld lessens the possibility of failure from tridimensional residual stresses; and even with failure, the stress relief has located areas that might have fractured in service. So-called "reaction stresses" may be controlled successfully in ship welding, but such control is not possible in many other types of structures, such as pressure vessels.

Requirements of Various Codes and Standards. For convenience, the stress-relief requirements of existing Codes and Standards have been condensed in Table III. In general, these requirements have been formulated from a consideration of carbon steel exclusively. Details have not been systematized yet for low-alloy and high-alloy steels and nonferrous materials. It should be remembered that Code rules establish minimum requirements only, and are based on average conditions of design and fabrication. Judgement must be used in applying such rules to complex structures.

Basic Causes of Service Failures in Metals

BY THE SUBCOMMITTEE ON SERVICE FAILURES*

THE CAUSES that might contribute to the failure of metal parts in service are too numerous to list. If it is assumed that a proper selection of metal has been made—and this is a reasonable premise, in view of the immense amount of data given elsewhere in this Handbook, concerning chemical composition and mechanical properties—then the causes for failures of metal in service may be grouped into three categories: design factors, processing, and service environment.

*The members of this subcommittee are H. L. Maxwell, *Chairman* (E. I. du Pont de Nemours & Company), J. O. Almen (Research Laboratories Division, General Motors Corporation), A. L. Boegehold (Research Laboratories Division, General Motors Corporation), O. J. Horger (The Timken Roller Bearing Company), J. B. Johnson (Air Materiel Command), H. W. McQuaid (Consultant), C. W. Obert (Union Carbide and Carbon Corporation), R. E. Peterson (Westinghouse Electric Corporation) and J. H. Romann (U. S. Engineering & Mfg. Co.).

The Influence of Design Factors

It is recognized that design is often a more questionable factor than the material used, when service failures must be eliminated. The proper distribution of stresses—a matter of paramount importance if mechanical failures are to be eliminated—is obtainable largely through the physical shape and position of the parts to be loaded.

Most design calculations are made on the basis of three elementary formulas:

For direct stress, $S = P/A$ where P is load, A is area.

For bending, $S = M/(I/c)$ where M is the bending moment and I/c is the section modulus in bending.

For torsion, $S = T/(J/c)$ where T is the torque and J/c is the section modulus in torsion.

These formulas apply only where there is no change of section for a considerable distance axially (of the order of the diameter or depth dimension), as shown in Fig. 1*a*.

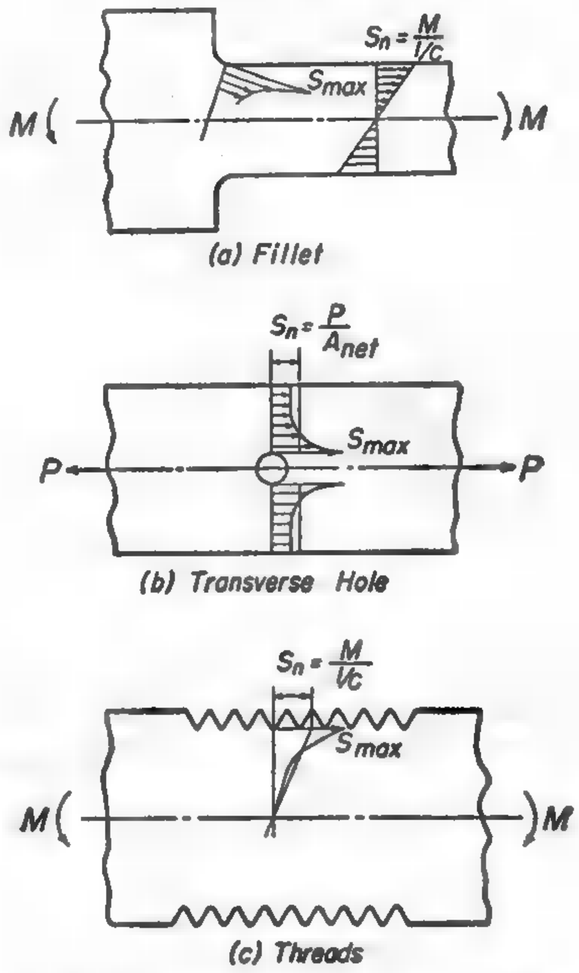

Fig. 1 Examples of stress concentration

In nearly all machine parts, however, the minimum section occurs at a region of changing section which, as shown in Fig. 1, introduces a redistribution of stress such that an increase of stress, or "stress concentration", occurs near the surface. The *stress concentration factor* is defined as $K = \frac{S_{max}}{S_n}$ where S_n = nominal stress (Fig. 1).

The nominal stress is computed by means of an elementary formula (usually on the basis of net area). This purely arbitrary procedure is convenient for designers; the simple basic definition should be kept in mind in proceeding to more complicated problems.

Factors of stress concentration are determined in numerous ways:[1] by mathematical analysis, photoelasticity (*see* Fig. 2), strain gages, brittle materials and coatings, soap film analogy and so on.

Values of the stress concentration factor for various examples are given in Fig. 3, 4 and 5. Such curves are of basic interest in design work, an example of which will be given later. When a metal part fails, the curves are useful in a relative way in judging the approximate benefit to be obtained by certain modifications. For example, if a shaft has a step-up of diameters from ⅝ in. to 1 in., a change of fillet radius from $\frac{1}{64}$ in. to $\frac{1}{16}$ in. (r/d of 0.025 to 0.1, corresponding to K_t' of 2.52 and 1.63 respectively, Fig. 3) results in a stress reduction of 0.89/2.52 = 35%; a change from ⅛ in. to ¼ in. radius results in 12% reduction.

When is stress concentration important? Generally in

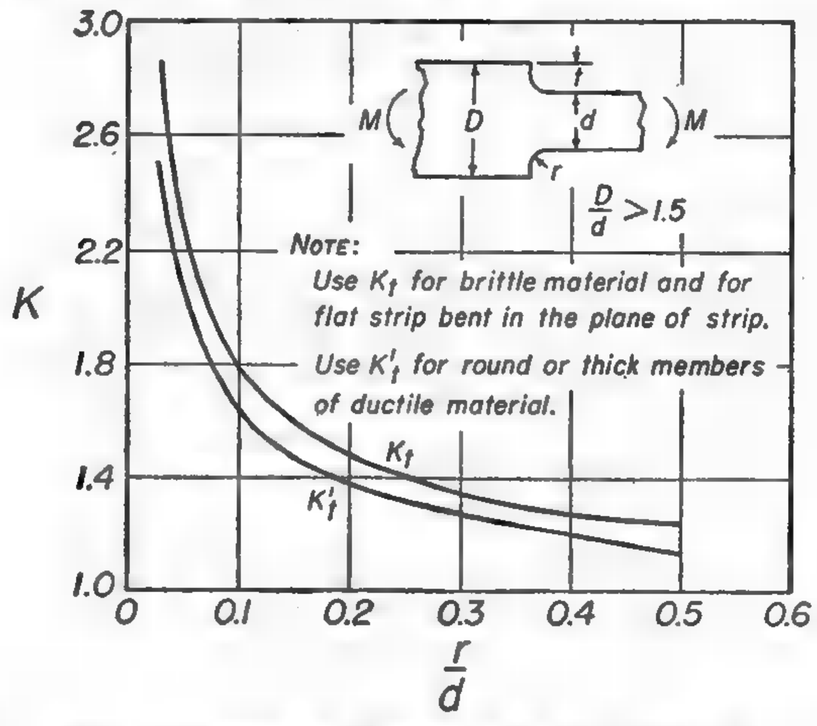

Fig. 3 K factors for fillets in bending. $D/d > 1.5$

brittle material or with repeated (fatigue) stressing. In such instances the material cannot flow and redistribute the stress more uniformly, as happens when a ductile material is loaded statically. For combined static and variable stresses, it is customary in design practice to apply the stress concentration factor to the variable portion only.

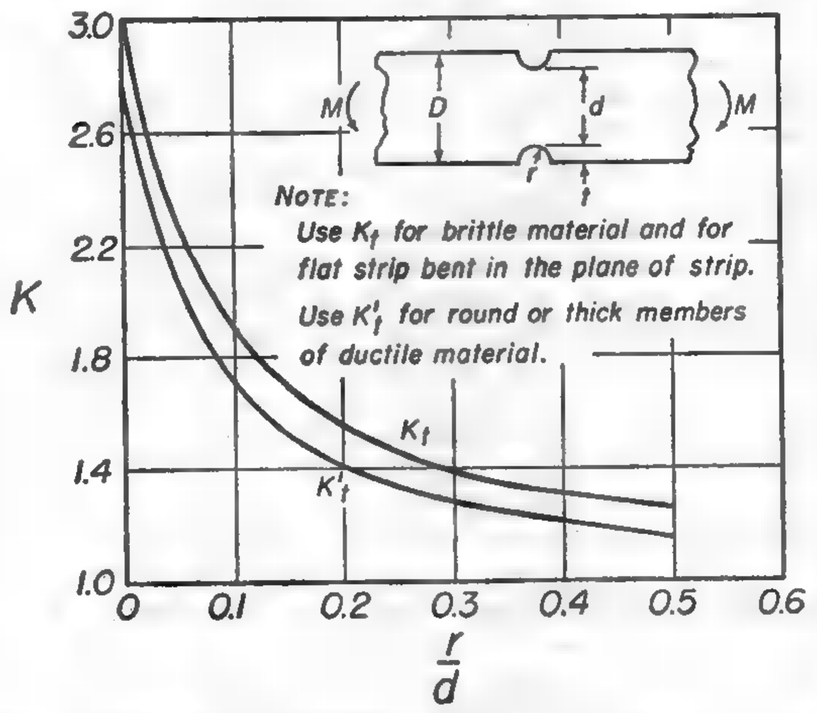

Fig. 4 K factors for semicircular notches and grooves in bending

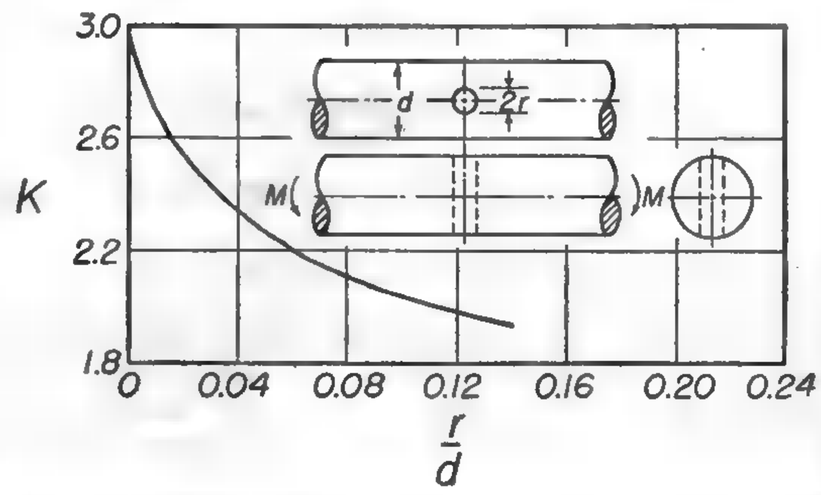

Fig. 5 K factors for shafts with a transverse hole (bending)

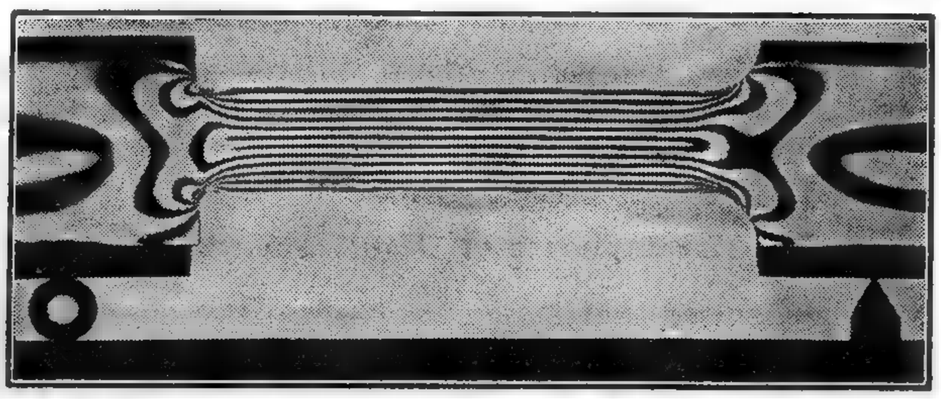

Fig. 2 Photoelastic fringe photograph of fillet section of a bar in bending. (Fringes are lines of constant shear stress. Uniformly spaced lines away from fillet correspond to linear stress distribution of bent bar. The crowding of fringes at fillets indicates stress concentration.)

This subject would not be complete without mention of "notch sensitivity". Experience has shown that in quenched and tempered steels, ordinarily the reduction in fatigue strength is approximately in accordance with the

stress concentration factor; but in hot rolled ("as received"), normalized or annealed steels the full reduction is not generally obtained and the amount of reduction depends on the geometry, chiefly the "notch radius".

The "notch sensitivity index" is defined as $q = \frac{K_f - 1}{K_t - 1}$

where $K_f = \frac{\text{fatigue limit of unnotched specimen}}{\text{fatigue limit of notched specimen}} = \frac{S_e}{S_n}$

The above definition of q provides a scale from zero, or no notch effect (that is, $K_f = 1$) to unity, or full theoretical notch effect (that is, $K_f = K_t$).

In Fig. 6, average q curves are given for a situation where the depth of notch or shoulder is not greater than three times the notch radius.

In a fatigue specimen or machine part that has a circumferential groove of semicircular contour or a transverse drilled hole, as the groove or hole becomes very small, the effect of strength reduction becomes less and

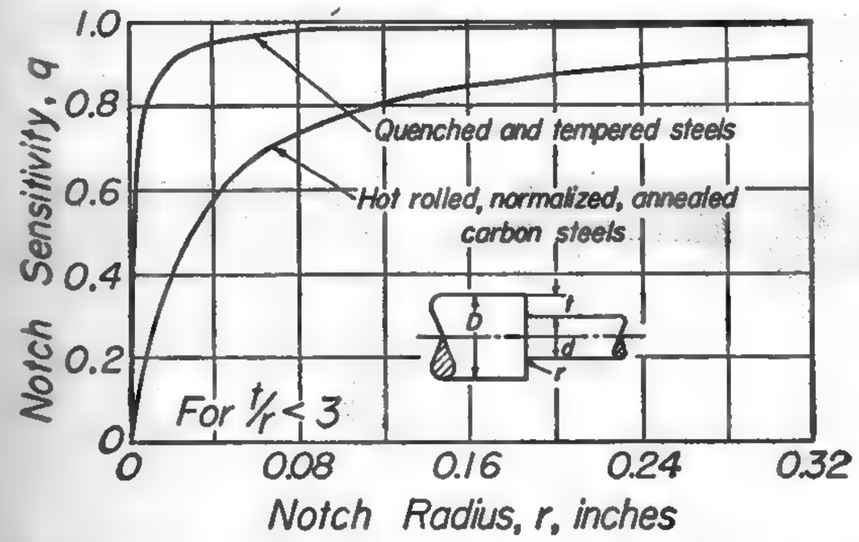

Fig. 6 Average notch sensitivity curves (grooves, fillets and transverse holes) for $t/r < 3$

approaches zero. This means that a tool mark might reduce the fatigue strength 10 to 20%, for example, instead of the full theoretical amount of about 60 to 70%; the exact amount depends on the material and shape of the groove.

An example involving the foregoing terms is illustrated by Fig. 7. The material is normalized SAE 1035 steel having an endurance limit of 34,000 psi. Figure 3 shows, for $r/d = \frac{1}{32}$, that $K'_t = 2.35$, and Fig. 6 shows that $q = 0.7$. The limiting stress in bending is

$$S_n = \frac{S_e}{1 + q\,(K'_t - 1)} = \frac{34{,}000}{1 + 0{,}7(2.35 - 1)} = 17{,}500 \text{ psi.}$$

Machine parts are not designed to this limiting value; the working stress used in design is the limiting stress divided by the "factor of safety".

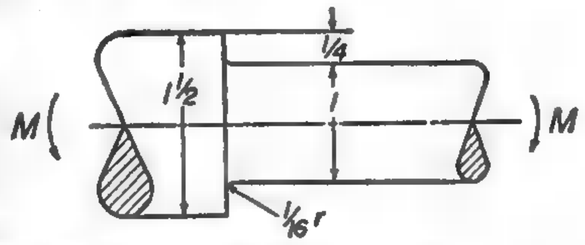

Fig. 7 Dimensions for design example

One of the implications of the foregoing discussion is that under certain circumstances, the gain in fatigue strength that can be obtained by changing, for instance, from a normalized axle steel to a quenched and tempered steel is not in proportion to the increase in tensile strength; in fact, in extreme situations there is no gain in fatigue strength. In general, the amount gained depends principally on the geometry (that is, notch radius and K_t). This fact is illustrated by Fig. 8 and 9, which represent average values for notch radii $\frac{1}{64}$ in. and ⅛ in. respectively.[2] It is evident that for small radii and large K_t values there is little or no gain in fatigue strength by changing to material high in tensile strength; whereas for large radii or low K_t values, or a combination of these, a large gain is obtained.

An obvious consequence of the foregoing is that if maximum benefit is to be obtained from heat treated parts, they should be designed carefully to reduce stress concentration to a minimum. Occasionally, however, the designer is left with factors of considerable magnitude; press fits and keyways, for example, ordinarily result in factors of two or greater. The general relationships illustrated by Fig. 8 and 9 will be helpful in judging individual problems.

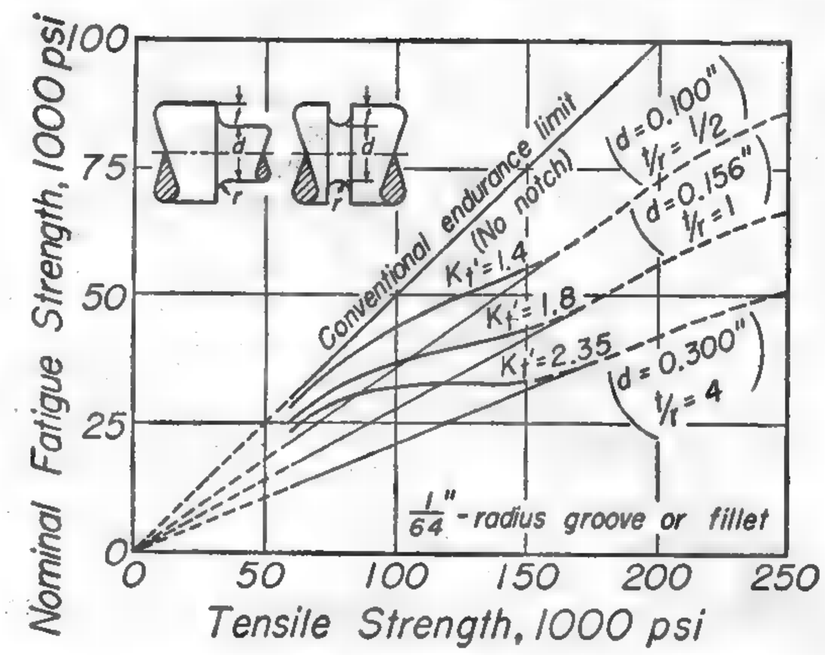

Fig. 8 Approximate fatigue strength in bending of steel shafts that have $\frac{1}{64}$-in. radius in the groove or fillet

In the foregoing discussion, a given condition of loading has been assumed for each example. Often the distribution or manner of loading is influenced by the deformations of the parts. The example of the overhung pinion is shown

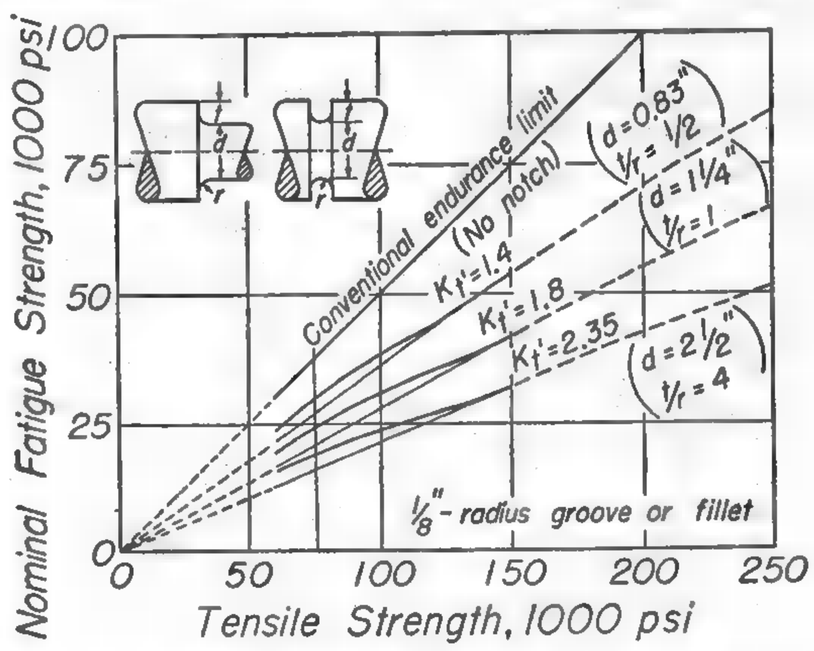

Fig. 9 Approximate fatigue strength in bending of steel shafts that have ⅛-in. radius in the groove or fillet

in Fig. 10. Instead of the uniform distribution usually expected, as in (*a*), the load distribution is more likely to be similar to (*b*) because of deflection of the shaft. In problems of this kind, deflections should be calculated or measured and account should be taken of the altered distribution of load in making the design. It is sometimes

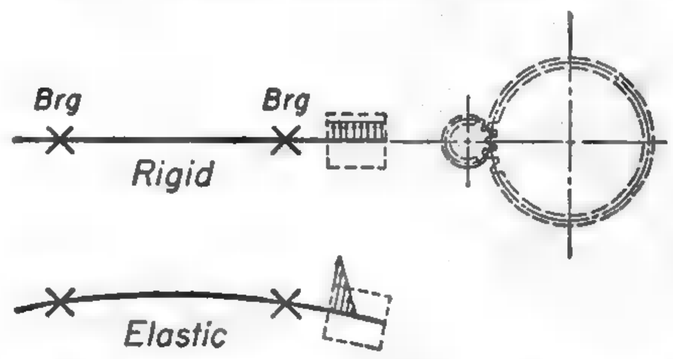

Fig. 10 Load distribution on overhung pinion

not recognized that a way to strengthen or reduce stress in a flat spring working between fixed stops (constant deflection) is to make the spring thinner. When combinations of materials are being used, the moduli of elasticity should be considered.

Influence of Metal Processing on Service Failures

Failures caused by poor design should be eliminated during the service testing of equipment before the production articles are approved. The majority of service failures that result in breakage or malfunctioning of equipment are caused by improper operation and maintenance; however, numerous failures are caused by lack of proper control in the inspection and fabrication operations during the manufacture of component parts. The responsibility for reducing failures in service is shared also by the mechanics who install the equipment; for example, "the man with the wrench" may nullify all the best efforts of design, metallurgical and process engineers, by overtightening bolts.

The large number of processes undergone by a piece of metal while it is being made into a finished machine part, requires that this discussion be restricted to the few processes that seem the most likely sources of service failures in metals. Metallurgical processing, such as heat treatment, is considered here, with emphasis on stresses induced during thermal changes; also, decarburized surfaces are discussed, with brief notes on induction hardening. Mechanical processing is included, with a brief discussion of shot peening, screw threading, surface rolling and straightening, and how these several processes may be related to service failures of metal parts.

Residual stress introduced in metal during heat treatment or fabrication may have an important influence on the service life of a part. For a discussion of this subject, see the article "Relief of Residual Stress", page 237.

Failures Related to Thermal Treatments Used in Processing. The responsibility for obtaining the correct thermal processing is shared by the mechanical engineer, the metallurgist and the supervisor of heat treating. The proper thermal treatment for obtaining the correct structure and distribution of residual stress in a thermally processed member, is only one treatment in contrast with a large number of possible wrong treatments. To consider all the possible wrong treatments and resulting structures would require many volumes.

The metallurgist may specify a satisfactory thermal processing to obtain adequate mechanical properties that have been specified by the engineer, but the heat treating department may fail to execute these specifications properly. The departure from the specified heat treating procedure may involve any one of a multitude of errors. The structure and mechanical properties associated with a failed member that has been improperly processed, may be characterized by an excessively overheated structure, lack of properly refined structure, lack of sufficiently hard structure, or the like. Examples of some of these inadequacies are given in accompanying illustrations.

Another class of defective material encountered outside the metallurgical specification includes defects that originate during the manufacturing of the metal. These defects, too, are caused either by the lack of adequate specifications and inspection for determining metal quality, or they result from failure to detect defects during inspection of the metal. This lack of thoroughness accounts for internal defects such as pipes, flakes, excessive banding, scale that has been rolled or forged in, and excessive nonmetallic inclusions—all defects that are frequently responsible for the failure of parts in service. Fig. 11 shows an example.

Failures in a second class originate from the engineer's neglect to specify suitable mechanical properties for withstanding the loads applied in service. The mechanical properties are specified by the engineer; then the metallurgist prescribes the material and heat treatment to obtain those properties. Although the material and heat treating processes may be faithfully executed, the part may still fail in service because the properties considered suitable by the engineer were actually inadequate. A deficiency in mechanical characteristics may be responsible for failure, in a variety of ways. The strength may be too low to resist the load in service; the hardness may be too low to prevent indentation as the result of concentrated loading; the hardness may be too high, with an accompanying lack of ductility or with accompanying residual tensile stresses that decrease the useful strength of the member; the hardness may be according to specification, but the heat treatment used for obtaining the hardness may be such as to produce an unsatisfactory structure.

Strength Too Low. Failure from too low strength may be illustrated by a bolt, heat treated to a hardness of Rockwell C 25 (equivalent to a tensile strength of 120,000 psi) and used in a highly stressed application, such as a cylinder-head bolt or a connecting-rod bolt, where the stresses involved require the use of material having a hardness of Rockwell C 32 to 36 with an accompanying tensile strength of 160,000 psi.

Hardness Too Low. Failure because of insufficient hardness may be illustrated by several different types of examples, one of which is in surfaces that are intended to be highly resistant to wear and are to have a hardness of Rockwell C 60 or higher. Frequently such surfaces are produced with the specified hardness by satisfactory thermal treatment and are then subjected to a grinding operation, which causes softening to a depth of 0.001 to 0.002 in., with the result that subsequent Rockwell tests fail to detect the soft layer at the surface—a layer that could be detected only by means of a file test. When placed in service, a member that has a soft surface fails very soon by scoring or galling.

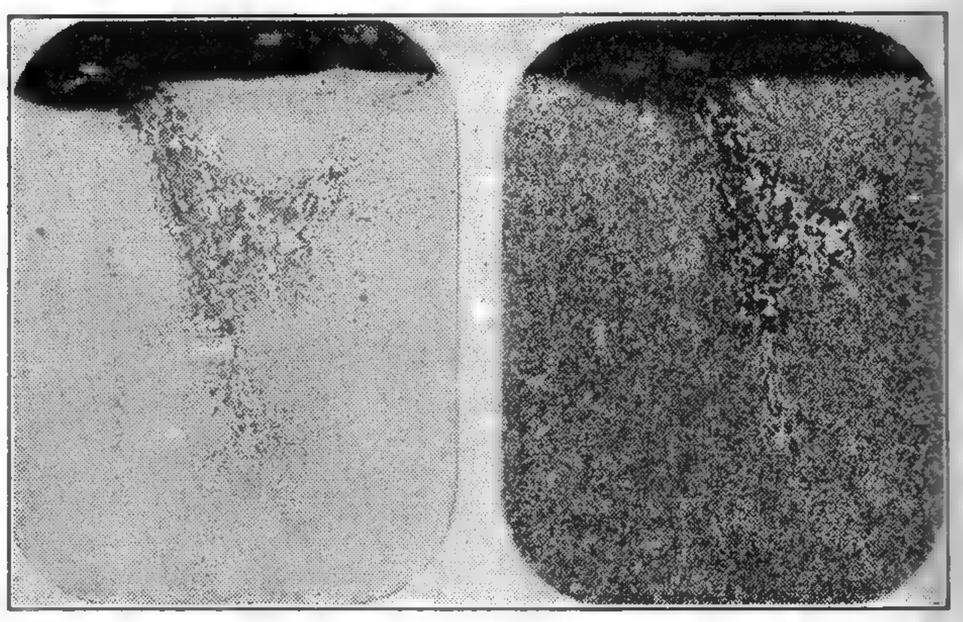

Fig. 11 Micrographs showing the nature of a forging lap in an aircraft engine part that gave a magnetic particle indication on the surface after a period of operation. The indication was caused by the forging lap shown, consisting of an enveloped area of forging scale. (× 100)

Another example is that of highly loaded gears that are made too low in hardness, in order to facilitate machining. The unit loading to which gear teeth are subjected determines the minimum hardness that must be obtained in order to prevent failure from wear in service. Some gears are quite satisfactory at a hardness of Rockwell C 25. On the other hand, highly loaded gears, such as automobile rear-axle ring-gears and pinions, must be file hard and not softer than Rockwell C 58; otherwise failure occurs from wear.

Hardness Too High. An example of failure resulting from too high hardness is the use of ball-bearing races or balls that have the full "as-quenched" hardness of approximately Rockwell C 65 to 68, without the application of any tempering treatment to relieve the quenching stresses.

Hardness Satisfactory but Structure Unsatisfactory. Associated with the type of failure that results when the hardness is satisfactory but the accompanying structure is not, the type of structure can be cited that is obtained in a carburized gear when the gear is allowed to cool in the box after carburizing, and is then reheated for hardening, to a temperature too low to redissolve the proeutectoid cementite. The case hardness, which, for example, may have been specified Rockwell C 58 minimum, may be satisfactory; but because of the presence of the cementite network in the case, failure may easily result from chipping caused by the weak cleavage surfaces along the cementite.

Failures from unsuitable metallurgical structure, as the result of an error made by either the engineer, the metallurgist, or the heat treater, can be traced to a wide variety of causes and deficiencies.

Case Too Thick. The majority of the failures that have occurred in carburized parts in aeronautical equipment have resulted from excessive case thickness in conjunction

with failure to mask off the thinner sections, such as webs and projections; consequently these thinner sections have been carburized all the way through and have failed under shock or impact loads in service.

Case Too Thin. Lack of case depth, encountered less often, is generally caused by a reduction in thickness of case as a result of grinding and machining operations. This lack is easily detected through the nonuniformity of case thickness in adjoining sections. Attempts to recarburize decarburized parts are not always successful. Under the carburized layer, there may be a band of soft decarburized material that is not strong enough to support the external load.

Since nitrided layers are thinner than carburized layers, the reduction in thickness as a result of grinding, may be more serious and must be watched, especially on cylindrical surfaces. Soft spots in a nitrided case have been traced to foreign materials that have adhered to the surface during the nitriding operation.

*Unfavorable Residual Stresses.** Another group of causes for failure results from the presence of unfavorable residual stresses produced either by thermal or by mechanical processing. The opportunity for setting up residual stresses of considerable magnitude exists in every type of heat treatment that is used for producing various types of metallurgical structure. The very process of heating or cooling a piece of steel is associated with temperature gradients and consequent accompanying volume-change gradients. These thermal gradients are complicated by temperature reversals and accompanying reversals in specific volume, which result in the generation of high residual stresses. The volume changes that occur at different times and at different locations in a piece of steel that is being heated or cooled, are first the result of the continuous expansion during heating and contraction during cooling, plus the retardation in expansion during heating through the transformation range and the retardation of contraction during cooling through that range.

The location of the transformation temperature range depends on the rapidity of heating or cooling. The rapidly cooling steel in the process of being quenched is damaged the most by these incidental stresses, because the gradients in temperature are high between surface and center and between light and heavy sections, and the volume change accompanying transformation at the temperature where austenite changes to martensite, occurs at a temperature where the steel is hard and lacking in plasticity. In steel that has been carburized, the volume changes that cause these stresses are further complicated by the fact that the high-carbon case changes much more in volume while passing through the transformation range than does the low-carbon steel in the core, and the temperature at which the change in volume occurs varies greatly with the content of carbon and alloying elements. It is impossible to measure residual stresses except by very tedious methods, and therefore it is necessary to perform empirical tests to determine the best combination of case depth and method of hardening, in order to leave the steel part in a condition of residual stress that will be most favorable to the requirements of the part in service.

The magnitude of the residual stress is affected by the relationship between the depth of the case and the thickness of the core, by the hardenability of the core and by the temperature used for hardening the piece. The exact method of cooling the piece during hardening at temperatures below 400 F, has a profound influence on the magnitude of the residual stresses.

When tests are performed on hardened carburized articles to determine the best heat treatment for producing the optimum properties, the results from the tests sometimes reflect the magnitude of residual stresses more than the strength of the heat treated structure. Ordinarily the residual stresses in the carburized and hardened surface layer are favorable in that they are usually opposite in direction to the applied stresses. Because the volume increase that occurs when the case hardens is greater than the volume increase that occurs in the core, the carburized case is in a state of compressive stress. This condition makes it possible for the part to sustain a higher external load—which normally tends to create tensile stresses—than if compressive stresses were not present.

The compressive stresses generated in the case are opposed by equivalent tensile stresses in the core. If the cross section of the core is insufficient to support the compressive stresses in the case, then failure occurs in the core—in some instances by transverse cracking through the core; in others, by cracking between the case and the core, causing a separation at the bottom of the case. Figure 12 illustrates the latter of these types of failure in the core of a carburized roller-bearing race. It can be realized readily that with slightly different conditions from those that were responsible for the cracks shown in this figure, the stresses resulting from hardening might have been not quite high enough to cause failure. However, the residual stresses would have been very high without actually showing evidence of their presence, such as the cracks shown in Fig. 12. When an article in this condition is placed in service, it is ready to fail at the first external load that is applied. Situations of this kind are probably more responsible for early failure than are unsatisfactory metallurgical structures. An acid treatment will sometimes reveal the presence of such high residual tensile stresses.

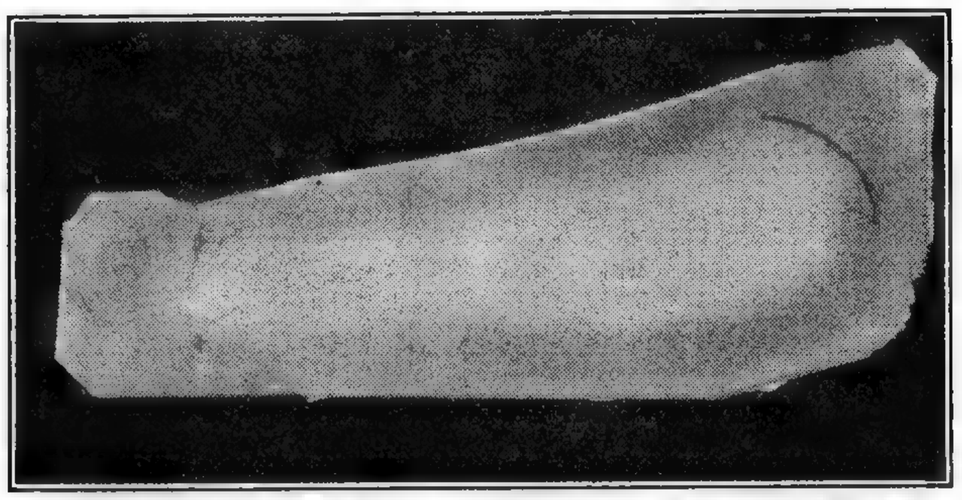

Fig. 12 Cross-sectional view of a roller-bearing race, showing separation of the case and core, resulting from excessive compressive stresses in the case and tensile stresses in the core. (× 5)

Carburizing steel of too high carbon content frequently results in tensile stresses in the case, instead of the customary compressive stresses. Whether the transformation of austenite takes place first in the case or in the core determines whether tensile or compressive stresses will be set up in the case. A high-carbon core will transform later than the case, because the core cools more slowly than the case. If the carbon content of the core is low enough, its martensite temperature will be high enough so that the core will transform before the case, in spite of the fact that the core cools more slowly. Figure 13 illustrates cracks in carburized gear teeth as a result of excessive core hardness.

Figure 14 shows an example of failure caused by residual stresses that resulted from the incorrect heat treatment of a carburized pinion.

Decarburized Surfaces. Various investigators have presented data showing the detrimental influence of a decarburized surface on resistance to fatigue. The decrease in carbon content of the surface layers is not always entirely responsible for the large losses of fatigue strength, since this decarburized surface is often accompanied by other deleterious surface conditions of a mechanical nature.

Hankins and Ford[10] and Burns[11] have made important contributions, and seem to be the only investigators who have shown the injurious influence of a decarburized skin both alone and in the absence of other damaging surface conditions. These investigators machined and polished steel specimens before heat treatment, and determined values for the endurance limit of a decarburized skin without surface irregularities. Another set of specimens was similarly machined and polished after heat treatment, in order to remove the low-carbon skin. The results indicated that depletion of surface carbon in itself, without surface irregularities, is a serious factor in giving considerably reduced values of resistance to fatigue for silicon-manganese and chromium-vanadium spring steels. Comparable data for other steels are not available.

* See also the article "Relief of Residual Stress", page 237.

Many other investigators who have contributed to this subject introduce in their findings the effects of both a decarburized skin and surface irregularities that constitute mechanical notches. The notch conditions are sometimes minimized, depending on the operations used in processing. In many instances, the combination of these surface conditions is the situation encountered in service.

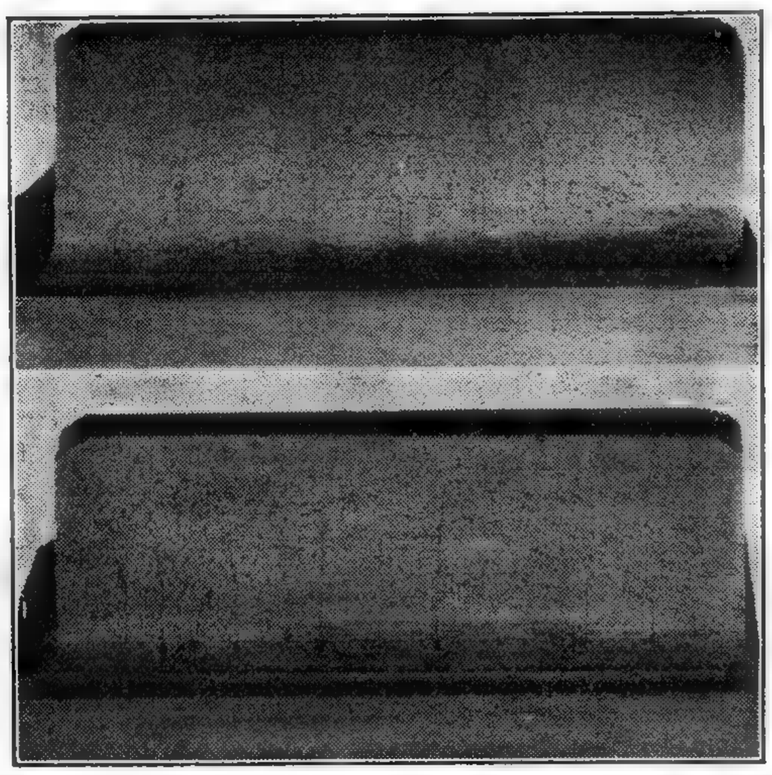

Fig. 13 Gear teeth showing cracks that result from high residual tensile stresses in the carburized gear teeth. Gears made of 2520 steel had excessive core hardness of Rockwell C 44 to 46, and case hardness of Rockwell C 58 to 62. The high hardness of the core indicates that the volume of the core has increased sufficiently to cause tensile stresses instead of the compressive stresses usual in a carburized case. (× 2)

Early systematic tests by Gill and Goodacre[12] gave a good basis for the manner in which a decarburized layer obscures the effect of carbon content on the fatigue resistance of patented drawn wire, 0.080 in. in diam. Their results indicated that the fatigue strength in reversed bending was virtually independent of the carbon content when a decarburized surface layer was present; the fatigue resistance of the wire was apparently determined by the fatigue strength of the material of lower carbon content in the ferrite skin. The example of the nondecarburized wire is in accordance with the usual relationship between carbon content and fatigue resistance.

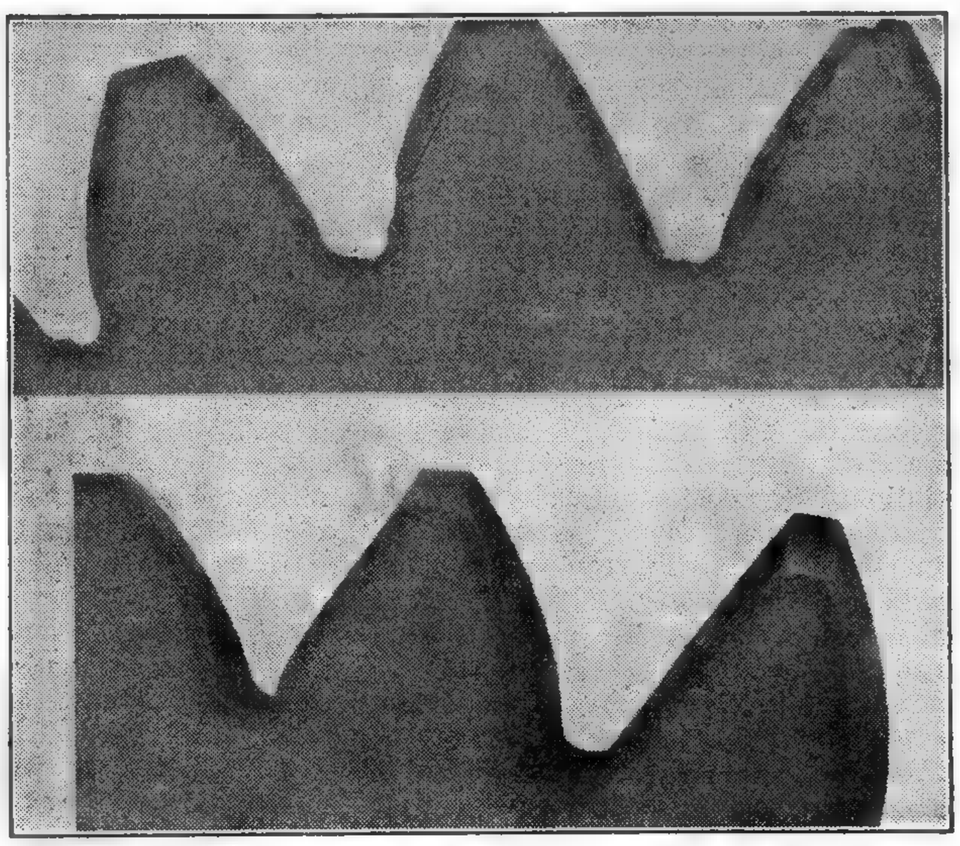

Fig. 14 Macrograph showing the cross section of two rear-axle drive pinions—the lower, in excellent condition after 30,000 miles of severe service; the upper, spalled after 3000 miles. The residual stresses in the short-life gear are the result of a double quench, using a low temperature for the second quench; thus a sharp decrease in hardness was produced between case and core, compared with a gradual decrease of hardness in the good gear, which was box quenched only. (× 2)

Hankins, Becker and Mills[13] made numerous investigations into the fatigue strength of steels for leaf springs, mild plate and forgings made from alloy steel of high tensile strength. Their findings indicate that it is highly inadvisable for forgings made of steel that has very high tensile strength, to be subjected to fatigue stresses in service when the surfaces are in the forged and heat treated condition. Spring steels with as-rolled surface subjected to plane bending (minimum stress, zero) had only about 60% of the maximum allowable stress obtained in the machined and polished state; for mild steel this ratio was about 77%. These reductions in resistance to fatigue are caused by a combination of (1) carbon depletion of the surface layers, which arises both in the manufacture and in the subsequent heat treatment of these parts, and (2) surface irregularities of shape, which occur as small pits and marks in rolling, drawing or forging operations, and as surface scale and oxide penetrations and inclusions.

Manteuffel[14] also obtained interesting torsional fatigue data for various surface conditions while investigating quenched and tempered chromium-vanadium steel spring wire, 0.492 in. in diam. In order to obtain the good results shown by recarburizing, the normally annealed spring material, having scale on the surface, was heated in a durferrite salt bath for 2 hr, then cooled, heated in the same bath to hardening temperature, quenched, and finally tempered in an air furnace. The increases in fatigue values given in this instance by recarburizing, are large compared with the relatively small increases found in similar steel and also in silicon-manganese spring steel treated in a carburizing bath of molten cyanide.[13]

McDowell[15] made rotating bending tests on killed, capped and rimmed steels. Capped steel specimens not heat treated gave an endurance limit value 18% lower than was obtained for the killed steel, with no depletion of carbon on the surface; but the rimmed steel was 25% lower.

Austin[16] made fatigue tests in rotating bending on an unalloyed steel containing 0.38% C and 1.51% Mn. Specimens that had a decarburized surface about 0.010 in. deep, gave an endurance limit of 38,000 psi compared with 47,000 psi for a nondecarburized surface, an increase of 42%.

Bollenrath and Bungardt[18] investigated aircraft wires; Eaton[19] and others[20,21,22] examined spring steels. They concluded that surface decarburization is an important factor in lowering allowable working stresses.

Figure 15 illustrates the fatigue failure of a leaf spring as a result of surface decarburization.

*Induction Hardening.** Surfaces hardened by induction offer high resistance to wear and fatigue but there are few published data concerning this resistance to fatigue. Such parts as piston rods in steam hammers often develop fatigue fracture in the tapered portion that fits into the ram; consequently this section has been induction hardened,[23] and a substantial increase in service life of piston rods has been reported by forge shops. A surface hardness of Rockwell C 50 to 55 is obtained with a core hardness of C 30 to 35.

Crankshaft journals are induction hardened in order to resist wear. Residual compressive stresses are present in the surface of the hardened portion and opposing tensile stresses are produced at the ends of the hardened portion. If hardening stops in the base of the fillet, then such initial tensile stresses have a deleterious influence on the fatigue strength of the journal radius. To overcome this damaging effect, the fillet is surface rolled.

Highly stressed gear teeth have been induction hardened along the tooth profile and root radius. Such gears have been reported[24] to run 3000 hr without failure in an accelerated fatigue test, whereas oil-quenched and tempered gears were pitted after 100 hr.

Comparative fatigue results have been reported from test specimens of three different steels treated in the furnace and by induction.[25] Also the influence of case depth on the amount of residual stress was determined for four different steels.[26] The residual stresses were shown to be compressive, ranging upward to ■ maximum of 100,000 psi before tempering. After being tempered at 390 F, a 0.45% C plain carbon steel had the residual stress decreased by 50%

* For information concerning the process of induction hardening, the reader may refer to the article on page 280.

but stress in an alloy steel (0.12% C, 1.3% Cr, 4.45% Ni, 0.85% W) was reduced only 25%. These initial compressive stresses have been associated with increased fatigue resistance;[27] the same investigators have stated that the complete elimination of ferrite in the hardened layer is probably desirable for applications involving fatigue, since cracks will form in this weak constituent at a much lower stress than in the surrounding martensite. It has also been concluded that tempering, after hardening by induction, is not advisable for parts in which maximum resistance to wear or fatigue is desired. It has been asserted that for applications where fatigue properties are important, it may be necessary to limit the higher heating temperature in order to obtain optimum residual compressive stresses in the case layer. Martin and Wiley[27] do not suggest that the fatigue strength would not increase after reaching an optimum magnitude and distribution of residual stress; however, this may occur. Apparently very high residual stresses result from induction hardening, and it seems questionable, until factual information is available, that tempering at a low temperature would have any beneficial influence on the resistance to fatigue.

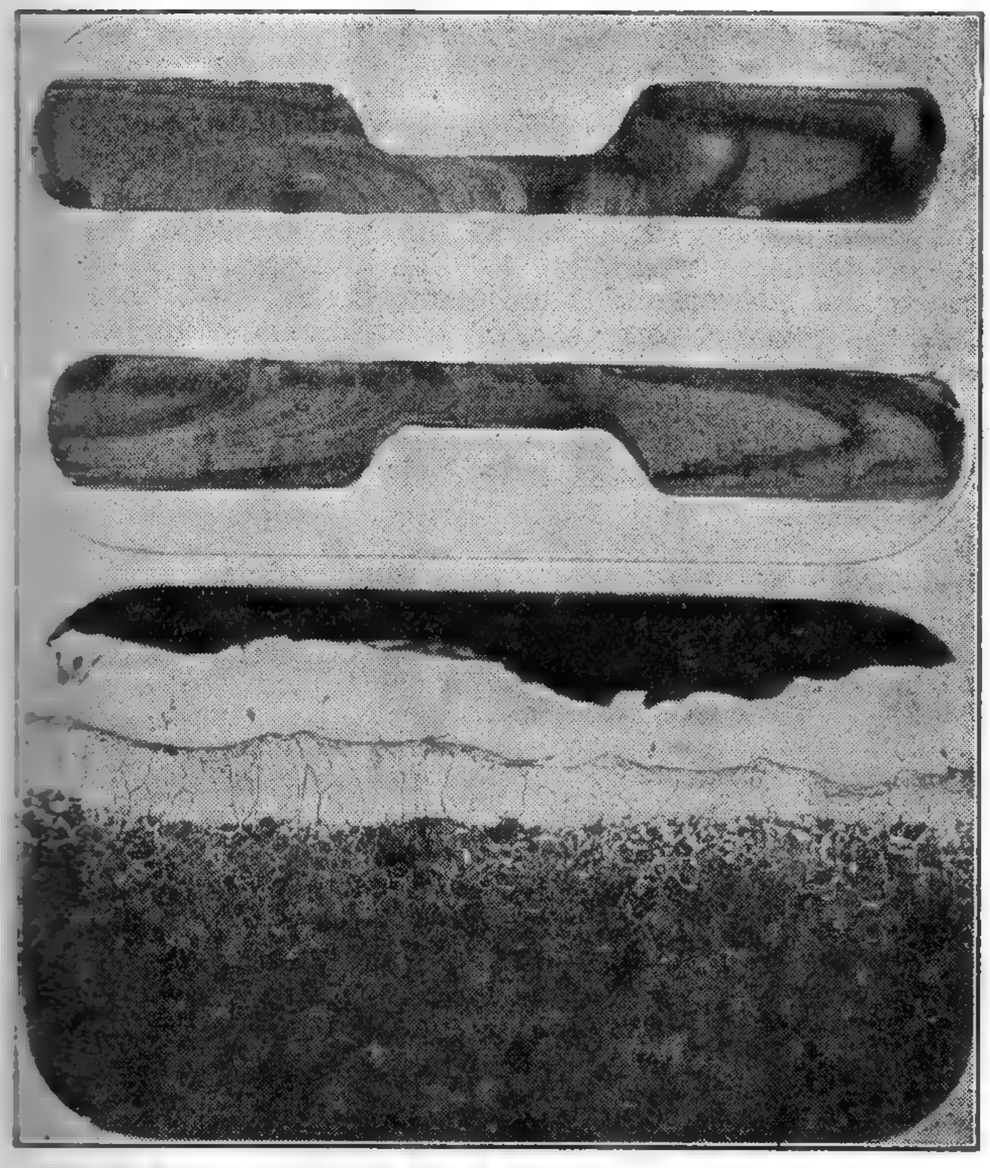

Fig. 15 Fatigue failure of a leaf spring, shown in the above macrograph, is attributed to complete decarburization at the surface, as shown in the above micrograph. (*Upper*, × 1½; *lower*, × 100)

For a further discussion of induction hardening and the resultant distribution of stresses, the reader is referred to J. O. Almen's article, Induction Hardening Problems, in Metal Progress, Dec 1944.

Welding. Welding involves the rapid application of heat near or above the melting point of the metals to be joined. This heating causes localized expansion and subsequent contraction of the metal during cooling, and also causes changes in metallographic structure and mechanical properties as a result of thermal effects. Service failures in welds are caused primarily by the presence of cracks and by lack of fusion. Other flaws in welded joints, such as blowholes, fisheyes and foreign impurities, may occasionally contribute to failure. Cracks caused by expansion and shrinkage can generally be eliminated by proper jigging, preheating, speed of welding and sequence of welding operations. Cracks look very much alike and it is often difficult to determine the cause positively. If the surfaces of a crack are decarburized, it can be assumed that the cracking took place while the parts were at high temperature. Laboratory investigation has established the fact that chemical composition and microstructure affect the tendency to crack. The cause of weld failures is often difficult to determine without a complete history of the materials and processes used in fabricating the weld.

Mechanical Processing. *Shot Peening.* Most equipment is subjected to dynamic loading or repeated stressing of the design members, and for such service the process of shot peening has contributed much toward improving resistance to fatigue. In fact, merely adding the operation of shot peening to the production of machinery and ordnance parts has often effected the difference between failure and successful performance in service.

Fatigue failure generally starts at the surface, where the stress is often greatest and boundary conditions are unfavorable. Therefore, it is only natural that consideration should be given to means of preparing and improving this surface layer. Increasing recognition is being given to shot peening or other methods of cold working, as a surface treatment that not only increases resistance to fatigue but also, in some instances, simultaneously eliminates the necessity for polishing and even machining the surface after heat treatment, and yet serves as a means of cleaning or descaling.

A shot peening operation is applied on production parts either by mechanical means or by compressed air so as to obtain considerable velocity of the shot against the work piece. The technique is discussed in detail elsewhere;[36] properties of different types of cast-iron shot have been investigated by Harder and Gow.[37] A bibliography concerning shot peening has been published that includes material released in 1945.[38]

The American spring industry was the first to make practical use of shot peening. Zimmerli,[39] apparently the first to publish technical papers on shot-peened valve springs, stated that in 1929 the company with which he was associated sent out the first production springs, in this country, that had been shot blasted to increase fatigue strength.

Steele[40] also used shot blasting on production springs. Gagnon[41] has stated that since 1935 such important automobile parts as axle shafts, connecting rods, steering arms, center arms and support arms have been shot blasted, with the result that fatigue failures in these parts are almost a thing of the past. Clutch-spring disks for Chevrolet[42] would not work until they were shot blasted. During World War II, Almen devoted much effort to the development and application of shot peening for machine elements.[43]

The engineer often finds it more desirable to prevent fatigue fractures by increasing the dimensions than by employing seemingly new methods of compressing the vulnerable surface layers. In springs, however, increasing the dimensions would certainly be an unsatisfactory method; the spring would become more rigid, thereby impairing its characteristics as a spring. This limitation of design encouraged the development of shot peening as a surface treatment and hastened its wide acceptance by the spring industry. An engineering expression of the value of shot peening coil springs of pretempered wire is shown by the modified Goodman diagram in Fig. 16. Here the permissible range of stress from minimum to maximum is given for peened and nonpeened springs, made of plain carbon or chromium-vanadium steel of valve-spring quality and having a wire diameter not exceeding 0.207 in. The designer would interpret Fig. 16, for example, to mean that the allowable maximum stress on a peened coil spring could be increased beyond that for a nonpeened spring, by the amounts shown in Table I.

Results by Lüpfert[44] in Fig. 17 indicate that the torsional fatigue resistance of spring wire may be increased by shot peening, even though surface defects are present on the wire. In condition (*a*) of Fig. 17, the fatigue resistance of wire that has no defects is increased 40% by peening. The wire in (*b*) had certain surface defects such as decarburization, flat or shallow scars, and ridges, yet peening gave an increase in fatigue strength of about 130%. In (*c*), wire with surface laps was improved 66% by peening, although the shot could not even penetrate to the bottom of the surface laps.

Micrographs contained in reference 45 illustrate the structure of the unmachined surface layer on both peened and nonpeened AISI 8650 forged steel automotive rear axles, 1⅜ in. in diam, which were quenched and tempered to a core hardness of Rockwell C 41 to 46. Structural changes approximately 0.001 in. deep were evident after peening, and micrographs indicate grain distortion, flattening, and sealing of the grain boundaries on the immediate surface that contains the ferrite layer. In this instance, the rotating bending endurance limit of the unpeened axles was approximately tripled by the shot peening of the forged and heat treated but unmachined surface.[45]

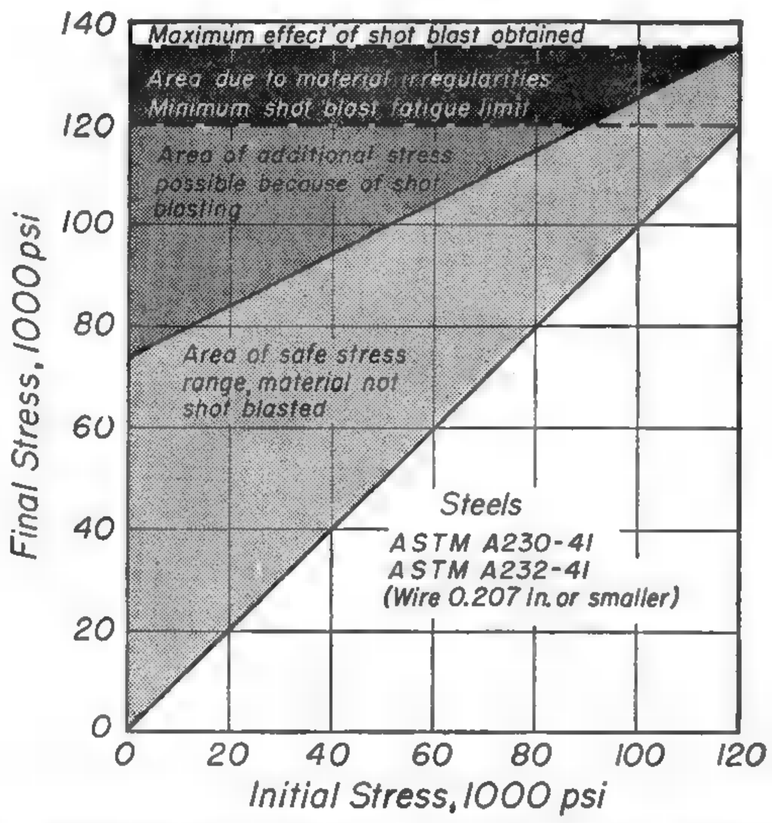

Fig. 16 Modified Goodman diagram showing that greater stresses are allowable on shot-peened springs of pretempered wire (Gibson Co.)

Shot peening greatly improves the fatigue resistance of steels that have been case carburized or quenched and tempered to high values of surface hardness. This increased resistance is important in intricately shaped parts that would be difficult to machine or grind after heat treating. Valentine[46] improved the resistance to impact fatigue in gun hammers. Improvement in other ordnance parts was reported by Frye[47] and by Lüpfert[44] on high-strength wires.

Additional literature[48] may be found on this subject, published since the bibliography[38] was compiled.

Table I. Increase of Allowable Maximum Stress on Nonpeened and Peened Coil Springs

Minimum Stress on Peened or Nonpeened Spring, psi	Maximum Stress Allowable, if Not Peened, psi	Lower Range of Maximum Stress Allowable, if Peened, psi	Minimum Increase in Stress Permitted by Peening, per cent
0	74,000	120,000	62
25,000	90,000	120,000	33
50,000	100,000	120,000	20
70,000	110,000	120,000	9
90,000	120,000	120,000	0

Prestressing. Prestressing, in its broad meaning, implies the stressing of a part beyond its yield strength.[56] For parts loaded in one direction, prestressing is a means of increasing the resistance to fatigue or reducing the danger that the part will take a permanent set later in service. The preload is applied in the same direction as that which occurs in service, so as to produce favorable residual compressive stresses and to increase the yield strength on the surface of the part. Prestressing could include surface rolling and pressing, shot peening and residual stresses obtained through heat treatment, but these phases are discussed under separate headings in this article. Special applications of prestressing will be discussed here.

The most common example of prestressing is the presetting or scragging of springs.[57,58] Although this treatment has been used for generations, the value of it has not been understood until recently.

Prestressing has been accomplished in guns[60] by shrinking several tubular members over one another; by wrapping wire under tension on a central tube; or, after World War I, by autofrettage. In autofrettage, a single cylinder is subjected to high hydraulic pressure so as to enlarge the bore permanently about 6% and to enlarge the outside diameter about 1% for the average wall ratio used. In this way, the elastic strength of a cylinder can be nearly doubled through the combined effect of the increased elastic limit and the residual compressive stress near the bore.

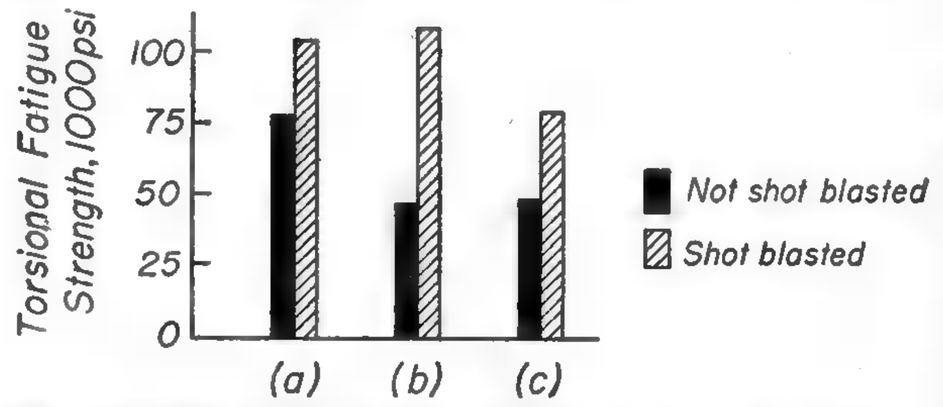

Fig. 17 Increase in fatigue strength of helical springs by shot blasting oil-quenched and tempered steel wire, 0.118 in. in diam with tensile strength 205,000 to 235,000 psi (*a*) without surface defects, (*b*) with small surface defects and (*c*) with surface laps (Lüpfert)

Fatigue failures often develop from holes or eyelets, as a result of sheared edges and poor surface conditions on the side walls of the hole. Stamping the edge of the hole and enlarging it with a conical pin,[61] as shown in Fig. 18, improved fatigue resistance 44%, as indicated in Table II. Almen and co-workers[62] have demonstrated that improvement in resistance to fatigue, in the presence of holes, may result from other types of cold working.

Table II. Results of Reversed Bending Fatigue Tests on Plates with Holes[a]

Condition	Endurance Limit Values, 2 × 10⁶ cycles: Conical Stamp psi	Conical Stamp %	Conical Pin psi	Conical Pin %
No stamping	34,100	100	34,100	100
Stamped, P = 1100 lb....	42,700	120	....	...
Stamped, P = 2200 lb....	45,500	133	49,100	144
Stamped, P = 3300 lb....	45,500	133	....	...

Cr-Mn-V steel annealed; 0.26% C, 1.1% Mn, 0.85% Cr, 0.13% V; yield strength 88,200 psi; tensile strength 106,700 psi; elongation 12%.

(a) See Fig. 20 (Burnheim[61])

A conventional tool for expanding boiler tubes was used to prestress the bores of connecting links,[63] as shown in Fig. 19. Resistance to fatigue around the bore hole was increased 25% max, by enlarging the bore 2.5% (Fig. 20). Other methods have been employed to cold work the bore ends of connecting rods[62] for internal-combustion engines.

Centers of cast steel driving wheels for steam locomotives are prestressed in the axle bore before pressing the wheel on the axle. This operation consists of pressing an oversize tapered plug through the bore[64] so as to deform the surface layers plastically. In this manner, the holding ability of press-fitted members is increased and they may be pressed on and off a number of times without losing their fit. Compressor and turbine rotors are also improved by overspeeding them as a means of obtaining centrifugal stresses higher than the yield point.[65]

Screw Threads. The screw-thread connection is one of the most important and most used machine elements, but often too little consideration is given to the way in which available methods of design and application can be utilized for obtaining great improvement in resistance to fatigue.[66] Ordinarily, threaded parts that fail do so in the first few supporting threads in the nut. This is explained as resulting from the fact that the first few threads transmit most of the force through the nut and the remaining threads carry a decreasing percentage of the load. The flow of force from the bolt through the nut must make a 180-deg turn (Fig. 21) resulting in a concentration of force on the first few threads. It is this concentration of force, combined with the notch effect of the thread shape itself, that results in low resistance to fatigue.

Many fatigue tests have been made on bolt threads alone, without a threaded connection. Such investigations[67] have shown how improved resistance to fatigue could be obtained by employing large root radii and certain thread forms. Values obtained in this manner are too high for purposes of design (Fig. 21). It is necessary to test the entire threaded assembly so that the flow of force through the threaded parts is comparable with the force to be expected in service. Tests have been made by Staedel[68] and others[69] concerning the influence of root radius, length of free thread under the nut, and general recommendations for the design of bolts.

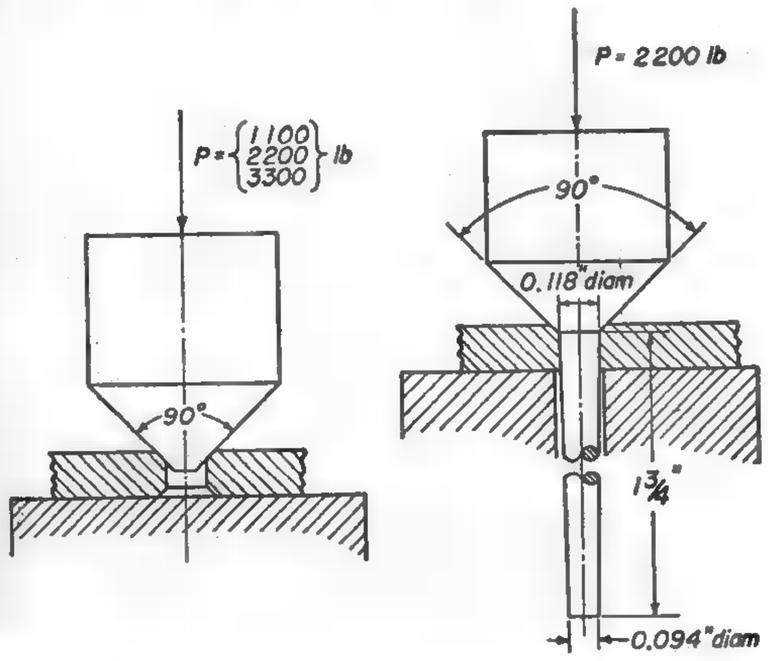

Fig. 18 Method of prestressing holes to improve fatigue resistance. *Left,* conical stamp; *right,* conical pin (Burnheim[61])

Other major factors influencing the fatigue resistance of threaded connections are (1) the material in the bolt, (2) the material and design of the nut,[69] (3) the flexibility of the bolt, (4) the tightening force or preload[71,72] and (5) the method of manufacture.[73] The effects of these and other elements have been referred to by Arnold[66] and considerable data useful in designing have been published by Martinaglia.[74] Manufacturing processes[75] have a decided bearing on fatigue strength, as shown by the superiority of the rolled thread in Fig. 21; the aircraft industry makes extensive use of rolled threads that can be produced so as to have thread tolerances in class 3 or better. Where the bolts are too large to form the threads by rolling, the threads may be cut and the root radii rolled.[69,76,77] Threaded connections of light metals are discussed by Lippert[78] and others.[79]

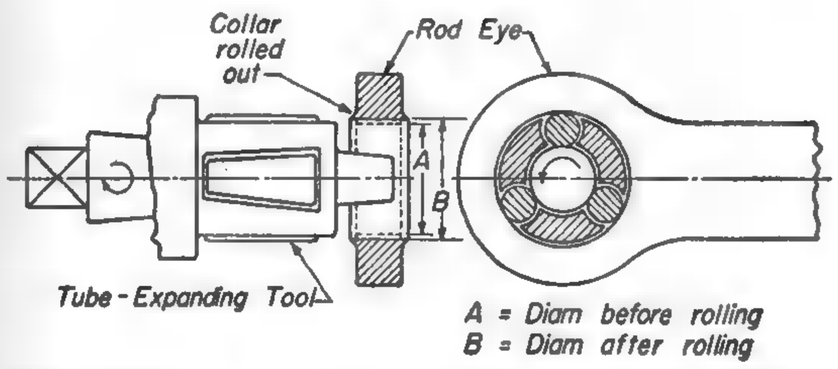

Fig. 19 Method of rolling rod-eye bore to improve fatigue resistance (Thum and Bruder[63])

Surface Rolling or Pressing. Surface rolling is very similar to the conventional burnishing operation used in shops for many years, in order to obtain a smooth surface as a means of decreasing bearing wear and friction. In surface rolling, however, the size and shape of the roller as well as the feed and pressure are controlled to obtain a definite plastic deformation of the surface layers for an appreciable depth. Such a cold worked layer has proved invaluable in decreasing the danger of failure of machine parts.[80] This general idea of cold working the surface layers by rolling, pressing or shot peening was developed by Föppl,[81] and reasons for the improved fatigue strength have been compiled from various sources.[80]

The method of rolling the fillet of a 5¼-in. shaft is shown in Fig. 22. By this means, the endurance limit in rotating bending was increased 30%. A hardness penetration of about ½ in. was obtained. Other investigators[82] have reported that fatigue resistance is increased by as much as 68%. Some automobile companies fillet roll the journals on crankshafts as standard practice.

A three-roller device has been used for rolling large shafts in the region where a press-fitted gear, pulley or wheel is applied. The endurance limit of shafts against breaking off in the fitted part is at least doubled by surface rolling. A hardness penetration of about ⅞ in. can be obtained with only 0.001 to 0.003-in. reduction in diameter of parts 9½ in. in diam; the depth of penetration depends on the surface roughness before rolling. Some railroads have adopted rolling as standard practice for fitted assemblies.

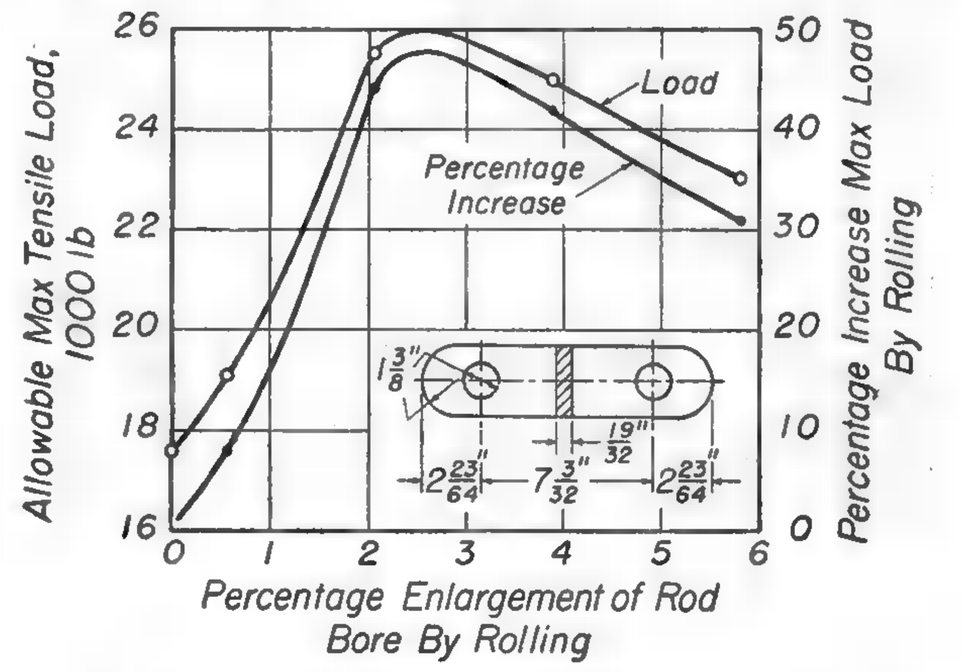

Fig. 20 Increasing load capacity of link rod by rolling bore

Shafts often fail through oil holes and Fig. 23 exhibits a method used for stamping notches on each side of the oil hole to improve resistance to fatigue. The use of 100,000-lb stamp pressure resulted in about one-third greater fatigue strength for 7¼-in. shafts than was obtained without the notches. This method of improvement was previously investigated by Thum and Bautz[83] on ¾-in. shafts that had $\frac{3}{16}$-in. oil holes, and an increase of as much as 88% was obtained. Design of stamp, pressure and kind of shaft material are important factors in obtaining maximum resistance to fatigue.

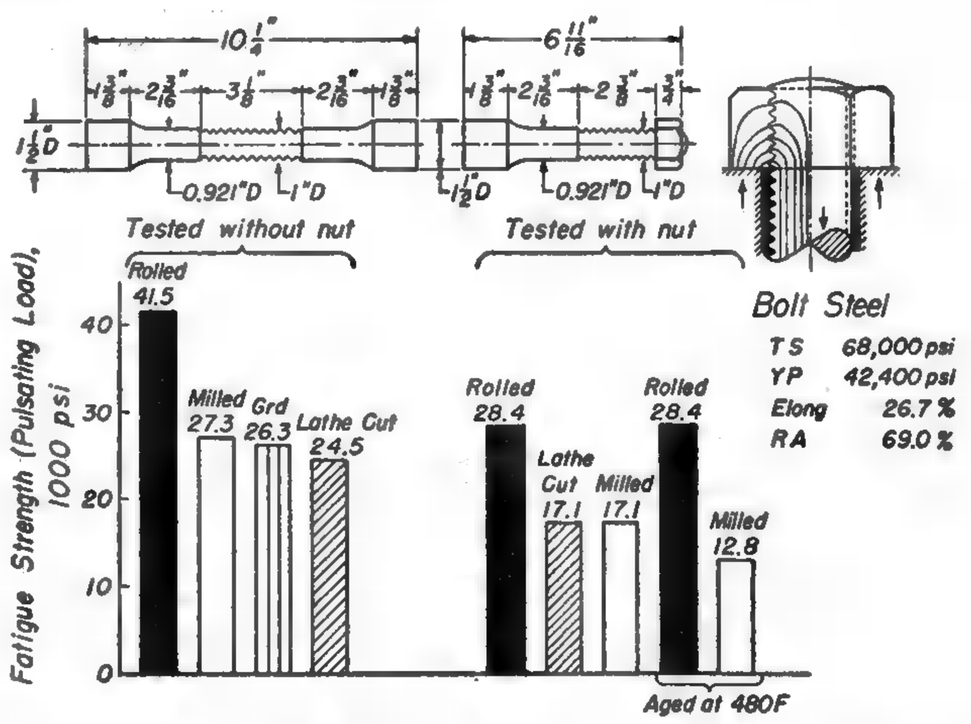

Fig. 21 Fatigue strength of 1-in. bolts having threads cut, ground, milled and rolled (Dinner and Felix)

The bore surface of railroad tires and the root radius of cut screw threads have been rolled. Other applications, discussed by Almen[84] and co-workers, present some novel designs of rolling equipment.

Straightening. Straightening operations are regular shop practice in producing certain manufactured parts. It has been found that the fatigue resistance of a part is often

influenced unfavorably by straightening. Schmidt[85] found that crankshafts for airplane engines developed distortion during processing and required a small amount of straightening when they were machine finished. When cold straightened, these crankshafts showed an endurance limit 20% lower in reversed bending than the limit for crankshafts that had not been straightened. The effect was even greater above the endurance limit, where the allowable stress was decreased by 33% for a life of 50,000 cycles and by 27% for 150,000 cycles.

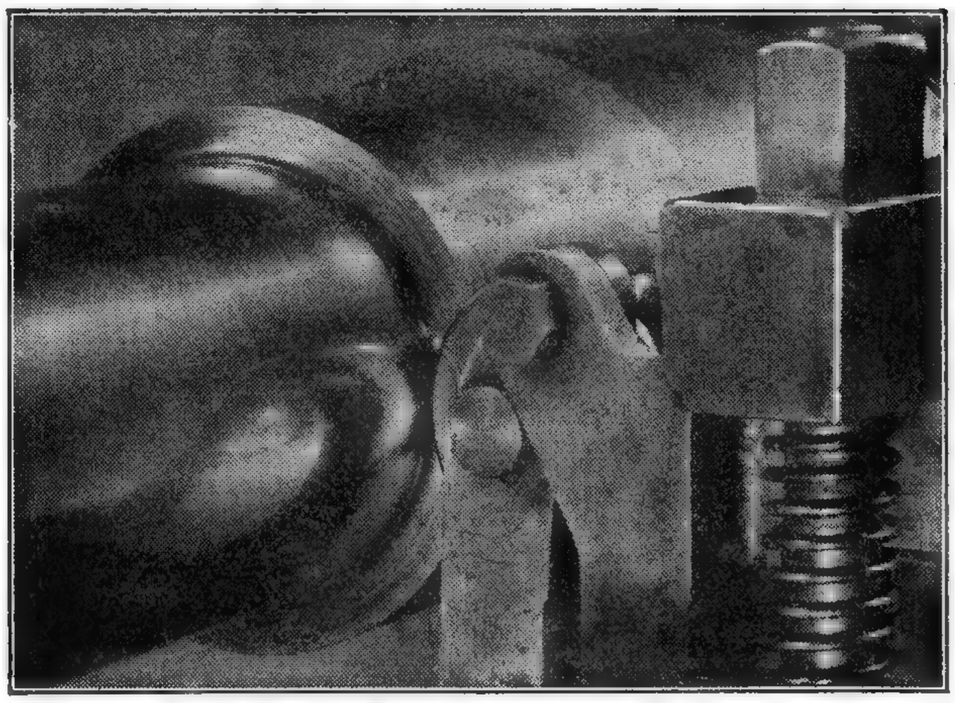

Fig. 22 Method of rolling axle fillet

Also, Horger and Lipson[86] found that the endurance limit in rotating bending of full-size automobile rear axles was 13,000 to 16,000 psi when the shafts were straightened in production. Similar unstraightened axles had an endurance limit of 20,000 psi, or at least 25% greater resistance to fatigue than the straightened shafts. The detrimental effect of straightening was overcome by shot peening after straightening.

In the above examples, the reduced resistance to fatigue found after cold straightening, was attributed to unfavorable residual tensile stresses established on one side of the crankshafts or axles.

Grinding. Residual surface stresses from grinding may be the cause of service failures (*See* Fig. 24 and 25).

Influence of Service Environment

A third general cause contributing to failure of metal parts is exposure to processes and environment, such as (1) corrosion, (2) galvanic corrosion, (3) corrosion fatigue, (4) fretting corrosion and (5) stress corrosion. Mechanical defects arising from the service environment may also cause failure. Limited space restricts the present discussion of a subject about which many volumes have been written.

Corrosion. The types of corrosive attack most commonly encountered may be limited to three: uniform thinning, pitting attack, and grain boundary attack. These are discussed in the various articles on corrosion.

Galvanic Corrosion. When two dissimilar metals are brought into electrical contact in an electrolyte, corrosion of the less noble metal (anode) occurs in excess of its normal rate in that electrolyte, while the more noble metal (cathode) is protected. This accelerated corrosion is known as galvanic corrosion. The amount of additional corrosion of the anode is proportional to the current flowing in the electrolytic cell, and the amount of current flowing is determined in turn by the emf of the cell, by the relative areas of the anode and cathode surfaces, by the conductivity of the solution, and by the rate of polarization of the electrodes. Galvanic corrosion is usually characterized by severe local corrosion at the point of contact of the dissimilar metals, if that contact takes place in the electrolyte. Galvanic corrosion is also frequently found at points, other than the contact point, where proximity of the dissimilar metal parts, relative anode and cathode areas, cell emf, and solution conductivity are properly adjusted.

Such solutions as rain water, sea water, battery acid, and some organic liquids may cause galvanic corrosion. In some instances, large quantities of salts such as hydroxides and sulfates are formed, which weaken the part through detrition and the building up of stresses, especially in faying surfaces. Corrosion of this type can be detected by visual examination.

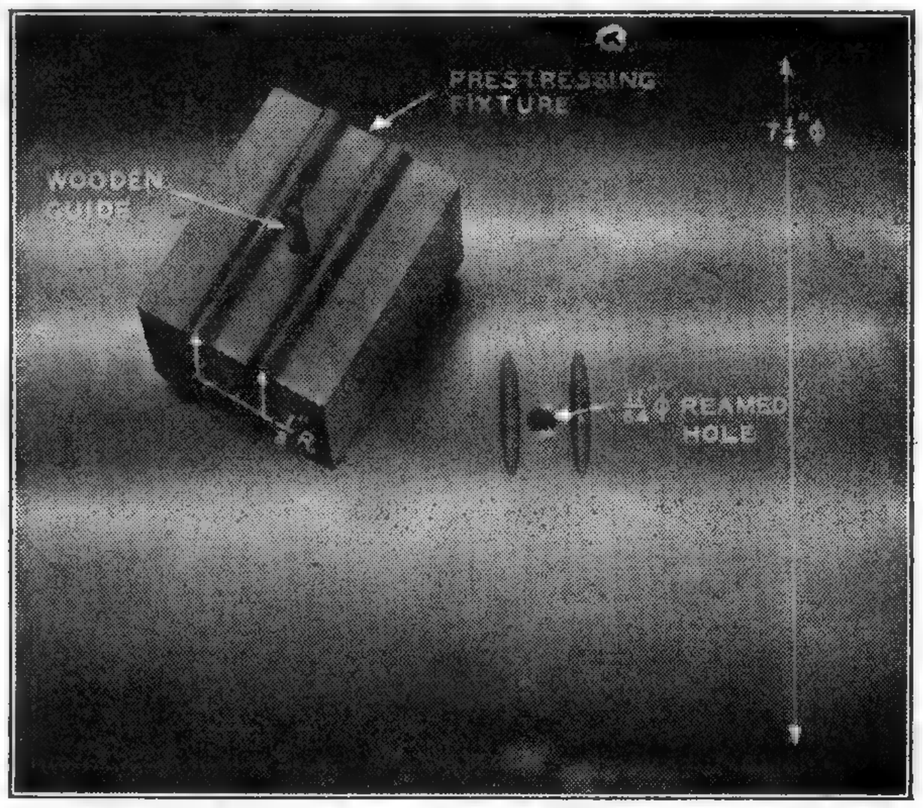

Fig. 23 Method of prestressing notches around transverse oil hole. Crankpin having transverse oil holes in bearing seat with 7.280-in. diam. Stamp used in prestressing oil holes and impression produced. Wooden plug protruding from stamp is used to locate stamp over hole. Pin No. A7-3; Type 5 oil-hole design

Corrosion Fatigue. Corrosion-fatigue failure in metals results from a wide variety of service conditions, ranging from those that are predominantly corrosive in character with minor effect from stresses, through the graduated conditions, to those in which corrosion is only a minor contributing factor and the destruction of the metal results almost entirely from mechanical stresses. Fretting

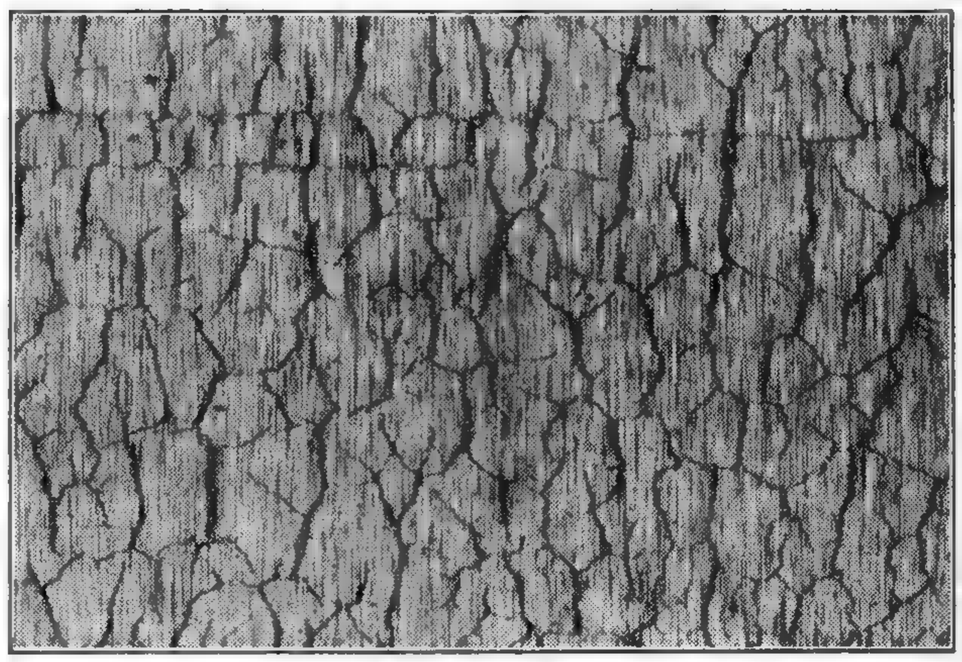

Fig. 24 Surface cracking caused by faulty grinding on a carburized and hardened 1020 steel guidepin. This type of surface on a part subjected to high stress will lead to early failure. (× 11)

corrosion, discussed below, is considered by many to be a special type of corrosion fatigue. The characteristic that identifies corrosion fatigue is the accelerating effect of a corrosive condition in promoting early failure of a member subjected to alternating stresses. Characteristically, the fractures are transcrystalline, the same as fatigue fractures in the absence of a corroding medium.

Fretting Corrosion. When two parts are clamped, press fitted or shrunk together and subjected to vibratory stresses, fretting corrosion may occur. In steel, this corrosion consists of the formation of red oxide[95] between the fitted surfaces, and particularly near the ends of the fit. Fretting corrosion is also known as "friction oxidation" or

"rubbing corrosion". Fretting is one of the most severe forms of weakening action on fatigue strength. A typical fatigue fracture resulting from this condition, is illustrated in Fig. 26. The endurance limit of a shaft to prevent breaking off in the fitted member is only about one-third to one-half of that for the shaft without a press fit.[96,97] Even though the shaft does not break off, because it is subjected to stresses lower than the endurance limit, fatigue cracks are often found when the assembly is pressed apart.[97]

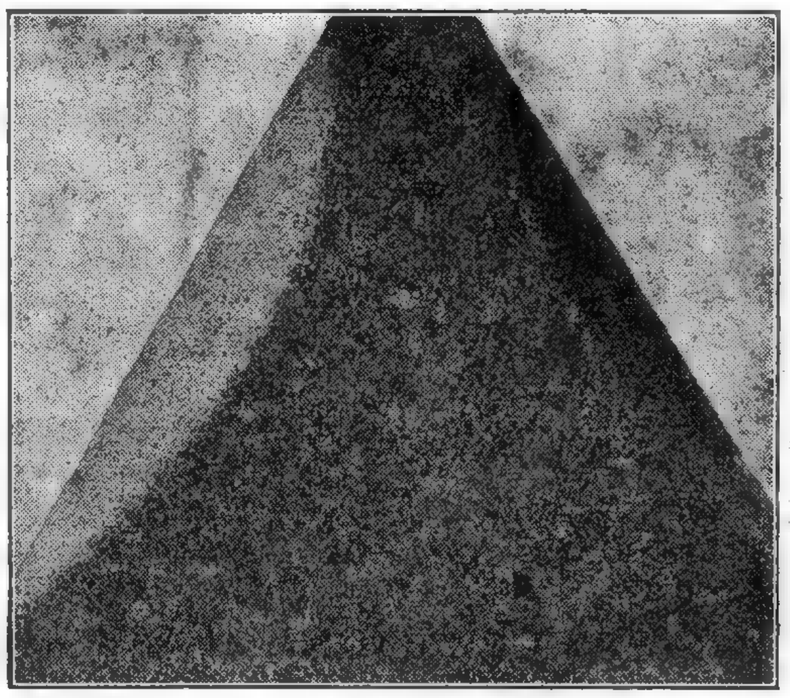

Fig. 25 Grinding of threads on bolts and screws is sometimes the cause of failure from residual stresses. The micrograph above shows hardening caused on the side of a thread by overheating in grinding. This hardening by heating in grinding leaves the thread in a highly stressed condition, which, coupled with service stresses, may cause failure. (× 100)

Fretting corrosion may occur when antifriction bearings are subjected to vibratory oscillating loads of small amplitude. Failures may be found in unused parts after shipment, and in used parts subject to the above conditions of loading. The failure is indicated by a "false brinelling" of the part and is generally accompanied by visible deposits of red oxide of iron.

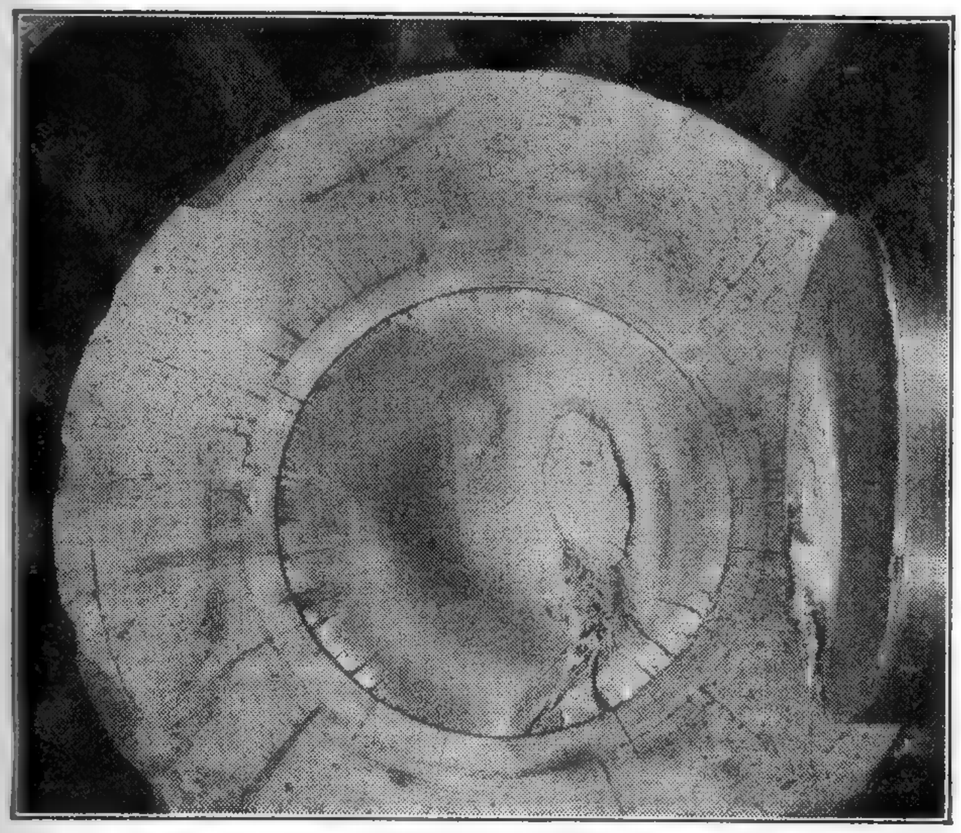

Fig. 26 Typical fatigue fracture of shaft, occurring at one end of a fitted part

Usually fatigue resistance in the presence of fretting corrosion can be greatly improved by the following methods: the shaping of the parts as shown in Fig. 27; residual compressive stresses obtained in the surface of the shaft by surface rolling;[96,97] the proper type of quench and temper;[98] induction or flame hardening;[98,99] nitriding or case carburizing; or a sprayed-metal layer of proper material.[99]

Stress-Corrosion Cracking. This type of failure in metals differs essentially from corrosion fatigue. The principles of stress corrosion are discussed in the article on page 227, and data are given there concerning the stress-corrosion cracking of common ferrous and nonferrous alloys. For information on stress relief, see the article on page 237.

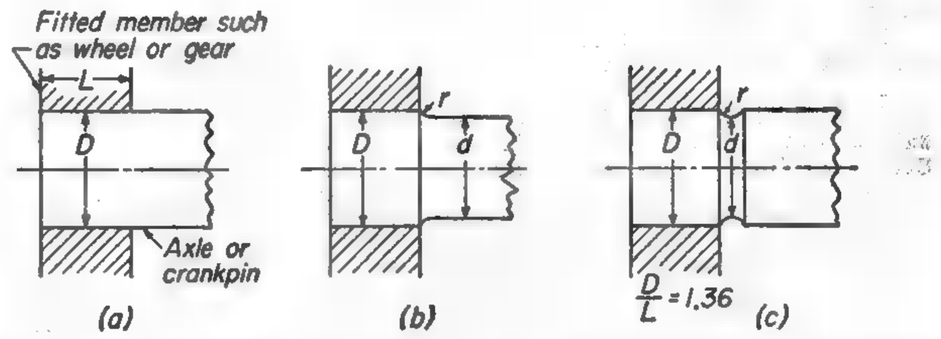

Fig. 27 Correct shaping of fitted parts. (*a*) Conventional method; bending fatigue resistance, 100%. (*b*) and (*c*) Improved methods; bending fatigue resistance, about 130%. Fillet and groove *r* to be surface rolled except when *r* in (*b*) can be large (about 0.4 *D*). If the portion of the shaft in (*a*), (*b*) and (*c*) over which outer part is fitted is surface rolled, then fatigue resistance is more than 200%. (The above data are based on breaking-off strength of full-size fatigue tests in rotating bending of shafts 7 to 9½ in. in diam and made of 0.50% C steel normalized and tempered.)

Mechanical Factors in Service Environment. Service environment may establish such conditions that the properties of the material are affected or the stresses in the material exceed the allowable design values. The loosening of a threaded connection, the hardening of gaskets and shock-absorbing devices because of aging and other factors that may affect clearances, change the rates at which loads are applied, which may mean that parts will be subjected to impact or repetition of loads that they were not designed to withstand. When the examination of a fracture indicates an impact failure or a progressive failure at a few alternations of stress, it is advisable to investigate the possibility that other parts of the machine may have become loose or distorted, thus throwing an excessively high or unusual load on the part that failed.

Temperature changes that result from unusual operating conditions, may cause failure on account of reducing the strength by an annealing action or by the melting and spheroidizing of the constituents that have low melting points. Measuring the hardness may indicate the damage, but a microscopic examination is often necessary, especially for aluminum-base and magnesium-base alloys. Low atmospheric temperatures are generally above the temperatures at which the properties of most metals are affected. However, high stresses may be induced by the unequal contraction of unlike metals with different coefficients of expansion.

Mechanical defects, such as scratches, cuts and bruises on the surface, are stress raisers and will lower the resistance to failure from alternating stresses. This subject has been ably discussed in a book entitled, "Prevention of Failure of Metals Under Repeated Stress",[70] prepared by the staff of Battelle Memorial Institute.

Heat Treatment of Metals

BY R. S. ARCHER*

THE PURPOSE of this article is to present certain fundamental principles applicable to the heat treatment of all metals, ferrous or nonferrous. Another article (page 613) deals more fully with the heat treatment of iron and steel. Both of these articles, general in nature, are intended as a foundation for specific articles that describe the heat treatment of certain parts, such as gears and dies, and of particular ferrous and nonferrous alloys.

"Heat treatment" is defined as an operation or combination of operations that involves the heating and cooling of a solid metal or alloy, for the purpose of obtaining certain desirable conditions or properties. It is usually desired to preserve, as nearly as possible, the form, dimensions and surface of the piece being treated.

General Principles. The desirable changes in conditions or properties may be considered results of changes in structure. Frequently metal is heat treated in order to change residual stresses. Usually it is desired to decrease or relieve such stresses, although occasionally it is necessary to set up stresses of a definite kind.

More frequently, the changes effected by heat treatment involve changes in the nature, form, size or distribution of the structural constituents. Changes in the nature of the constituents result from the effect of temperature on phase equilibriums or from changes in the composition of material, as in carburizing or nitriding. The form of constituents is affected by the conditions under which they separate from solid solutions, and by the tendency to assume equiaxed shape at temperatures that permit diffusion and atomic rearrangement (spheroidizing). In a solid metal, changes in the arrangement or distribution of constituents can be brought about by solution and reprecipitation, as when the granular cementite of an annealed tool steel is converted to the lamellar cementite of pearlite by normalizing.

Factors in Heat Treatment. Heat treatment consists of subjecting a metal to a definite time-temperature cycle. The chemical effect of the medium surrounding the metal may be of importance, as in carburizing and in nitriding. The time-temperature cycle may be divided conveniently into three parts: (1) heating, (2) holding and (3) cooling.

Heating. The *rate* of heating determines the changes within the metal during heating. The heating medium is important since it affects this rate, and causes or prevents chemical changes, such as oxidation, that proceed from the surface of the metal. It is necessary to consider not merely the average rate of heating, but the rate of heating desirable or permissible at each stage of rise in temperature. The rate of heating is seldom constant and usually decreases as the final or holding temperature is approached, so that this temperature can be attained more accurately and uniformly.

The heat actually consumed, in the practical heating of a metal to a given temperature, is equal to the heat content of the metal at that temperature, minus the heat content of the metal at the beginning of the heat treatment operation, and plus the heat losses from radiation during the heating process. Other factors being equal, these heat losses increase with the duration of heating.

From the standpoint of the effect on the metal, the rate of heating may be important, since it influences stresses, distortion, grain growth or chemical changes such as oxidation.

If a piece of metal originally free from stresses is heated uniformly, no residual stresses will be set up. If the heating is not uniform, so that different parts of the piece acquire different temperatures at a given time, stresses will be set up that will cause distortion and, in brittle metals, may cause rupture. Uniform heating is favored by uniform application of heat, slow application of heat, and high heat conductivity of the metal itself. Particular care is required in heating brittle metals that have poor heat conductivity; for example, hardened high speed steel.

The extent of normal grain growth is determined chiefly by maximum temperature and the time at or near the maximum temperature. However, abnormal grain growth or germination may be affected by the rate of heating. Germination is likely to occur in metals that have been work hardened slightly rather than severely, or in metals in which the degree of work hardening varies considerably from one point to another. When such conditions exist, it is frequently possible to prevent or to minimize abnormal grain growth by heating the metal very rapidly to above the germinative temperature, which usually means heating rapidly to a temperature well above the temperature of recrystallization.

If other factors are equal, surface changes that result from contact with the heating medium are naturally slighter during the heating cycle, the shorter the duration of this cycle. On the other hand, rapid heating obtained by the use of a strongly oxidizing and active flame might result in more oxidation than slower heating with a more neutral flame.

Holding at Temperature. Usually a certain time period, more or less definite, is required at the maximum temperature of the heat treatment. First, the time must be sufficient to permit the entire article to come to a uniform temperature, except in comparatively rare instances where a nonuniform distribution of temperature is desired, as in the localized hardening of steel. The length of time required for attaining uniform temperature, increases with the thickness of the heaviest section of the piece and is greater the lower the thermal conductivity of the material. The rate of heating employed must also be considered, since with slow heating, a fair degree of uniformity may exist shortly after the metal has come to temperature.

The next requirement is that the time at temperature be sufficient to allow the desired changes to take place

* Climax Molybdenum Company, New York

within the metal. Most of these changes involve diffusion, and in wrought metals, grain growth. The solution of constituents such as carbides in steel depends on diffusion away from the particles of such constituents. The conversion of combined carbon to graphitic carbon in the annealing of malleable iron castings involves the diffusion of carbon from the carbide particles to the graphite nuclei. Case carburizing is accompanied by the diffusion of carbon from the surface toward the center.

Grain growth does not occur to any appreciable extent during the reheating of cast metals that have not been subjected to plastic deformation after casting, except in iron and ferrous alloys that recrystallize during heating through the transformation range. Metals that have been deformed plastically, either hot or cold, exhibit grain growth at temperatures above what is known as the temperature of recrystallization. This grain growth is responsible for the softening of work hardened metals during annealing. Grain growth is therefore not only desirable but necessary in the annealing of cold worked metals for the purpose of softening. Occasionally a very large grain size is desired, as in the treatment of certain metals for strength at high temperatures. In general, however, the development of large grains should be limited, because excessively large grain size leads to various undesirable properties. Since both diffusion and grain growth require atomic mobility, these processes usually occur within approximately the same range of temperature. In the heat treatment of steel, it is commonly desired to bring about certain structural changes that depend on diffusion, and to avoid, as far as possible, the grain growth likely to occur in the same range of temperature.

It is thus evident that the laws of grain growth and diffusion have an important part in the determination of temperature and time at temperature.

Temperatures for the recrystallization of certain metals after severe cold plastic deformation are given in Table I.

Table I. Recrystallization Temperatures*

Approximate Lowest Recrystallization Temperature, deg Fahr			
Iron	840	Magnesium	300
Nickel	1110	Tantalum	1830
Gold	390	Tungsten	2190
Silver	390 (a)	Molybdenum	1650
Copper	390	Zinc	Room temperature
Aluminum	300	Lead	Below room temperature
Platinum	840	Tin	Below room temperature
		Cadmium	About room temperature

(a) Indications are that under certain conditions silver will recrystallize at lower temperatures.

These temperatures are higher, the less the amount of cold working. Time is also a factor; recrystallization can be brought about at lower temperatures if a longer time is allowed at temperature. Impurities and alloying additions raise the temperature of recrystallization; for example, brass requires a higher temperature than copper.

Grain size normally increases with both temperature and time of exposure. At ■ given temperature, eventually an apparent equilibrium grain size is reached that does not change greatly even if the time is increased further. The time required for attaining this condition may be a few seconds at temperatures just below the melting point, or a matter of days just above the recrystallization temperature. In heat treating, the temperature is usually high enough to permit fairly rapid approach to equilibrium of grain size, so temperature rather than time is the more important factor governing grain size. In general, however, time is sufficiently important that the duration of a heat treatment is not prolonged unnecessarily beyond the period required for producing whatever other changes in structure are desired.

The rate of diffusion increases rapidly with temperature, and also depends greatly on the nature of the dissolved substance. In most instances it seems that the dissolved substance diffuses in atomic form, and rapid diffusion is perhaps opposed by large atomic volume. Carbon diffuses rapidly in iron at temperatures above A_3, while phosphorus and certain other elements diffuse very slowly, even at much higher temperatures.

The time required for bringing about a certain change that involves diffusion, depends not only on the rate of diffusion, but also on the distances through which diffusion must take place. The time required is therefore longer, the coarser the initial structure of the material.

Metals and alloys that are elastic at ordinary temperatures are left in a state of stress by all commercial cold working processes. High residual stresses can also be produced by uneven temperature changes. Rapid cooling, uneven sections, and mass, contribute to such stresses. Severe stresses are set up in steel during the hardening operation, both by uneven changes of temperature in themselves and by the changes in volume incident to hardening and aging.

The reduction of residual stress by heat treatment depends on a slight plastic flow that is allowed to take place by the lowering of the elastic limit at the temperature at which it occurs. The extent to which stresses are removed is greater, the higher the temperature and the longer the time of heating. Even after stresses have been largely removed by heating at a relatively high temperature, new stresses may be introduced during cooling.

Sometimes the objective of heat treatment is best attained at temperatures just below the melting point of the most fusible portions of the material. This is likely to occur where the effect desired depends on bringing into solution one or more constituents of which the solubility increases progressively with temperature up to the point of incipient fusion, as in the hardening of high speed steel and duralumin. Occasionally materials of this class can be heated to such a temperature that some fusion takes place and then, either with or without subsequent treatment, they may have desirable properties. As a general rule, however, it is not safe to heat treat at temperatures that cause any fusion within the alloy.

When the purpose or one of the purposes of heat treatment is to bring about certain phase changes in an alloy, there are rather definite temperature limits within which the desired change can take place. The permissible range of temperature is defined by the phase diagram of the alloy. The selection of the most desirable temperature within the permissible range is influenced by the considerations mentioned above regarding grain growth, diffusion and residual stresses, as well as by other practical considerations of distortion, scaling and economy of operation.

Above the recrystallization temperature, metals deform plastically under low stresses. Therefore, pieces undergoing heat treatment may deform under their own weight or from any means of handling that imposes even fairly low stresses on the material. Low temperature and short heating time minimize the distortion of pieces under their own weight. Special means are often employed to hold articles in shape during heat treatment. Castings may have special sections cast into them solely for this purpose; such sections are cut out after heat treatment. Fixtures may be employed in the heat treating furnace to prevent sagging at high temperature. Closed hollow articles may be supported by internal air pressure.

The cost of holding metals at a given constant temperature is determined by the heat losses of the furnace because of radiation and the like; by the burden on the heat treating equipment; and, in long heat treatments, by the cost of holding the material itself in process. Heat treatments of long duration involve interest charges on the material itself, and also certain losses or difficulties resulting from interference with precise scheduling of manufacturing operations. The energy consumed or given off as a result of changes that take place within alloys during heat treatment, is very slight in comparison with other factors that affect the cost of heat treatment.

Cooling. Pure metals or single-phase alloys formed into simple shapes, are usually heat treated primarily for the purpose of softening after cold working. In such instances the rate of cooling is likely to be quite unimportant and therefore determined largely by convenience. The rate of cooling after the annealing of copper and alpha brass, for example, has little effect on the properties of the material, although the specific manner of cooling may have consid-

* Jeffries and Archer, "The Science of Metals", McGraw-Hill Book Company, 1924, p 86

erable effect on the surface of the material. Some commercially pure metals contain enough of certain impurities to produce appreciable effects during cooling. It is now recognized, for example, that very small amounts of carbon, oxygen, nitrogen and perhaps phosphorus, may cause substantial changes in the properties of iron at temperatures below the transformation range.

When the constitution of the material being heat treated is different at the maximum temperature of heat treatment from the constitution that is stable at low temperatures, the rate of cooling is of great importance in determining the result of the heat treatment. Very slow cooling permits full development of the constitution that is stable at low temperatures. Rapid cooling may preserve in an unstable condition the structure that was produced at the high temperature, as in the quenching of austenitic steels and duralumin. Frequently, as in plain carbon steels, the most rapid cooling possible will not preserve the high-temperature structure.*

Iron-carbon alloys, when cooled from above the transformation range slowly enough to permit the full development of structural equilibrium at low temperatures, would consist either of ferrite and graphite or ferrite and spheroidized carbides. The intermediate structures obtained in the hardening, normalizing and annealing of steel, thus result from intermediate and controlled rates of cooling. Not only the average rate of cooling, but also the rate of each stage of the cooling operation is important.

Heat Application. Heat is imparted to metal objects by the usual processes of radiation and conduction. At high temperature, radiation is a very important factor in the transfer of heat. In furnaces operating below approximately 1000 F, positive circulation of the furnace atmosphere is desirable to promote rapid and uniform heating. Heat may also be developed within the metal by the passage of electric current, which is led into the metal by means of contacts, or generated by induction. Means employed in heat treating include furnaces heated by oil, gas, coke or coal; furnaces heated by electrical resistors of both metallic and nonmetallic types; liquid baths of lead, salt or oil, in which the objects to be heated are immersed; and containers into which steam is introduced.

Heating by Electrical Resistance. The heating of metals by the direct passage of electric current through the work material itself, is quite limited in practical operation for obvious reasons. If a uniform temperature is desired, the metal object must have a uniform cross section. In order to heat steel tubing for hardening, contacts may be applied at the end of each tube and current may be passed through the tube until the desired temperature is reached. The passing of the tube through the transformation range is indicated by the discontinuity in thermal expansion. Resistance heating has been used in heating bar stock for forging, in heating rivets, and in the sintering of tungsten briquettes. In certain instances where a nonuniform distribution of temperature is desired, an article of nonuniform cross section may be heated by resistance (for example, when heating ends of valve stems for hardening).

Temperature Gradients in Heating. In resistance heating, the inside of the metal is normally hotter than the outside surface. Consequently, the estimation of temperature by the color of the piece, by radiation or optical pyrometers, or by thermocouples placed outside the piece, is likely to give low results.

In other methods the heat is introduced into the metal through the surface, and as long as the temperature is rising, the surface is hotter than the interior. Allowance must be made for this difference, and in practice, it is recognized that a certain period of time, increasing with the size of the section, is required for the penetration of heat through the entire cross section of the piece. Heavy sections therefore lag in coming up to temperature.

Limitations on Rate of Heating. With resistance heating, the rate of heating is limited only by the current available. With heat externally applied, the rate of heating is limited by the thermal conductivity of the metal. If it is assumed that the surface of the object to be heated is maintained at the maximum permissible temperature (for example, by immersion of a small object in a large bath of lead), the time required for saturating the object is determined by the heat capacity at the desired temperature and by the thermal conductivity of the metal under the temperature gradients that exist.

Fuel-Heated Furnaces. Any temperature employed in the heat treatment of the common metals can be readily attained in fuel-heated furnaces of either the directly fired or the muffle type. Furnace parts, including muffles, made of heat-resisting alloys can be used at temperatures as high as 1800 to 2000 F, but may be attacked by fuels of high sulfur content. Refractories are satisfactory up to considerably higher temperatures for hearth, walls and muffles. Conveying mechanism and rails, which must be made of metals, are at present limited to furnaces operating below about 2000 F, unless these parts are artificially cooled or are placed and operated in such a way that they do not attain the full temperature.

Electric Furnaces. Electric furnaces heated by metallic resistors of the nickel-chromium or nickel-iron-chromium types, are limited in working temperature to about 1800 to 2200 F, depending on the type of work and the cost permissible for replacement of resistors. Platinum-wound furnaces may be used at temperatures as high as 2700 to 2900 F, and resistors of molybdenum or tungsten operated in hydrogen provide furnace temperatures at least as high as 3100 F, limited by the refractory rather than by the resistor. Carbon (or graphite), in solid or granular form, can be used as resistor material up to very high temperatures, but carbon is attacked by both oxygen and hydrogen. Industrial electric furnaces operating above the temperature range for resistors made of nickel-chromium alloys, at present are usually heated by synthetic resistor bars consisting largely of silicon carbide, or by alloy resistors of the iron-chromium-aluminum type.

*Furnace Atmospheres.** One of the problems in the heat treatment of steel and some other metals is concerned with oxidation or the formation of scale,[1,2] and much is said regarding so-called "neutral" atmospheres. The only genuinely neutral atmospheres are the rare gases. These have actually been employed in special instances, but are too expensive for ordinary work. Other furnace atmospheres are to be regarded as chemically active; the kind and extent of the action depend on the composition of the metal and of the atmosphere as well as on the temperature.

The most common atmospheres are those resulting from the partial or complete combustion of coal, oil or gas. The possible ingredients of such atmospheres include oxygen, nitrogen, carbon dioxide, water vapor, carbon monoxide, hydrogen, hydrocarbons, sulfur dioxide, and (rarely) hydrogen sulfide. Of these, oxygen, carbon dioxide, water vapor, and sulfur dioxide are oxidizing. Hydrogen is reducing. Carbon monoxide may be reducing or oxidizing, but for iron its effect is predominantly reducing. Nitrogen is generally neutral toward most of the common metals at heat treating temperatures, but it reacts with magnesium at temperatures higher than about 750 F to form a nitride. Sulfur dioxide and hydrogen sulfide may impart sulfur to steel.[3,4] Hydrocarbons and carbon monoxide may carburize steel, while the oxidizing gases, and also hydrogen, may decarburize it.[5]

The most common kind of action during heat treatment is oxidation. All the common metals are oxidized readily at heat treating temperatures. The heat-resisting alloys depend for their protection on the formation of a thin scale of a kind that prevents or retards further oxidation.[6] The elements commonly used for producing these protective films are aluminum, chromium and silicon. It is interesting to note that all three have in themselves a very strong affinity for oxygen.

$$2\,Fe + O_2 \rightarrow 2\,FeO \qquad (1)$$

$$Fe + CO_2 \rightleftarrows FeO + CO \qquad (2)$$

$$Fe + H_2O \rightleftarrows FeO + H_2 \qquad (3)$$

Reactions (2) and (3) are reversible. If relatively rich in CO_2, a mixture of CO and CO_2 will oxidize iron at ele-

* It has been demonstrated that, in certain steels at least, the amount of austenite retained is greater after moderately rapid cooling, as in oil, than after more rapid cooling, as in water. Presumably this is because the residual stresses set up by water quenching, help to initiate the change from gamma to alpha iron.

* For a more detailed discussion of this subject, the reader may consult the article on page 294 of this Handbook.

vated temperatures, but if relatively rich in CO, such a mixture will reduce iron oxide. Likewise, a mixture of hydrogen and water vapor is oxidizing if high in water vapor, but reducing if high in hydrogen.

The compositions of gas mixtures that are neutral with respect to oxidation and reduction vary with temperature.[7, 8] For example, a mixture containing 65% hydrogen and 35% water vapor will reduce iron oxide at 1600 F, but will scale iron at 1000 F. Thus a piece of iron could be heated in such an atmosphere indefinitely at 1600 F without scaling, but would form a thin scale while cooling to room temperature in the same atmosphere. This atmosphere will not prevent the formation of scale on high-chromium steels even at a high temperature, because slight traces of water vapor will oxidize chromium. However, the scale will no longer have the normal brown appearance (caused by iron oxide) but will have a dark green color characteristic of chromic oxide.[9]

The gases discussed above (resulting from combustion) also include most of those that are sometimes injected into furnaces or heat treating containers to produce a definite desired atmosphere. Ammonia is of special interest since, in decomposing, it becomes a fairly inexpensive source of a mixture of hydrogen and nitrogen.

Steam Tanks. Steam may be used conveniently for attaining temperatures as high as 300 F, and has been used especially in the precipitation heat treatment of aluminum alloys. Condensation of the steam on the cold parts of the charge automatically results in rapid and uniform heating, and temperature can be controlled closely by the regulation of pressure.

Liquid Baths. Liquid baths are available for heat treatment at temperatures as high as 2400 F. The baths commonly employed cover approximately the following ranges:

Water	Up to 212 F
Oil	Up to 500 F
Salt	300 to 2400 F
Lead	650 to 1700 F

The range of temperature given for salt baths covers several types of salt, since no one type is suitable for the entire range. Liquid baths exclude air and furnace atmospheres from the work and are therefore protective unless the bath material itself has some undesirable action on the metal. Liquid baths have the advantage also of providing rapid heating, and great uniformity of temperature can be attained when the bath itself is circulated sufficiently and the work material is left in the bath for a sufficient time. The rapidity of heating, especially in a lead bath, is useful, too, for localized heating when this effect is desired.

Measurement of Temperature. Accurate measurement of temperature is vital in heat treatment. Usually it is best to measure the temperature of the work material itself, and the importance of placing thermocouples properly for this purpose is discussed in the section about "Pyrometry", on page 174 in this Handbook. In the heat treatment of many articles of the same material, form and size, when the articles are in the furnace for the same length of time, or travel through the furnace at the same rate, the operation is regulated by measuring the temperature, not of the articles themselves, but of some point in the furnace where the temperature bears a reasonably fixed relation to that of the work metal. In continuous furnaces, especially, this may be the most convenient method of control. There are obvious uncertainties in this method, however, and whenever possible, it is preferable to determine the temperature of the work metal itself.

Quenching. Heat can be removed from a solid object only by dissipation from the surface. The rate of cooling of a given work piece from a given temperature depends therefore on the surface temperature of the piece during the cooling process. The shortest possible time of cooling is obtained when the surface is maintained at or very close to the temperature of the cooling medium; the time required for cooling then depends largely on the thermal conductivity of the material.

The decreased surface temperature necessary to promote rapid cooling may be obtained by removing the object from sources of radiant heat, so that the metal can radiate its own heat freely without receiving return radiation; and by bringing into contact with the surface of the object some cooler material, which may be gaseous, liquid or solid. A fine wire or thin sheet will cool rapidly by radiation alone, especially in the high temperature range; for example, the filament in a vacuum lamp cools very rapidly when the current is turned off. Dissipation of heat by radiation is slow at low temperatures, however, and even at high temperatures is too slow to result in rapid cooling of any but very thin sections.

"Quenching" is the application of a cooler material to the surface of an object to promote rapid cooling. This may be accomplished by use of a current of some gas, such as air, or a spray or jet of liquid, such as water; by immersion in a liquid, such as water; by application of a cold solid, as in cooling (quenching) between plates or in a press; or by combinations of these means.

The cooling medium can seldom be applied to a clean surface of the metal itself, because the surface is usually covered with some sort of scale or oxide film. These nonmetallic coatings have lower thermal conductivity than the metals, and so retard cooling. Heating in such a way that oxidation is prevented or minimized, is therefore conducive to more rapid cooling during quenching.
